Crop treatment.—The most important matter under this head is thrashing. Owing to the steadier running of the electric motor, the output of good corn from an electrically-operated thrashing machine is increased by 5 per cent. Not a very large figure, but, as grain is comparatively valuable, it is one that is well worth while obtaining. Then there are many ways in which, by the aid of electricity, the farmer can circumvent the clerk of the weather and expedite work generally, such as by making hay without sunshine and the curing of crops in the ricks instead of by stooking in the fields. The author has made very considerable progress in this process since he last read a paper before the Institution and he can now treat the largest commercial ricks. Further, no internal structures are now needed within the rick, which greatly facilitates both the process of making the rick and the work of the farm labourer who has to cut and truss the hay before use. The underlying principle has been corroborated by the Ministry of Agriculture and the Oxford Institute of Agricultural Engineering, who have carried out a great deal of most useful laboratory investigation. Owing to the fact that it is possible to treat straw crops in the rick, the harvest fields can be ploughed earlier, as they should be. Further, the damage to the stooked corn by weather and vermin is eliminated. Again, the quality of the grain treated in this new way is greatly improved; a better milling wheat can be obtained, a superior malting quality of barley is produced, oats have a better appearance, whilst peas can be so treated as to retain their green hue instead of having their more usual blanched appearance.

Electro-silage.—Whilst the only electrical method of making silage in this country exists on the farm of the author, the process has made great strides on the Continent, where many hundreds of such silos are now in existence. The electrical method has proved a better way of preserving green fodder for the winter than the ordinary silage method. The principal improvement that has been made recently is the addition of electric tubular heaters, which are plunged into the mass of the material being treated. Previously it was the practice merely to pass a current between a live plate on top of the stack and an earth plate at the bottom. When plates only were used the current was negligible at starting, reaching a maximum in 24 hours. Now the load is kept constant during the whole time that the silage is under treatment; and the load factor of the process is therefore excellent. By the electrical method, silage is made without more than a trace of butyric acid, which, if present in sufficient quantity, is objectionable to those farmers who attempt to make butter or cheese from the milk of cows fed on ordinary silage. The current consumption with the present process averages 1½ kWh per cwt. of material.

Central manuring plant.—A few years ago a commencement was made in the manuring of Swiss fruit farms by means of stand-pipes in the orchards. These are supplied by underground mains from a tank adjoining the main buildings. In this tank is collected the urine from the cow-sheds, and, further, when the stand-pipes are about to be used old rotted manure is thrown into the tanks, the contents being agitated by means of electric motors, either by driving revolving arms or by circulation through centrifugal pumps. A force pump, taking its supply from this tank, pumps out the mixture to the stand-pipes in the orchards, from which the liquid is distributed by a hose pipe and nozzle. The

* The coulter is either a disc wheel or a cutting wedge which opens up or cuts the surface of the soil to facilitate the work of a ploughshare in turning over a furrow.

author's opinion at that time was that although this method might suit orchard or market-garden practice, the installation would be too expensive for ordinary farm work. The process has, however, since developed and to-day is found to save so much labour, both of horses and of men, that it is being adopted in general farm practice. As the distribution pipes are laid about 3 feet in the ground, comparatively cheap pipes can be employed, which greatly reduces the cost of the installation. Further, the uniformity of the mixture helps to produce uniform fertility of the soil.

Irrigation.—The mains thus used for manuring the fields with liquid manure can, of course, also be employed for watering them in exceptional seasons of drought, thus enabling an individual farmer to obtain more satisfactory crops than his neighbours. In Switzerland and Germany special watering machines are attached to the stand-pipes, some of which have mechanical progression devices or, alternatively, simple methods for adjusting them to water fresh areas. The consumption of electric current for liquid-manuring and watering in accordance with this process amounts to 90 units per acre, and is therefore an attractive load from the point of view of the electricity supply undertaking. Mr. Pepys Goodchild in this country has designed even larger machines than those employed on the Continent.

Conclusion.

To obtain the utmost advantages from electricity the farmer will have to be asked to do many things in new ways. For this purpose it is essential for the engineer to make a careful study of the principles of the farmer's present methods. There are many problems, both interesting and intricate, to be solved. Difficulties are still in the way, but difficulties are made to be overcome, especially as the load is so valuable. Further, it is of vital importance to the whole nation that agriculture should be placed on a sound basis, and on this account alone the question is well worthy of the most serious investigation by the electrical engineering world.

APPENDIX.

Bibliography.

Standard electrical engineering practice is followed in supplying a rural load, hence no special literature has been published. The all-important requirement is data on which to estimate the load to be supplied. Most of the electrotechnical and agricultural journals deal with the subject from time to time. In particular, reference may be made to the following :—

C.R.E.A. Bulletin (The Committee on the Relation of Electricity to Agriculture, 1116 Garland-buildings, Chicago); *Landsbygdselektrifiering och Motorkultur* (edited by Dr. A. Ekstroem, Vasagaten 6, Stockholm); *Electro-Farming* (Electrical Press, London); also the *Electrical Review*, of London, the *Electrical World*, of New York, the *Farmer and Stockbreeder and Agricultural Gazette* and the *Implement and Machinery Review*, of London, as the editors of these journals are taking a keen personal interest in the matter.

Among publications which are intended to be of assistance to farmers and their advisers, are A. H. Allen's "Electricity in Agriculture" (Pitman's, London); "Electricity for Everybody" (Electrical Press); the "Solicitor's Handbook" (National Electric Light Association, New York). A chapter entitled "The Electro-Farmer" appears in Sullivan's "Our Silent Partner" (Eyre and Spottiswoode). The following papers and reports have also been presented on the subject :—

"Electro-Farming": A lecture before the Royal Dutch Institute of Engineers at Nijmegen, published by the British Electrical Development Association, Inc., London, October 1921.

"The Uses of Electric Power in Agriculture": A lecture before the Farmers' Club, *Journal of the Farmers' Club* (London), 1922, part 3, p. 45.

"Electro-Farming, or the Applications of Electricity to Agriculture": A paper read before the Institution of Electrical Engineers, *Journal I.E.E.*, 1922, vol. 60, p. 725.

"Electro-Farming, or the Applications of Electricity to Agriculture": A lecture before the South Wales Institution of Engineers, *Proceedings of the South Wales Institution of Engineers*, 1922, vol. 38, p. 757.

"Hay and Corn Harvesting by Artificial Methods": A lecture before the National Farmers' Union (Manchester Branch), *Preston Guardian*, 3rd March, 1923.

"Electricity on the Farm," B.E.D.A., No. 486 (with illustrations of applications at Greater Felcourt Farm, East Grinstead), published by the British Electrical Development Association, Inc., London, 1924.

"Electro-Farming Economics": A paper (No. 266), read before the First World Power Conference, 1924.

"Rural E.H.T. Distribution": A paper read before the Third International Conference on Extra-high-tension Systems, Paris, 1925.

"Electric Power in Agriculture": A report by C. Dampier Whetham, *Journal of the Royal Agricultural Society of England*, 1924, vol. 85, p. 246.

"Electricity in Agriculture": A report of the Electricity in Agriculture Committee, *Journal I.E.E.*, 1925, vol. 63, p. 838.

"Electro-Farming": A continued series of articles in the *Electrical Review* (London).

"Book-keeping Made Automatic, or Auto-Countancy": A handbook designed to assist farmers in easily keeping accurate costing and main accounts. (In the press.)

"Electro-Farming or the Applications of Electricity to Agriculture": A scientific textbook (in the press) to be published by Ernest Benn, Ltd., 8, Bouverie Street, London, E.C.

For a more comprehensive list of references, see "Bibliography of Electro-Farming Literature" in the *Electrical World* (New York), 1923, vol. 82, p. 333. Also see *C.R.E.A. Bulletin* No. 2, 15th October, 1924, and each issue of *Electro-Farming* (London).

Discussion before The Institution, 4 March, 1926.

Sir Daniel Hall : As the author remarks, we may see upon the Continent in many districts a good deal more use of electricity on the farm than we have yet met with in this country; that is to say, power is distributed more widely over the countryside and the farmers are taking advantage of it; but we must clearly distinguish between the two methods of application. We have first of all the use upon the farm of what we might call the ordinary domestic load; that is to say, the lighting of the farm and farm buildings, and the carrying out of those minor power operations such as chaff-cutting, root-cutting, pumping, and so on, and thrashing in its turn, of which the author has shown lantern slides. That is the normal kind of thing in, say, an electrified area like Southern Sweden, and many parts of Czecho-Slovakia, where the power lines have been taken all over the countryside. One will find the ordinary small farm taking advantage of the electrical supply in carrying out those particular sets of operations by means of a portable motor working from two or three points situated about the stockyard, and there is not the slightest doubt that if there were a similar distribution of electrical power over our countryside we should find the farmer equally ready to take advantage of what I may call that domestic load. That, however, is not a very heavy load for the farm. What load can be picked up by doing the operations of cultivating the land? What prospect is there of getting the farmer to turn over from horses to electricity for many of these major operations which consume the greater part of the power expended upon the farm? Now, the author has laid stress upon what can be done in the way of ploughing by means of the various types of tool—the very large Siemens-Schuckert tool which will plough 20 or 30 acres a day, and the smaller tool which will work only a couple of furrows at a man's walking pace. What prospect is there of doing the ploughing so much more economically by the application of electrical power that horses will be largely displaced? We must beware of taking too rosy a view of the economies that we can effect in that way. The author draws up a contrast between 25s. an acre, which he puts down as the cost of ploughing, and either 2s. 6d. a day or 1s. 1d. a day, according to how many factors are taken into account when the cost of ploughing by electricity is calculated. That, however, is not at all the comparison that we have to draw. In the first instance, however open-minded the farmer may be towards new developments, one has to remember that he is bound to employ a large number of horses on his farm for all kinds of continual operations, such as carting crops and fodder. These are, in effect, the big operations upon the farm that call for the horses. Ploughing is in many respects a by-product, and a farmer who has really studied the economics of his farm operations will often point out that the ploughing comes very usefully into his scheme as a means of employing his horses when they would otherwise be idle in the winter. But he by no means regards the ploughing as the main draft upon power on his farm, and therefore in making these comparisons as to comparative costs we must beware of costing out our ploughing on the basis of a horse-day throughout the year, and imagine that we can dispense with those horses and replace them by a totally different source of power. We have in steam ploughing an extraordinary economic operation, yet though we have had steam ploughing sets at work all over the country for the past 40 or 50 years, they have not displaced the horse. Rather the reverse is taking place, in fact. Recently tractors have been added to the farmer's equipment, but after making all allowances for the facts that these have been in many cases badly designed, and in many other cases abused by those who use them, we do not find that there has been such a development of their use as might have been expected. The tractor is taken up by the farmer as a means of getting a lot of work done in a short time, but it has not displaced horses, and it is not actually, at the present time, taking a proper system of costing over the year, cheaper than the horse, having in view the fact that a certain amount of horse labour is necessary for the odd jobs of the farm. Therefore, let us be very careful about basing our calculations of economy upon costing a particular job. We must consider the costs in the light of the part the operation plays in the complex organization which a really well-run farm represents. Then there are, of course, other possibilities of which we know very little at the present time. The application of electricity, for instance, in the overhead high-tension discharge has possibly a stimulating effect on crops. We have these mysterious effects of ultra-violet rays, mercury-vapour lamps, and so on, in stimulating animal development, and even in affecting the quality of food. There are many possibilities for the future on those lines, but as yet we cannot say that they are so far forward that we can promise on their account an economic use of electricity upon the farm. Take that very effect of the overhead discharge; there has been no more difficult, no more debatable question to study. Years ago the most remarkable results were presented to us by various experimenters. We have been at work in this country for, I think, the past 7 years, and the results are still disappointing. Year after year we get contradictions; we are gradually sorting out the elements of the problem and are beginning to see how we can ensure a positive result, but we are by no means certain even yet that we can repeat the successes. But until we have obtained more facts, until we know, for instance, at what particular period of the growth the discharge must be applied, we cannot begin to calculate the possible economics of the process. Doubtless great developments are possible in cultivating the land by new methods of applying power—but do not let us confuse the application of electricity with farming. Farming requires the utilization of power, but the farmer does not care whether he gets his power from electricity, from coal or from horses. The question that interests him is how to use that power economically, and how to get it cheaply, and some of the author's illustrations rather confused the issue as to whether the question was

farming or whether the question was electricity. For instance, one lantern slide showed a man making a milk examination with an electrically driven machine. It really does not matter whether the machine is driven by electricity or by hand. Again, whilst it is very convenient with either an incubator or with a brooder house to switch on electrical heat, which is clean, convenient and quick, is it as cheap as the anthracite stove working directly? There is no magic in electricity; the results depend upon the man who is using it. It is easy to disparage the methods of the farmer, but he is the man who has to live by farming, and he knows that he is gambling anyhow—gambling against the weather. Long centuries of experience have made him conservative, traditional. He must be conservative and traditional, because he has no spare capital for experiments. He can run no greater risks than he already runs from the vagaries of the weather. Therefore I say he will be slow to move; he will be traditional, he will be conservative. Let us clearly bear in mind that it is the electrical engineer who must carry out the experiments. It will not be the farmer. He has too much at risk already; he is not going to be a pioneer in these particular experiments.

Mr. Ll. B. Atkinson: It is about four years since the author gave his first paper before the Institution on electro-farming. He then brought us up to date as to what was being done, and he has carried us forward somewhat to-day. If in this further record we feel, perhaps, rather disappointed as electrical engineers that the actual progress he is able to record of the work done in this country is rather small, I think we must not, bearing in mind the shortness of time, too readily lose heart, because really a great deal has been done—more, perhaps, than appears from what he has shown us of work in this country. As Sir Daniel Hall has already remarked, farmers are, like all peasants who are rooted in the soil, necessarily very conservative, very slow-moving, and indeed for the most part are anxious not to turn over from the methods to which they have been accustomed, to new methods. So we must slowly carry them with us; and furthermore we must recollect that the engineers—at all events, the electrical engineers, who are dealing with this problem from the engineering and electrical sides—are under the disadvantage for the most part of not having had an opportunity of closely studying or getting saturated with the ideas which are at the basis of farming and agricultural work. We therefore bring the two groups together, each of them looking at the problem from a different point of view, and each of them very largely ignorant of one side of the problem that has to be dealt with. There are two outstanding fundamental facts which, from the electrical and the engineering points of view, have to be dealt with. The first is that it has been proved to be easy—where there is a supply—to get farmers to take up the supply and use it for most of the purposes that the author has shown on the cinematograph films. They use it because, although it is true, as Sir Daniel Hall said, that some of these things could be done as well in some other way, they cannot be done as cleanly and simply in any other way. This, however, leaves the real problem—the distribution of electricity to the farmers—to be solved. The author has pointed out that we must not take the square mile, but the mile of route, and it has been clearly shown that where there are many houses and villages on the road to be lighted and supplied, the mile of route in most cases, if worked energetically from a salesman's point of view, does provide a load for which it is worth while for supply undertakings to run lines if they are not too expensively constructed and designed. But the other point on which we have to fix our minds is that we must get this power for the cultivation work brought into use in ways that I think we have not yet really touched. Those large-scale ploughing experiments and ploughing work about which the author has told us are all very well in certain parts of England and a great deal of the Continent, where there are no hedges, and where the fields are very large and very open, but, as has already been pointed out, on very few of the farms of this country can that large-scale ploughing with big and multi-shared ploughs be used on that scale. The problem we have to solve is some form of easily handled ploughs or cultivators working on smaller areas of ground. Personally I am gradually getting of the opinion that the plough is the wrong implement for the purpose we are considering. With horses pulling slowly and with a big dead pull, it is probable that the plough is an exceedingly adaptable implement, but we are dealing with high-speed motors, and for ploughs we have to reduce speeds; and why should we? Those other cultivating machines that the author has shown us are the type of implements that are needed on the farm; of high speed, with a light cut, so that heavy pulls and weights are not called for. Their action would be rather that of a cutter than of a wedge. The difficulty will be to find out what kind of cutting tools can be used on wet ground. I think that the author has done a real service in giving a concrete worked-out case for covering a certain area with high-tension, medium-tension and low-tension lines, but I cannot help thinking that to get much further we really need fairly large-scale experiments, and I agree with Sir Daniel Hall that it is not the farmer who should make the experiments. We ought to take an area of a good many square miles, or a good many miles along a road, get it equipped if necessary by lending all the equipment to the farmers with an option to purchase it presently, get the whole thing working under the superintendence of an electrical engineer who has studied the requirements of farming, and let him stay there for two or three years so that the scheme does not collapse because the farmers do not know exactly how to maintain the apparatus. It will teach the engineers a great deal; we may hope it will teach and educate the farmers, and it will teach the supply undertakings and indicate to them what are the real possibilities of such a supply. I agree with the author's remarks on the subject of the insulation of portable lamps, because portable apparatus at 230 volts on a farm is likely to be a dangerous thing unless steps are taken to guard against danger. In regard to the question of lighting poultry laying-houses, I have done this for some years, but only this year encountered a rather curious phenomenon. Up to this year I have used the light breed, Leghorn poultry, but this year I

have used the heavier breeds, and I find that the light breeds stay down and go on feeding and working as long as the light is on, but the heavier breeds get up on the perches shortly after the sun has set, whether the light is on or whether it is not. I do not know that it affects their laying; I have an idea, but it wants investigating, that they have larger bodies and can take in more food in a given time and do not have to go on so late. The author mentions that, under the influence of light, plants grew 3 inches in a night. I do not know whether it is the universal experience, but the plants I have observed always grew in the night and hardly at all in the day. Some creepers that I was watching last year grew 3 inches every night, and scarcely ½ inch during the day, so that we must not run away with the idea that that big growth at night was actually produced by the light. I am not saying it was not, but my opinion is that plants naturally grow more during the night.

Mr. B. M. Jenkin: My remarks will be more from the farmer's point of view than the engineer's. The first thing that strikes me is the author's splendid optimism. He says that it requires imagination to put forward his views, but he has let his imagination carry him away, I think, with reference to the possible load that might be obtained from farming. He speaks (at the foot of page 802) of the 57 million acres of land which we have in this country as if it were all suitable for agriculture, but of course it is not. It includes all the rocks and woods and forests. Now there are only 14½ million acres of arable land in the country, so that if all this were electrified the resulting load, at the ideal consumption of 275 units per acre, would be a quarter of that 16 000 million units to start with; and again, 275 units per acre, I think, can hardly be said to be based on present practice. The 100 units is an exceptional case, I believe, in Germany, and must already include the 40 units per acre for dealing with crops, but to this the author adds 75 units for haulage, and I cannot think that on any farm at present the haulage is being done electrically; so that there again one would have to divide that 275 by about 4, which would bring the total demand down to about 1 000 million instead of 16 000 million units. Within the reach of how much of the arable land in the country will the lines be? Again, when it is brought within their reach how many farmers are going to take the power? If it is sound business to supply electricity for farming, it should be possible to put the case forward without this amount of imagination. It makes one feel that there is something very unreal about the author's proposals. Another point to be considered is that, in farming, one's first object is to avoid useless capital expenditure. If one is a tenant one tries to get one's landlord to supply capital for fixtures. He is not likely to supply it for installing electrical power on the farm, or for running pipelines for manure. It must always be remembered that at the present day the question is: "Can I carry on my arable farming, or must I sow down to grass?" It is useless to put a lot of capital, in the way of fixtures, into the land if next year it will be put down to grass. The farmer will purchase the cheapest possible implement. A tractor will do all the things we have seen illustrated on the cinematograph films. It does the ploughing; it transports itself; it will drive the chaff cutter and all the other apparatus. It will go to the station and haul loads. To suggest electric ploughing on a farm is to me very much like suggesting to run the cross-Channel steamers electrically, the steamer laying a cable down across the Channel and picking it up as it comes back. It can be done, but will not when it competes with the ordinary steamer. Similarly, the electric plough cannot compete with the other methods. The author refers to Mr. Dampier Whetham's Report to the Royal Agricultural Society. I think that that Report states the case extremely soundly and sensibly. It says: "Electric ploughing is therefore being abandoned in many districts on the Continent, and, for the time being, till some more efficient method is devised, or some new idea is forthcoming, it is unlikely to be successful in England." Another point is the question of rotary tillers. The author has not pointed out the fundamental difference that comes in here. In his earlier paper he gave a very interesting description of how he had put a belt-driven dynamo on his paraffin tractor, carried an electric transmission back to a binding machine (a harvesting and binding machine for cutting corn and tying it up), and how he was able to cut a great many more acres per day with that tractor than when it was done in the ordinary way. The ordinary binder was originally designed to be drawn by horses, and the power for working the knives and the canvases (for cutting and transmitting the corn when it is cut, tying it up and throwing it out in sheaves) is obtained from what is called the bull wheel. It is a big wheel underneath the binder with strakes on it, and as it catches the earth it drives all the machinery in the binder. Now, if that is drawn by a tractor, it will be noticed that the tractor with its wheels is pushing the earth back and the binder is pushing it forward so to speak, so that the earth is acting as a belt between the wheels of the tractor and the bull wheel of the binder. Is it possible to imagine a poorer medium for the transmission of power than a belt of earth? But that is how it is done. The author got rid of that loss in using the earth as a belt, by putting a dynamo on his tractor, and a motor for driving all the machinery on the binder, and transmitting the power electrically. He was therefore able to drive his tractor on a higher gear and cut a larger acreage. It would not do it when it was driving through the earth as a belt: the engine was not strong enough. In ploughing, the tractor has to get its power transmission through the earth to the plough. It is squeezing the earth with its wheels and the plough is squeezing the earth as it turns it over, and resisting the pull of the tractor. But the rotary tiller is driven from the engine of the tractor, so that the power obtained at the engine goes direct to moving the earth by these rotating tines. That advantage is beginning to be recognized by agricultural instrument makers. Last year at the Royal Society's Show a tractor was exhibited with a direct mechanical connection from the engine of the tractor to the gear of the binder, the equivalent exactly of the author's electric transmission, but it was done by universal joints and rods. This inefficient transmission through the earth is again shown in the cinematograph film where a paraffin tractor is drawing

a mowing machine. Nowadays the Fordson tractor has a connection by which the knife is driven direct from the engine, avoiding that transmission through the earth. That is the direction in which, it seems to me, the development of agricultural machinery will have to take place.

Mr. W. Fennell: On the Continent apparently a good deal of electric work is done on the farm as compared with England. That may be due, of course, to the greater intelligence of the Continental farmers as compared with the British farmer, or to lack of enterprise of the supply undertakings in England as compared with those on the Continent. I am not qualified to say which, but I think it can be said that the reason why on the Continent there is a great deal more use of electricity in agriculture is that the supply engineer is allowed to take the mains to the farmer with far less hindrance than he is here. That, I think, is the root of the matter, and I think it explains the differences between the progress being made—if indeed it is progress, judging from the remarks of some of the previous speakers—with electric farming on the Continent and in this country. At the present time supply engineers are being urged by politicians to take electricity not only into the highways but into the byways. I think we shall be doing a good work in carrying it into the country to help the farmer and the country resident. My company is connected with an area of about 120 square miles in Cheshire, and we find that the country people do want electricity, and do use it when we can take it to them, but we meet with difficulties of all kinds in providing the supply. First of all there are Parliamentary difficulties. In extending an undertaking into the country it is necessary to pass over the old boundaries and come into new areas. For this a new Provisional Order—or at least a Special Order, as it is called—is needed. A company's undertaking may be nearing the period when it can be purchased, and capital liabilities then arise for the comparatively unproductive new area. The local authorities may purchase the central undertaking and leave the company with the outside area. In order to extend over the boundary we need a modification of the "Fringe Order" which is, at present, an Order enabling an undertaking to go over the boundary and supply Mr. Jones, but the Order is so framed that only Mr. Jones can be supplied. Now, we want an Order whereby we can take up contiguous areas instead of individual, named consumers. The only alteration that is needed for that purpose is that, instead of specifying any individual, the Order shall specify an area, by reference to the deposited map. Under the present "Fringe Order" system we have had to refuse to supply a resident by whose door our mains passed, because it was far too much trouble to go through all the formality again. We also require increased facilities for running overhead lines. I appeal to those who have influence, to help the willing electrical engineer to run these overhead lines on something like a practical basis. I hope to continue my remarks at the Manchester discussion later in the month.

[The author's reply to this discussion will be published later.]

Adjourned Discussion before The Institution, 11 March, 1926.

Mr. Montague Fordham: I wish to express the point of view of a countryman, somewhat different from that put forward by Sir Daniel Hall and Mr. Atkinson. I am finishing this week a series of some 250 meetings throughout England dealing with the question of rural reconstruction. I find a growing consensus of opinion in the country districts that the future of the English countryside depends on two things, the first a good supply of electricity, and the second the use of the dung cart. A good reply to Sir Daniel Hall's pessimism will be found in his very interesting book, "Agriculture after the War," which gives what is—or at least was—his unofficial opinion. Another book of very great importance to all electrical engineers is the Report of Lady Hall's "Committee on Rural Reconstruction," which gives special attention to electricity. What is there to learn about the relation of electricity to rural reconstruction which is so important to engineers? The rural problem is this. For 100 years the country people have left the villages for the towns. That tendency has destroyed every civilization of which we know the history: it need not destroy this civilization, because we have this new power, this power of electricity, which can be used in many ways to turn the drift back. As a countryman, I ask the electrical engineers of this country to work out an effective plan for bringing electricity right through the country districts so that we may both bring our workshops out of the towns and reconstruct agriculture. The details of the author's proposals interest the ordinary village audience to an extraordinary degree. The method employed by the author, and no doubt by many others, of drying corn crops and hay, is recognized to be of immense practical importance to farmers. In February I was speaking in Buckinghamshire at 15 villages and small towns. No matter whether my audiences consisted of 6 or 600, they were all extremely interested in the details of the use of electricity, and saw in it a way to reconstruct their country life. It is now for the electrical engineers to work out the details of the application of electricity to our countryside: country people will support any proposals which come forward from so important a body as the Institution. Let us confer together.

Mr. F. H. Clough: It seems to me that the first matter to consider is how to get electricity out into the country; once we have done this the uses of electricity are bound to develop. Even if we do not depend on the farmer, there are many country residents within a reasonable distance of supply who are potential users of electricity. Many of these have their own small lighting sets; but I think that the majority of these people would be very willing to take a supply from some central station. The cost of wiring a house and the cost of generating electricity are the same in the country as in the town. The only difference is in the transmission,

which is not entirely a matter of engineering but largely a political matter. If the politicians remove the legal difficulties, I think that the engineers will be able to overcome the technical difficulties. Much is heard nowadays about proposals for running large power mains across the country and tapping off to the farmers. Obviously that cannot be done. The cost of big-capacity switches on such a main would be prohibitive. If we take electricity out to the country we must run at higher voltages, because the distances are greater; but the higher voltages need not necessarily be associated with higher power. Perhaps it might be useful to take an example. Assume a line 10 miles long with a power demand of, say, 1–2 kW per mile, making a total demand of about 15 kW. Such a line could be supplied from a 15–20 kW transformer at 3 000 volts, and the short-circuit capacity would be approximately 200 kW. Tappings would be made to the consumers at suitable points along this line. Each tapping would consist of a weatherproof switch fuse and small pole-mounted transformer, and with the limitations given above for voltage and power these tappings can be quite inexpensive. Inexpensive lightning arresters suitable for these conditions are also available. The line itself might be single-phase in the first instance, and would resemble the usual telephone or telegraph line; in fact, the same poles could be used. Satisfactory small single-phase motors are available, and later on when the power demand has increased and the line has been converted to three-phase, three-phase motors can be installed. Underground cables would not be suitable for such a line as I have described, as the cost of insulation and armouring would be too high to be economical. Touching the economics of the matter, if such a line is installed it is obviously to the interest of both the consumer and supply undertaking to make full use of it. This means a low price per unit, and I think the interest charges on the line should be kept separate from the charge for power. If the line is designed economically the interest charges per kW of demand should be considerably less than the interest charges on a self-contained plant, which is the only alternative, and the cost of power will be very much less. I think the consumer will prefer to pay his share of the cost of the line, especially if this be made reasonable, and get his power at a cheap rate, rather than pay a high rate for power. A low power rate will ensure rapid development of the uses of electricity, and many of the interesting devices described by the author will be used. I shall now show a couple of lantern slides of a disconnecting switch-fuse suitable for controlling the power supply to such a rural line as I have described, or to a small town. It has a rupturing capacity of about 15 000 kVA and works at 11 000 volts. I have not slides of the switch-fuses for individual consumers, but these are very much smaller and cheaper.

Mr. H. M. Sayers: Major Caldwell has sent me the following figures referring to the results of lighting and feeding hens at night during the winter months. With a flock consisting of 271 pullets (one-quarter light breed, Leghorns, three-quarters heavy breed) during four weeks in November last with no light and no meal after 3 p.m., these hens laid 1 182 eggs, an average of 295 per week, or 1·09 egg per hen per week. During 8 weeks in December and January, when a late meal was given at 9 p.m. with lights on for 15 to 30 minutes, the same breeds laid 6 733 eggs, an average of 842 per week, or 3·11 eggs per hen per week. There were 9 lamps each of 300 candle-power—that is, 1 lamp to 30 birds—but a flock twice the size could have been comfortably admitted to the same light. It was found that the light breed, which were about a quarter of the flock, responded to the treatment within two days, whereas the heavy breed were slow to benefit; but their performance afterwards was more consistent. It is important, once the lighting is installed, to keep it on. Owing to an intermission of three nights at Christmas time, the yield dropped from a daily average of 130 to 93 eggs; but this was adjusted within a day or two after the regular lighting was resumed. I should like to point out another possible connection between electric supply and agriculture. It is well known that about 70 per cent of the heat units of coal are wasted in the modern steam turbine. That loss is part of the cost of the most valuable form of kinetic energy. It is a by-product for which we have not found any use up to the present. The temperature of the water is too low for any industrial use and for most domestic purposes. It warms the water of the river, estuary or sea, or it humidizes the air around cooling towers, with some annoyance to the neighbours. One use to which that warm water could be put would be extremely remunerative, sending it through buried pipes and warming cultivated soil up to probably 15 or 20 degrees F. above the air temperature. I believe that in that way the effect of glass-houses would be obtained. As to the magnitude, it is only possible to make very rough estimates at the moment; probably 1 000 kW maximum load at 30 per cent load factor would suffice for an acre of land. Experiments are wanted to find out the proper depth and pitch of the pipes, and the amount of pipe area required for the necessary cooling, so combining cooling with the heating of the land. Besides warming the land, the rising warm air and vapour would defeat the radiation frosts which so often do damage in spring-time. Occasionally with strong cold winds, the top crust of the earth might get frozen. I think that in the coldest weather of South England, the earth temperature would be 50° to 60° F., well above the minimum growing temperature. It will be necessary to investigate what is the best succession of crops for the utilization of this (at present) lost heat. That is a matter which must be left to the market gardener and the food raiser; but I suggest that the market gardener would get crops the whole year round. He could choose to some extent the climate for what he was trying to grow. If it proved in some cases that, although growth was good, ripening was slow, then, as the author has shown, intensive lighting could be used for the purpose. This connection between electric supply and agriculture deserves to be thoroughly thrashed out. Experiments can be made at a very small expense; and I trust that some of the central stations which are favourably situated with regard to market-garden land will make some before long.

Mr. E. B. Wedmore: The author has worked as a

pioneer in a field which he has made his own. The problem now is how to extend this effort and get other workers into the field. Mr. Atkinson has emphasized the importance of further experimental work being done, not only at the agricultural but at the electrical end. I think that such work should be done by co-operation between all the interests involved. We have in the Electrical Research Association the machinery for carrying out co-operative research, and to a limited extent funds are available. I conceive that there is no one better fitted than the author for preparing a preliminary schedule of the sort of problems that could be tackled experimentally by co-operative effort at the present time. I hope that he will give some thought to that aspect of the subject where electricity touches the agricultural side, and communicate with the Association after he has done so. I am not quite sure how the author's scheme of employing electricity to provide artificial climate for bee-keeping and producing the equivalent of the South of France would work out in the long run against the importation of bees raised in the South of France and used on the apple crop in this country. I believe that it is only the difficulties of transport and the number of hands through which the goods have to pass between England and France that leave any loophole for the author's method of heating to be really economical in competition with the alternative that I have suggested. Already we import queen bees from abroad. One is accustomed to breeding sheep in one part of the country, fattening them in another, and selling them in another part of the country, so that the idea of importing bees is by no means to be neglected on the economical side. There is, however, another method of employing electricity for heating a bee-hive. Let us consider for a moment what is the normal procedure in a bee-hive. The temperature of the hive is high, and is maintained by the consumption of honey by the bees. Honey is a good food ; but it is on the pollen that the bees depend for the nutritive side of their diet ; and the energy in the honey is converted very largely into heat in the hive. A hive which may produce, year in and year out, a surplus of 35 lb. of honey would consume 70 lb. during the course of the year. One knows that the bulk of that consumption is for heating within the hive. There is fuel consisting largely of water, and therefore an inefficient fuel, worth possibly £100 per ton, being used by the bees for the production of the heat necessary for the maintenance of life and carrying on the work of the hive. It seems to me that this is where artificial heat could be supplied in the form of electricity. On a very rough calculation a supply so furnished continuously throughout the winter months at a cost of 1s. or 2s. a year in actual energy would represent a saving of the consumption of a very large part of the honey that is used during the winter for counteracting the effects of the cold atmosphere. The bees consume the honey when they are in a cluster, and thus the whole of the heat goes straight to the bees at an efficiency of 100 per cent. The individual bee, as soon as it has filled itself with honey, proceeds to go through a series of mechanical exercises. There are several recognized types of mechanical exercise which are used by the bee for the purpose of simply converting that honey, so that the heat is made available just at the point where it is wanted in the middle of the cluster. Various attempts have been made to heat bee-hives artificially from without ; but they are very inefficient as compared with the system that the bee has had to develop to meet the very high cost of the fuel it uses. Undoubtedly the proper method of heating is to heat from the centre of the cluster. The instincts of the bee are adjusted to deal with the circumstances which arise when heat is produced within the cluster, the outer atmosphere being at a lower temperature. Any attempt to reverse those conditions in the hive is quite against the instincts of the bee.

Colonel R. E. Crompton : I agree with Mr. Fordham that the curse of industrialism is the crowding of the workers together in insanitary conditions in the towns, and the draining of the country life into those towns. Electrical engineers must reverse that process. The paper under discussion is enthusiastic and imaginative and should therefore tend to encourage the scheme of rural electrification. So far as I have been able, I have tried to analyse some of the tables and figures given in the paper ; and I think they are extremely hopeful. I have tried to imagine the price which will be charged for electricity in the country, but the only certainty is that the price can only be low if the demand is very large and very evenly distributed. So long as large plant is doing work in which it can be only partially employed, it must be a very heavy tax on somebody, either the company which has erected the works, and which has to pay interest on the cost of the works, or, if the Government give a subsidy, which it is probable they will not do, the burden will take the form of guaranteeing interest on capital at a low rate. That being so, we must try to popularize our electrical developments among the rural population ; and I think we could learn a good deal from other countries. Electric light is used all over the great district surrounding Milan, where there is one of the oldest supply undertakings in the world. There they have cultivated the demand by giving a lighting supply at an extremely low rate, and consequently the heating demand followed. I believe the same is true all over the South of France, and the author indicates that the same thing is being done to a large extent in Germany. He has shown very many ways in which the farmer can use power. But, looking at the figures, the maximum demand does not appear to be very great. I think that the electric silo will give a large and very steady load at a very good power factor. Then, again, a considerable amount of light will be used for stimulating the production of eggs, for stimulating the early germination of seeds, and getting increased growth in the early stages. That is undoubtedly the proper method of gradually inducing farmers to use the electric supply. We are told that the industry of enriching the soil in Germany by producing nitrates from the air has assumed gigantic proportions, but the results are shrouded in mystery. Can the author give any information in regard to this industry ? He is undoubtedly right in saying that if we can aerate the soil by continually turning it over, we can largely increase the productive power of that soil. But, speaking as a mechanic and as a man who has been much interested

in machinery, I can see greater difficulties than may first be supposed in the various apparatus shown for ploughing in the fields with cables alternately wound on and unwound off the plough. We had some experience of that 26 years ago, in the Boer War, when we had to coil and uncoil the cables for our projectors. Undoubtedly some development on those lines is necessary. I think that the load factor of all agricultural districts will be approximately the same. There will not be that advantage of diversity of load factor which occurs when part of the supply for industrial districts is worked at certain fixed hours and another part is for lighting after those fixed hours, and, during the last few years, for heating and cooking after those lighting hours. The habits of the agriculturist, of the hens, of the bees, and in fact, of everybody who will be affected will be the same all over the country, so that we cannot really look for a diversity load factor unless we do something else. For instance, we might by some means or other use our plant in the small hours, say for charging accumulators for driving farm vehicles. Mr. Sayers's project is very interesting, but I do not know how he is going to use his cooling water so far away as 50 miles from the power station. If anything, his idea is an argument in favour of having small power stations distributed all over the country, which is contrary to the idea of the new Electricity Bill.

Major T. Rich: Some years ago it was brought home to me that farmers in European countries, which have been cultivated not far short of 2 000 years, have now to meet the competition of countries where foodstuffs are being sold under economic cost. In the Eastern States of the United States and in Canada much of the land has produced nothing but wheat year after year until the country is chemically exhausted. The result is that in many parts to-day they find it necessary to buy nitrates from Chili and elsewhere. I was in Western Canada about 15 or 16 years ago, and I was laughed at when I spoke about the rotation of crops. I believe that electricity will tend to put us in a position in this country to compete with that economically fallacious system. We want, however, more than super-power stations; we want facilities for distribution. We do not want an army of new officials, nor a subsidy, hidden under the name of a guarantee. In France there are many thousands of miles of inexpensively constructed rural distribution lines, running along the roadside. In England a pressure of 250 volts (alternating) to neutral is often arranged in houses, yet a high-tension line over the roadway in the country is held to be dangerous. In France the laws and regulations are founded on common sense, so far as electricity is concerned. They are interpreted by an organization called the Electrical Committee, which is largely a committee of technical and business men. This committee, which has as its secretary an engineer from the Ministry of Public Works, considers how the Acts are to be interpreted, and what is to be done in cases of difficulty. In France, though it may seem somewhat strange, the rural authority is entitled to veto the use of overhead lines; but as a rule there is but little obstruction. The pioneer lines all over France were laid along the roadside. The reason for that, especially in the North, is rather interesting. In many parts the land is held on a similar tenure to that which was customary in England under the old Norman and Saxon days before the Enclosure Acts came into being; that is to say, many holdings are made up of a number of little strips of land, scattered round a village. There was, therefore, a great deal of difficulty in France in getting wayleaves, because of the number of owners; facilities were therefore given to run lines by the roadside for a small fee per kilometre of line; and that fee is paid to the rural or other road authority. The result is that the road authorities are not hostile to the use of electricity. We learn from the paper that in many parts of the Continent 220 volts is being used for lighting on farms. That is not general in France at all. The great bulk of the supply is at 110–190 volts, although a certain amount of rural low-tension distribution is being commenced at 220–360 volts. In the North of France, and in many rural districts of France, 15 000 volts is the general high-tension distribution voltage. Once the pressure exceeds 3 000 or 4 000 volts, it does not cost much more to go up to 15 000 volts than it does to go to 6 000 or 7 000 volts. One engineer in the Bethune Colliery district has been running some 15 000-volt single-phase lines into the villages with iron wire overhead conductors. As soon as the load has increased sufficiently, the iron wire is taken down and replaced by three-phase copper conductors. A question has been raised recently as to whether there should not be an intermediate voltage to enable one transformer station in a village to supply it direct and also a considerably larger area surrounding it through house transformers; at Grenoble Exhibition last year there were shown some double-voltage transformers which stepped down from 10 000 or 15 000 volts to 660 and 110 volts. Ploughing by electricity is increasing very much, I believe, in Italy and in France; for small holdings motors of about 7½ h.p. have been used. It has been said that the use of electric power follows the use of electric lighting. One thing in which our country is probably worse off than any other country in the world is that in proportion to the cost of living, apparently, we pay more for our electric lamps than any other purchasers of electricity. It should not be so. The real value of a 2s. 6d. or 3s. lamp is about 8d. or 10d. We ought to be able to get lamps in this country, judged by the cost of living in other countries, for 1s. or less. It is all very well to talk about economies from super-power stations, but the supply of lamps at a reasonable price would do more to further the use of electricity in this country than all the politically inspired Government projects put together.

Mr. W. J. Minton: One of the previous speakers in the discussion said that the use of the steam plough is dying out in England. That is quite possible, because steam ploughs do not always plough at the required rate. Ploughing has a twofold object when turning over the ground: (1) to provide fresh soil for the next crop and (2) to kill the weeds. At 10 m.p.h. the plough will not do that. The farmer who is a business man is dissatisfied and says the contract has not been carried out. The correct power machine to use is a cultivator, which breaks up the soil and sub-soil in the same way that an

allotment holder digs 2 spits deep. This should be done every 5 years and is work too heavy for horses. I think it ought to be pointed out to the British farmer that he can get a " snatch " crop with the aid of electric power. In one case a farmer who went 50 miles to fetch a huller to get a snatch crop of clover seed made £500 extra profit. The British farmer must cultivate more snatch crops, and electricity will help him to do this. Has the author had any experience of laying tram-lines over farms ? This would justify an overhead conductor to supply power for general use, including the tractor whether it is on or off the tram-lines. One potato farm in the Fens has tram-lines running round it; and it has enabled the owners to make a large fortune out of that farm. Does he advocate the single overhead conductor with an earthed return or an insulated return lightly buried ? In my opinion we shall have to develop high-tension direct current, and I expect that its use will shortly be increased in England. The author does not mention the comfort of the farm labourer. Get the labourer to have a few lights in his cottage, and he will be as enthusiastic as his master to get electricity on the farm. Supply the local District Nurses' Association with apparatus so that nurses can compare farms with and without electricity. There will not be a general demand for electricity on the farm until the actual men who are going to use it are enthusiastic for it. Occasionally it is hinted that the farm labourer has not much intelligence, but on one particular farm of which I have knowledge an ordinary farm labourer takes the petrol tractor down, decarbonizes and rebushes it, making a very satisfactory job. We must convince the farmer that his business is an engineering proposition. Manufacturers have to contend with a law of supply and demand quite as variable as the weather, and there is a gap of 2 to 3 years between the manufacture and use of a stock article. Farmers must produce finished articles, not raw materials for others to reap the benefit. That will be the way to prosperity.

Mr. W. A. Turnbull : A few years ago the author visited Aylesbury and delivered a lecture on farming and the use of electricity on the farm. I am pleased to say that the Aylesbury Council have placed an order for rural electrification round Aylesbury and I feel that this result is largely due to the author. The cost of overhead lines works out at £600 a mile. That is what we had to pay for a short length about 18 months ago, but we are now getting them erected for less than that. I still think that 11 000 volts is a good transmission pressure. It is possible to obtain a good 10-kW transformer at 11 000 volts (single-phase) to tap off for farms. It is my intention to tap off any farm I can, but if the pressure adopted is 20 000 volts I am afraid it will be out of the question. I am putting up steel branch lines at 11 000 volts. Such lines will easily carry 200 kW. The usual load is only about 20 kW, and if a day load does develop, a voltage-drop does not matter during the day. Later on, as the load develops, the copper main transmission lines can be taken down and replaced by steel-cored aluminium lines at 11 000 volts, which will considerably increase the capacity of the line on those same poles. The cost of the steel line is just about half the cost of the copper line, and in time I think the cost of overhead transmission will fall to £300 per mile, which will be a good proposition for the electrification of rural areas. For the wiring of cowsheds I am thinking of devising a simple vulcanized-rubber system on porcelain cleats, as I think this preferable to steel tube. I should like the author's opinion on this project.

Mr. R. H. White : Can the author give any information in regard to wind-driven generators, which I believe are now being used very largely in Germany for the production of power for agricultural purposes ?

Mr. A. H. Allen : I should like, in view of some reference which has been made to the necessity of cheapening distribution, to emphasize that point as much as possible. We hear repeatedly from engineers in the country that they cannot get on with their rural distribution on account of the high cost of lines, owing largely to the regulations imposed upon them and the difficulty of obtaining wayleaves. Those are two of the most important things to be attended to in extending electricity supply into the country. With regard to those regulations, I should like to mention a point which has just arisen. We know that every endeavour is made to make the supply of electricity in the country as free as possible from danger to the person ; we try to do that by means of elaborate protective devices. Since the beginning of this month one of these cradles, put up to protect electric lines at a crossing, was swayed by the wind and broke the live wire. The wire fell into a field and unfortunately was picked up by a boy, who paid the penalty with his life. The conditions were much worse than they would have been if there had been no cradle at all. Tramway trolley wires run down our main streets at 500 or 600 volts and we seldom hear of any trouble arising from them, yet in the country it is thought necessary to have these devices, ostensibly to save life, with the result that I have mentioned.

Mr. A. E. Jackson : I should like to refer briefly to two points arising out of the discussion. One is with regard to the use of circulating water referred to by Mr. Sayers. Has he considered that when the circulating water would be most particularly required for warming the earth, namely, during the night-time, the load of the generating station would probably be at its smallest ? The other point is in connection with Mr. Turnbull's remarks about the cost of his transmission lines. The Chief Engineer of the Adelaide Electric Supply Co. recently told me that he was constructing his overhead extra-high-tension lines at a bare cost of £180 per mile, excluding standing charges, supervision charges or profit. The poles are of the reinforced concrete type, consisting of two **I** beams bolted together with concrete in between. These are spaced about 10 to the mile.

Mr. G. S. Francis : There is one fact about the financial side of rural distribution which it might be of interest to mention. Two years ago, when visiting Bavaria, I was informed that, as the supply undertaking did not care to be burdened with the cost and trouble of developing rural distribution, this work was being undertaken by farmers' associations, etc. The initial financial difficulties were overcome by the use of a financial instrument, which I think is unknown in this country, and which is described in their somewhat cumbrous

phraseology as a "State-guaranteed, extinguishable non-interest-bearing credit." It certainly tends to advance rural development if the farming community are prepared to shoulder some of the work and responsibility which, at present, usually fall on the engineering undertakings.

Mr. F. Creedy: What, in the author's opinion, is the most suitable type of current for farm work? The lantern slides which he showed were apparently of direct-current motors. One can see difficulties in transmission from the direct-current point of view. Obviously, alternating current gives greater advantages for transmission. Clearly, three-phase squirrel-cage motors are the simplest and cheapest of all, but three-phase transmission for lightly loaded areas is by no means as simple as single-phase, which can be done with a single wire. In addition to this, metering, switchgear and other subsidiary points are a good deal cheaper on a single-phase system. Without enlarging on this point at present I may say that, though rather more expensive, the single-phase motor can be made just as satisfactory as any other type. It would be very interesting if the author would, in his reply, discuss the pros and cons of the different types of current.

Mr. P. Johnson (*communicated*): The author mentioned the use of endless track vehicles on the land. I have long been convinced that such vehicles would ultimately prove to be by far the most practicable and generally applicable method of cultivation. I do not suggest that for large areas such machines would entirely displace the cable system of cultivation, especially where great depth of tilth is required, as for sugar cane and some of the root crops. I entirely agree with the author in his specification of what is required, and I suggest that it might be of interest to the members to know what is now being done in the direction of machines fulfilling in all essential respects the author's specification, with the exception of the electrical operation. A machine already in production (by the Sentinel Co. of Shrewsbury) is a steam tractor weighing about 8 tons fitted with steerable endless tracks to support the weight on soft ground. This machine will cross-plough on ploughed land without damage to the work already done, owing to the light pressure per square inch. In stiff clay soil it has ploughed to a depth of 8 in. at the rate of 4 acres an hour, turning 8 furrows at a time and giving a continuous drawbar pull of 3 to 3½ tons. No difficulty is experienced at the headlands, owing to the lateral flexibility of the tracks and the small turning circle thus obtained. A small tractor on rather similar lines but weighing only 2 tons is about to be put on the market (by Messrs. Morris Commercial Cars, Ltd.). The construction of this machine is somewhat novel, but preliminary tests appear to indicate that it will have many advantages over the more conventional types. One of the main features is that the steering wheels are at the rear instead of the front. They carry a very small proportion of the weight of the vehicle and, being close up to the track units, give it a very small turning circle. In order to obviate the tendency of the load behind the machine to prevent steering and also to counterbalance the torque reaction at the sprockets tending to impose too much weight on the rear wheels, a novel arrangement of drawbar has been designed for this vehicle but has not yet been actually tested. The drawbar is so designed as to pivot on a vertical spindle close up to the centre of the machine and is then carried over the rear wheels so as to swing clear of them and, if necessary, assume extreme angles up to 90° with the longitudinal centre line of the vehicle. Coupled with the lateral flexibility of the tracks, this enables short turns to be made at the headlands and provides against any interference with the steerage due to the load behind. Alternative positions for coupling up to the plough are arranged on this drawbar in the vertical plane, and by coupling low down on it the tendency of the torque reaction of the sprockets to put excessive loads on to the rear wheels can be neutralized. It is suggested that there would appear to be no insuperable difficulty in adapting such tractors as the above for electrical operation.

Dr. B. A. Keen (*communicated*): I am not competent to pass any opinion on the first two sections of the paper, which deal with technical matters connected with the supply of electricity. However, the third section—Work on the Land, and Haulage—directly interests me, as for some years past we have been making at Rothamsted a study of soil-cultivation processes. My main comment is that the various possibilities cited by the author are largely independent of the particular form of power employed. With the exception of the electrical method devised at Rothamsted for reducing the friction between cultivation implement and the soil, on which I comment below, the processes themselves could be—and in many cases are—carried out with internal-combustion engines and steam power. They could, of course, be equally well operated by electrical power and, granted a general extension of such facilities to rural districts, there is little doubt that they would be so operated. This is largely a matter of economics, once the very understandable reluctance of the farming community to change any given method is dispelled by actual demonstration over a period of years, and under a variety of conditions. In this connection I wish to support Sir Daniel Hall's view that the impetus, and the initial financial outlay of complete demonstration, must come from the electrical engineering industry itself. This is the only sure way, and it is in fact the method adopted by other industries having a market among the farming community. As the author points out, there is nothing magical about electricity for agricultural purposes; it is merely an alternative way of providing power. If it has considerable advantages in such matters as convenience and cost, these facts alone will ensure its increased use on the farm. However, in considering its application to work on the land, I wish to enter a plea that it should be approached from a broader angle than the comparatively simple aspect of substituting one form of power by another. Any form of power is a means to an end, which is in the present case the cultivation of the soil. We know very little about the *science* of cultivation, although the *art* has been developed to a high level by age-long experience. Were the science more developed, electric power could then be applied to the best advantage; the implements and the tractive mechanism could be developed as a

unity. It is impossible to assume that the present designs of cultivation implements are final. They have slowly evolved, with an infinitude of empirical trial and error, from the tree branch and spear of prehistoric times to their present forms, and their future designs may well show a corresponding advance on present-day patterns. There is more than a hint of this possibility in the electrical method of reducing the draught of cultivation implements. By passing a current from the coulter to the ploughshare, a film of water is deposited on the latter, due to the phenomenon of electro-endosmose. This film acts as a lubricant, reducing the friction between the share and the furrow slice, and the draught is therefore reduced. In the tests we made at the author's farm, the current was supplied by a small dynamo mounted on the tractor drawing the plough and driven by the tractor engine. When the current was switched on, although the available drawbar pull for direct haulage was reduced by the extra load imposed by the dynamo, yet the reduction in friction at the mouldboard more than balanced the loss and, as a result, the speed of the tractor increased. This result was obtained in preliminary field trials, and, with further attention to the design and position of the electrodes on the plough, there is every reason to expect results of the same order as those obtained in laboratory experiments, i.e. a reduction in draught of 25–30 per cent. The increase of speed when a reduction of draught is achieved by any means, brings out an important principle in soil cultivation and stresses the necessity of considering the problem in its widest aspects. In tests with tractor ploughing we have shown that the drawbar pull only increases slowly for a considerable increase in speed. Thus an increase from $2\frac{1}{2}$ to 4 m.p.h., which would mean a 60 per cent increased area ploughed in a given time, was accompanied by only a 7 per cent increase in drawbar pull. The cost of the extra fuel needed to sustain this increased pull could only be a small fraction of the saving in labour costs due to the extra work done in the given time, and, in addition, the ability to complete work at a rapid rate is of immense advantage to the farmer, especially in unfavourable seasons. In practice, limits are set by the bad work of the present implements travelling at high speeds, and by the heavy wear and tear on the tractor. In the case of electric power, the question of design for a high speed of travel should be comparatively simple, in view of the inherently robust nature of the motors and the almost entire absence of complicated moving parts. Nevertheless, if attention were concentrated on this, to the exclusion of the equally important question of the design of the cultivation implement itself, the chance of a successful outcome would be very slight. The design of the cultivation implement to fulfil these requirements may at first sight appear entirely a matter for the agricultural engineer, but this is by no means the case. If he is to be in possession of a complete specification he must have much more information on the physical properties of the soil than at present. The Rothamsted work is directed to this end; its aim is to obtain, for soil, information of the kind that, under the collective title of "properties of materials," the engineer already has for the various metals, etc., used in the implements. This information is of especial importance when the possibility of a new form of tractive power is considered. It enables the designer to consider the prime mover and the implement as a coherent whole. The alternative is empirically to adapt existing implements to the new tractive force, as was done, for instance, when the internal-combustion engine came into use for land work. The early vicissitudes of this change were as much, if not more, the fault of unsatisfactory implements as of incorrectly designed tractors.

Mr. W. E. Poole (*communicated*): I think that the author presents a case the supply undertakings would be delighted to believe might be true, but the amount of electricity he suggests as a possible demand seems to me beyond what it would be wise to count on when reckoning the financial side of the overhead lines and other equipment necessary to take a supply to an average country district. If such amounts could be sold, even after a few years, we might not trouble about the high cost of overhead lines due to the high standard required by the Commissioners or the super-safeguarding demanded by the Post Office. Those of us who are connected with the business of erecting overhead lines on a self-supporting basis are basing our figures on very much smaller demands from the farmer and the country dweller than the author suggests, and we find it impossible in very many cases to show how the most simple line (complying with regulations) can pay its way. The cheapest three-phase line complying with the regulations costs not less than £500 to £600 per mile, and if it encounters Post Office lines a further £100 per mile must be added for unnecessarily elaborate guard nets, and I am of opinion that if the wish of the Commissioners as expressed, I think, by Sir John Snell some time ago, that "Electricity should be available to every house in the kingdom", is to be realized, we must have a drastic revision of the regulations with regard to secondary lines—sacrificing somewhat the reliability of the supply to the individual consumer or small group of consumers but safeguarding the main supply—and a much more reasonable attitude on the part of the Post Office. There are in some parts of the country secondary lines which are very far from complying with the present regulations, but they afford a supply to consumers who would otherwise have to go without. They do it with a reasonable efficiency and they have proved themselves safe from the public point of view. Why should we then insist on something more costly and more elaborate, and add several pence to the cost of the unit?

[The author's reply to this discussion will be published later.]

North-Eastern Centre, at Newcastle, 8 March, 1926.

Mr. J. M. Heslop: The paper deals with quite a new application of electricity. The author says in his opening remarks that the consumption of electrical energy on American farms amounts to 850 million h.p.-hours per annum, that is to say, approximately 640 million units per annum. This seems a very large

figure, but of course the United States must be considered as a Continent rather than a country and, as their total output of electrical energy is approximately 64 700 million units per annum, it would appear that the consumption for farming purposes is only of the order of 1 per cent of the total. In consequence, it can hardly be said that the farming load is at present very much developed in the United States. There is something to be said for the author's suggestion of calculating revenue and consumption on the route-mile basis rather than on the basis of the square miles of area served. After all, railway receipts are quoted in terms of the train-mile or passenger-mile. I cannot agree, however, with his figures for minimum profitable return. He quotes 5 000 units per annum per mile as being profitable, but I am afraid this is very much too low. If one assumes that a high-pressure overhead line can be erected for as little as £500 per mile—and this is much below prices which I have seen recently—then interest and depreciation alone would represent 2d. per unit on the minimum consumption mentioned. It would seem, therefore, that a minimum consumption of 20 000 units per annum per route-mile is more like what is required to ensure the commercial success of a projected rural distribution line. It cannot be gainsaid that the whole subject is one of paramount importance nationally, inasmuch as we spend abroad every year something over £500 000 000 for foodstuffs, i.e. approximately £12 per annum per head of the population. If, therefore, the use of electricity is going to result in an increased yield of home-grown foodstuffs per acre under cultivation, the benefit is at least three-fold. The farmer will get a greater return for his labour, the individual member of the community will benefit, one hopes, by a decrease in the cost of foodstuffs, and the community as a whole will benefit by an improvement in the trade balance of the country. It seems clearly established that the use of electricity for agricultural purposes results in very definite improvements in the yield of produce. From information published in the technical Press, one gathers that the electrical stimulation of plant growth yields increased crops up to 50 per cent in the case of grain, 25 per cent for mangolds, 33 per cent for sugar-beet, 50 per cent for carrots, and 90 per cent for strawberries. Electric ploughing, it is claimed, results in a 20–25 per cent bigger crop yield, and electric thrashing, the author tells us, yields 5 per cent more grain than existing methods. This, it seems to me, furnishes the basis on which the problem should be attacked. Taking the case of wheat, apparently we import every year wheat to the extent of 220 million bushels, and we raise at home approximately 57 million bushels, making the total requirements of the country 277 million bushels, or approximately 6·6 bushels per head of the population. The average yield per acre by present methods of cultivation is of the order of 31·5 bushels. Now, if electric ploughing gives 20 per cent crop increase, electro-culture gives 50 per cent increased yield of grain, and electric thrashing yields 5 per cent more grain from a given crop, then it seems reasonable to say that 31·5 bushels per acre could be increased to $31 \cdot 5 \times 1 \cdot 2 \times 1 \cdot 5 \times 1 \cdot 05$, that is to say, to approximately 60 bushels per acre. If that be possible, then the acreage required for 277 million bushels would be rather more than 4 million acres, or a little more than twice the acreage at present under wheat. Again, the current price of wheat is approximately 6s. per bushel. A yield of 31·5 bushels per acre at 6s. a bushel gives a return per acre of £9 9s., whilst 60 bushels per acre at 6s. a bushel gives a return per acre of £18. If the farmer can be shown how to increase his yield per acre from £9 9s. to £18, then I have no doubt he will be not only willing but eager to electrify his farm. The author is, I think, the man to do this and he may rest assured of the hearty co-operation of the supply engineer, in view of the size of the potential market for energy. The author takes a figure of 275 units per annum per acre as possible under ideal conditions, and proceeds from this to calculate the potential agricultural load of the country as 16 000 million units per annum. This, of course, is most attractive for the supply engineer looking for fresh markets, but, unfortunately for the author's case, and still more unfortunately for the supply engineer, the whole 57 million acres of land comprising this country are not all agricultural land. Only 32 million acres are under cultivation, and of these, some 18 million acres are permanent pasture, leaving 14 million acres under crops, divided roughly as follows: 7 million under corn crops, 3 million under grain crops, and 4 million under other crops and grass. Now, on page 803 the author gives as probable consumptions:—

General uses	10–30 units per acre
Ploughing and cultivation ..	45–60 units per acre
Total	55–90

or a mean of, say, 75 units per acre, which for 14 million acres = 1 050 million units per annum. Then there is a thrashing load of 24–45 units per acre, or a mean of, say, 35 units per acre. A consumption of 35 units per annum per acre for 7 million acres under corn crops = 245 million units per annum, or a total potential consumption for agricultural purposes of 1 050 million plus 245 million = 1 295 million units per annum, which is very much less than the author's figure of 16 000 million units per annum. To illustrate the point, I know a factory where, in one small shop 90 ft. × 30 ft., the consumption amounts to 90 000 units per annum. This is equivalent to $1\frac{1}{2}$ million units per annum per acre, but that does not justify me in saying that the potential consumption of electrical energy in the country for manufacturing purposes is $1\frac{1}{2}$ millions multiplied by the 57 million acres which constitute Great Britain. I am sorry that the author has taken such a figure, because I feel that it is definitely open to objection as being misleading. It is not valid to take the total area of the country as being agricultural land, neither is it necessary to adopt such an argument. A potential energy market of 1 295 million units per annum is well worth serious consideration without inflation.

Mr. R. E. Robson: Farming, in addition to being the greatest and oldest industry, is also the most conservative, and it is very difficult to make any headway with the North Country and South of Scotland farmer. The easiest types of farmer to persuade to introduce

electricity are the gentleman farmers, the dairy owners and the breeders of valuable stock. I should like to ask the author what he considers to be a fair price for current on farms. In my opinion, the suggestions of the Electricity Bill now before Parliament have set back the advancement of electricity in rural districts. Farmers and country residents now think they can get cheap and abundant supplies of electricity almost immediately, whereas it will be many years before they can be supplied in most districts. The idea of procuring a cheap supply immediately is preventing the sale of private plants to many intending users. The private plant on farms is the pioneer for a public supply, and far more encouragement should be given to the publicity and advertising of private plants than is given at present. Once a private plant is installed, as soon as the supply undertaking is able to supply current the customer is already trained to the uses of electricity and is anxious to get more electric power. There are nearly 20 uses to which electricity can be put on a farm, even from a 2-kW set. With regard to mechanical ploughing, I believe that there are a large number of farmers who specially breed horses and wish to use them for ploughing. I also understand that thrashing is done to a large extent by contract. With reference to e.h.t. transmission lines, if we take a district such as that between Newcastle and Edinburgh there is very little load to pick up, as there are very few towns and not many villages. I am somewhat astonished at the author's suggestion of tapping 33 000-volt lines in a temporary manner, and I should like to have more details as to how this is carried out. What load are the tappings carrying where this is done abroad? I agree with the author's methods of running cables in farm buildings and confirm that I have found ordinary vulcanized-rubber cable run on cleats very satisfactory. I am against the use of hand-lamps where a fixed light could be used. Does the author consider mechanical milking to be satisfactory? A friend of mine, an electrical engineer, once used it but eventually gave it up.

Mr. T. Carter: As the sting of a scorpion is in its tail, so is the point of the paper to be found at its latter end. Agriculture should undoubtedly "be placed on a sound basis," for our national safety in any time of difficulty depends greatly on the extent to which we can feed ourselves. However sound may be the counsel to buy in the cheapest market, the process cannot be successful unless a long view is taken of the real meaning of "cheapest"; and the temporary advantage of low cost of agricultural produce brought from abroad when things go smoothly is a poor thing to set off against a possible failure of supplies in a time of trouble. To be self-contained is a thing worth paying for, because it will be cheapest in the long run, and may prove to be of literally vital importance. But it is difficult to convince people at large that the proverbial rainy day will ever come, and hence the importance of cheapening agricultural production in this country is extraordinarily great. To continue a phrase of the author's, if we are not in the van we may find ourselves in the cart. The author refers to the individualistic tendency of the minds of farmers in this country, and it is therefore particularly necessary to convince them that it will somehow benefit them to adopt his proposals. Otherwise they will hesitate before they arrange to do things in new ways, or to alter the existing routine of their work. I should like to put forward a few questions and comments with a view to making some points clearer through the author's reply than they appear to me to be in the paper. The farmer is said to prefer a fixed charge plus a low rate per unit. I think this depends on the amount of the fixed charge; one farmer friend of mine, at least, objected very strongly to what he thought an entirely excessive demand. However that may be, the basis of price used in the paper is not obvious. Table 1 seems to be founded on 3d. or 4d. per unit, and not on a fixed charge plus a unit charge. The 275 units per acre mentioned as a possible consumption would thus cost something of the order of £4 per annum; and if the rent of the farm is £1 or £2 per acre per annum, the farmer will need to be convinced that he will get back, in return for this (to him) considerable expenditure, as much as will make it worth his while to incur it. I do not know whether rural methods of book-keeping are of the most accurate; and if it is as difficult to make the farmer see all that he is saving by using electricity as it is to make many other people see it, I do not envy the author his task. An important question will be how much of the cost of a transmission line should be charged to the rural supply. If the line is required for interlinking two places in any event, and the rural consumption is taken from it merely because it is there, the cost of the line is obviously not chargeable to the rural supply. I hope that a supply will not be refused to an out-of-the-way corner of the country because no line goes near it. Arrangements ought then to be made for either the supply undertaking interested in the district, or some private person or company willing to undertake the supply, to put down a local power station; and when it would be more expensive to carry a special line to a place than to erect and work from a local plant, there ought to be no hesitation in deciding on the local plant. I cannot think that consent will easily be gained to the connection of temporary loads by hooks to 33 000-volt lines. It is surely inadvisable to have things that are dangerous where there are essentially unskilled persons, even if a skilled man is in charge; and the cost of the skilled man would not be lost sight of by the farmer. The author refers to the constant raising of the standard of wiring in farm buildings; but why not simplify the whole problem by using really low pressures in these places? Not only hand-lamps, but fixed lighting too, might very well be supplied from 25-volt or 50-volt circuits, and the consequent cheapening of the wiring would be a valuable thing. It is surprising to read of motors of comparatively small outputs working successfully at 5 000 volts. They must have been expensive in first cost, and large in size compared with those that would be required for lower pressures, and it would be interesting to have fuller details of this particular equipment. I commend what the author says about the usefulness of ball bearings. They need practically no attention in respect of lubrication, one charge of grease sufficing for many months, and, if well fitted at the outset, they run excellently. The curves about eggs are interesting, but obviously the price curve

is as it is only because the great bulk of egg production is under unlighted conditions. If all poultry farmers provided their hens with the forcing plant described by the author, the taking on by the egg curve of approximately the shape of the present price curve would certainly be accompanied by a change in the shape of the price curve to something like that of the present unlighted production curve. Whether, therefore, eggs would bring more profit in the end if lighting were generally adopted, remains to be seen. What is of importance, however, is that more eggs would be produced in this country, resulting in a nearer approach to the self-containedness that I have already referred to as highly desirable, if not essential. Finally, I would refer to the suggestion that a creeper-tractor should be equipped with storage batteries, and would ask where it is proposed to obtain direct current for charging the batteries. The paper seems to contemplate the exclusive use of alternating current, and presumably, therefore, some rectifying or transforming apparatus would be required in conjunction with the batteries. This adds a complication, and increases the cost of electricity to the farmer, both because of the additional plant and because of the necessity for skilled attention to it. Presumably the author has some quite definite proposal for a means of charging the batteries, but it is not obvious from the paper how it is to be done.

Prof. D. A. Gilchrist: As to increasing the growth of corn crops by electricity, we are already, owing to improved methods of cultivation, manuring, and improved varieties, getting under good conditions as heavy corn crops as will stand. Under adverse conditions such as attacks of insects or plant diseases, the use of electricity would not give us help, nor would it be available on short notice. One of the cinematograph films exhibited by the author showed an electrically driven plough with three furrows to take furrows each 15 in. wide and 12 in. deep. I may explain that most of the land in Northumberland is lying on a boulder clay subsoil and it could not be ploughed to anything like that depth. About 80 years ago, when there was a boom in steam cultivation, much of such land was spoiled by bringing the poor subsoil to the surface. As to a point made in the discussion that the best farmer was the gentleman farmer and a man who had another business as well, this certainly is not my experience; in fact the bulk of our farmers are ready to adopt a good thing when it is placed before them. A Hexhamshire farmer, now in New Zealand, stated in a letter to me to what a large extent the farmers there are making use of electricity. We should get full information as to what is being done in that country. I believe we are ready to make considerable use of electricity on the farm in this country if it can be done at anything like the cost suggested by the author. I believe that a good ploughman and a good pair of horses are still of great value on a farm. During the war, tractors were put on the land, but unfortunately this was done hurriedly so that it was difficult to chose the best type of tractor and to work it as it should be done. For this and other reasons the use of the tractor is not being continued in many cases. As to a statement in the discussion that thrashing is all done in a few days at one time of the year, I may point out that this is not desirable and that thrashing operations are distributed over a considerable part of the year. I should like to see a really good farm selected where an electrification scheme could be carried out in co-operation with the Institution. Mr. Elliot, of the Northumberland Farmers' Union, who is present, would, I am sure, assist in the selection of such a farm. If you approach us in this way we should have the conditions quite clear as to what the total cost will be, and it should be done in such a way that it will be a demonstration of how it can be brought within the reach of any farmer. The author has shown cinematograph films of electrically-driven milking machines, but in clean-milk competitions it is frequently found that hand-milking under proper conditions is most likely to give the cleanest milk. Statistics as to acreages of farming land in this country have been given by one or two of the speakers, but we must remember there is much land that cannot be profitably farmed under arable conditions in this country.

Mr. W. F. T. Pinkney: With reference to Table 1, showing the units and revenue per mile of route, it will be noted that in the comparison of the consumption of energy between rural and urban areas, for rural areas lighting, cooking, heating, and barn work on farms are taken into consideration, whereas in the urban area lighting only appears to be considered, the consumption in the urban area being 200 units per annum per consumer. I have some recent figures available for just under 100 houses where the average consumption is over 2 000 units per house per annum, so that a very much higher consumption than 200 units per annum should be considered in the case of the urban areas, and it may very well be argued that the figure can easily be increased by 10 times. There is a great deal to be done in the direction of applying electricity to agriculture, and it will be very desirable to get some farmer in this district to have his farm equipped electrically, so that we can satisfy ourselves as to the economic value of it, and also demonstrate the value of other appliances. The author suggests, under the heading "Distribution System," that it will undoubtedly be the practice in rural areas to work with a greater voltage-drop than will be permissible for city work, and I should like to point out that, however desirable this may be, the existing regulations absolutely prohibit any appreciable variations in voltage.

Mr. J. A. Anderson: From the farmer's point of view electric power supply in and about the farm buildings would be very desirable, and Fig. 10 gives a fairly comprehensive idea of the uses to which electric power could be adopted for power and heating, in addition to which there is always the lighting of the farmhouse buildings and cottages. From this load alone, however, the power supply undertaking would be disappointed with the results, particularly if a supply were given at a low price per unit. On a good arable farm of about 400 acres the thrashing and crushing-mill motors would probably be used only about 10 hours a day for about 60 days in the year. The chaff-cutter and root-slicer would probably be used about ½ hour every day, so that as far as the load in and about the farm buildings is concerned the load factor would likely

be a poor one on any individual farm, and I doubt if it would be as good as that shown in Fig. 5 for a mixed dairy farm. It would, I think, only be in very exceptional cases where the 35 per cent load factor mentioned by the author at the foot of page 803 would be obtained in this country. If a number of farms were connected to the same line and if arrangements were made for different farms to thrash or crush on different days, the load factor on the whole would be improved. This arrangement would, I think, be preferable to the cutting off of the cooker and other plant on thrashing-mill days. The bulk of the farming done in this country consists of growing grain, hay and root crops, and feeding stock. The making of butter and cheese, and the production of eggs and vegetables, are more or less dependent upon local conditions, and I do not think that the electrification of farms will make much headway until the work on the land can be done by mechanical means. When that time comes, if it is done by electric power the supply undertaking will not, I think, have much cause to trouble about load factor during the working hours of the day. To me the most interesting part of the paper is that dealing with the work on the land and haulage. As far as cultivation is concerned, the author gives a fair idea as to how this part of the work could be dealt with, although I am afraid that the Home Office Regulations would prohibit the use of 5 000–10 000-volt motors and trailing cable in this country. Under the heading of "Small Electric Plough" the author describes a plant requiring 25 h.p. Judging from the size of the motor I should have thought that a plough of this size would be capable of ploughing 20 to 30 acres per day of 10 hours. This acreage would, of course, depend on the depth of the furrow and it would be interesting to know what horse-power is required for the large plough mentioned on page 809. It would also be interesting to know the limit of weight per square foot to prevent hard pan from being formed. Can the author give any information in regard to any attempts which have been made to handle crops mechanically, such as stooking, picking up stooks and stacking, turnip thinning, topping and handling, potato digging and lifting? In regard to harvesting, many crops, owing to their bulk, have to be cut one way, and the return journey with a mechanical vehicle could be travelled at a higher speed. I think it would be easier to the engineer in tackling this problem to take little or no account of the existing implements on a farm. The engineer's ideas would be very much cramped in doing so. No doubt it will be tried, as was done in the case of the development of the motor car, but the motor-car designer soon dropped the idea of converting old dog-carts or phaetons into motor-cars by the addition of a petrol engine and gearing. It should also be realized that it will not generally be an economical proposition to introduce mechanical appliances for any particular section such as cultivation, and until all the operations on a farm can be handled mechanically little progress will, I think, be made. Particular attention should therefore be given to the handling of crops. The author mentions certain districts where the steam plough has made progress. Without knowing the localities, I imagine that the land in these particular districts is of heavy clay. I am acquainted with a farm in Scotland consisting of 500 acres of very heavy clay land where steam ploughs were introduced successfully. The farmer was able to dispense with 7 or 8 horses, but on most farms under cultivation to-day no reduction in the number of horses would be possible by the mere introduction of mechanical cultivators. When all operations on a farm can be handled mechanically, I see a great future for the more extensive farming of land in this country. One would more readily appreciate this if the author gave comparative food values of different crops. As a rough estimate I should say that a grain crop produces 3 times as much as grass land, and root crops 9 times as much. Taking a broad minded view of the matter, one has to visualize the future farm to be one consisting of 2 000 to 3 000 acres with fields correspondingly large. The economical size of the farm should be in proportion to the capacity of the units. The author mentions a cultivating plant capable of dealing with 27 acres a day, corresponding to the work done by about 14 horses or, say, the number used on an arable farm of 500 to 600 acres. Using, say, 5 such units with one spare, I estimate that the most economical size of farm would be about 2 000 acres. Unless the size of the present farm, which generally consists of 300 to 500 acres, is considerably increased, the capital cost of installing mechanical appliances would, I think, be prohibitive. It is interesting to note the different appliances which have been adopted on the farm by an electrical engineer who has turned farmer. The lubricating effect of passing electricity between the coulter and ploughshare is particularly interesting, but I should like to know if the author puts the proposition forward as a practical and economical one. It would be interesting to have some figures in connection with this. The value of the paper would also have been enhanced if the author had given figures as to the cost of installation and operation of crop driers. In this connection the farmer can usually gather the whole of his crops in fairly good condition except once in about every 10 years. The crop driers would free him from a certain amount of anxiety, but I do not suppose he would be willing to pay much for this. I should also like to know if the crop drier is capable of producing hay completely dried, as is done in the northern counties and in Scotland, or if the hay can only be cured in the manner generally adopted in the south, where it is not completely dried before being put into a stack. The figures in regard to poultry and bees indicate that turning night into day for the hens and the bees is a paying proposition. From the load-factor curve given in Fig. 12 it would appear that electric power is used to some extent throughout the whole 24 hours. In regard to electro-silage, does the method cited by the author prevent the considerable amount of waste which was experienced by the old method of merely applying pressure to the fodder?

Mr. L. C. Grant: The introduction of electricity to a farm and the high cost of the service are probably the greatest difficulties. Farmers cannot understand why a high-voltage line crossing their land cannot be tapped easily. It is almost useless to talk to them of the cost of high-rupturing-capacity switchgear, high-voltage transformers and so on. Distribution through

a cheaply-constructed line at 3 000 volts or under seems to be one solution, provided that there is a possibility of the district being worked economically at some future time, but, even so, the scheme has to be financed and finding the financier is no mean task. I often think that something could be done with the present high-voltage cross-country aerial lines at 6 000 volts and above. In this district we have 20 000- and 66 000-volt lines which are crossing farm land for the greater part of their routes. To tap these (for a farm) in the orthodox way by means of switchgear and transformers is almost impossible. Switchgear of considerable breaking capacity must be used and the general engineering must be up to a good standard. I have been investigating the question of tapping such lines by means of condensers with or without transformers. If condensers are used, no switchgear is required, except perhaps for isolation, and the transformers, if used, can be built for comparatively a low primary voltage. Condensers suitable for up to 500 000 volts (R.M.S.) have been developed recently. At this voltage and at normal periodicity such condensers are capable of passing a usable amount of power, and as the purchase price is but a fraction of the cost of switchgear, it seems to me that something might be done, at any rate in the early stages of development, to give supplies in this way. Artificial hay-drying seems to be a promising field as a means of introducing electricity to the farmer. Here there is a load of the order of 10–20 h.p., and to make hay in this way removes one of the farmer's greatest anxieties, namely his dependence upon the weather for hay-making. Against the cost of the energy for the heater and fans can be placed the cost of handling the hay while it is lying in the field, and the decreased risk of damage while the hay is lying out in the field. The additional cost of carting undried hay to the drying apparatus seems likely to have some bearing on the economics of the proposal. Egg production by means of artificial lighting seems to be a reasonable proposition and, of course, the provision of electric light and small domestic appliances in the farmhouse appeals to the imagination of the farmer—or his wife—and is likely to be of considerable help in the early stages of development. The introduction of a small petrol-electric lighting set for this purpose is a good way of demonstrating the possibilities and might pave the way to greater developments. I think that the artificial treatment of seedlings and the rapid development of plants by means of artificial light is a subject of great interest and should be brought to the notice of interested persons. The scheme is helpful both to secure rapid development of early flowers for the market and also to ascertain if a newly developed variety is likely to revert. Seven days' energy consumption at 6 hours per day and 1d. per unit gives a cost of 3s. 6d. to produce flowers in 7 days. Has the author any recent information in regard to the economics of milk treatment by ultraviolet rays ?

[The author's reply to this discussion will be published later.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 10 MARCH, 1926.

Mr. F. J. Moffett : On pages 808 and 809, instances are given of the value of lighting in increasing egg production, stimulating plant growth and encouraging bees to produce a larger output of honey. In the latter case the use of heat as well as light is advised. It appears to me that the application of heat would greatly assist in many directions other than increasing the yield of honey. If poultry houses were heated to a moderate temperature in addition to being artificially lighted, it is reasonable to suppose that the output of eggs during the winter would be even better. On the subject of the stimulation of plant growth by means of low-grade heat, I have received an interesting letter from Mr. H. M. Sayers, who suggests that the warm circulating water from electricity generating stations could be used to warm the soil and neutralize the effect of the spring-time frosts. He calculates that the surface temperature of one acre would be raised 10 to 15 deg. F. above the air temperature, for every 1 000 kW of load on the power station, and that this temperature would enable the crop to grow during the winter and take full advantage of the spring sunshine. Apart from the use of heat for poultry houses, beehives and stimulation of plant growth, there is a considerable heat demand in the farm house, particularly in the kitchen, stables, cow-sheds, piggeries, etc., both for warming the buildings and heating the food. The cheapest way to provide the bulk of this low-grade heat on a farm is to use a self-contained generating plant driven by either a steam or internal-combustion engine, and to utilize the heat which would otherwise be thrown away. In the case of the steam engine there would be the heat units in the exhaust steam, and in the case of the internal-combustion engine the heat in the jacket water and in the exhaust gases. The author does not mention self-contained plants for the generation of electricity on the farm, probably on account of the difficulty of skilled attendance, but such generating plants, at any rate in the case of those driven by internal-combustion engines, can be made almost automatic in operation. In any case, for the handling and upkeep of electrical gear there must be someone with a certain amount of engineering skill. There is no doubt in my mind that if the heat which is usually thrown away during the generation of electricity were made use of, the self-contained plant would give the best results from the point of view of running costs. If the use of electricity on the farm is to wait for the establishment of rural transmission and distribution systems throughout the country, it will be many years before many of our farmers in the more remote parts of the country can hope to obtain a cheap supply of electricity.

Mr. F. Forrest : The author has not dealt with the question of transport on the farm, and where the area is considerable this question must be one of some moment to the farmer. It is difficult to see how electricity might assist him in this matter. It would appear, therefore, that a self-propelling machine which could be

used for transport and for driving the various farm implements would be the best arrangement from a general utility point of view, and this convenience should be set against the higher running cost of the plant. The figure mentioned in the paper read by Herr Wallem before the World Power Conference showed that the average consumption of electricity on farms in Germany varied between 6·4 and 10·4 units per acre per annum. This is an extremely small amount, and it is doubtful whether a power supply undertaking would be willing to incur much capital expenditure on transmission lines to pick up such a supply.

Mr. P. M. Pinder: The tilling machine so well illustrated in the cinematograph film appeared to be doing its work very well, but I doubt its ability to work well in a good stiff clay, as in the film this implement was evidently working in a sandy, or light loam, soil. The author mentioned in passing that a thrashing machine driven by an electric motor yielded 5 per cent extra corn; is this to be taken as a selling point, as one hears of similar points being raised in the sale of electric ovens? The author stated that ploughing was done 18 in. deep, but I think it would be impossible to plough clay soil this depth, at least as a commercial proposition. From the farmer's point of view it is regrettable that no details of costs are given in the paper, such as the capital outlay required for equipping, say, a 200-acre farm, and the average length of time required to recoup that outlay. In considering the general exodus of farm labourers into the towns, is it possible to carry out the same amount of work on a farm with fewer men after installing electric light and power in the homestead?

[The author's reply to this discussion will be published later.]

NORTH-WESTERN CENTRE, AT MANCHESTER, 30 MARCH, 1926.

Mr. R. H. Wadsworth: The application of electricity in a town or an industrial area enables a fairly continuous load to be obtained during the day, and at night it is made use of for domestic purposes. Why cannot we have some means of electrifying the agricultural districts, so that a continuous load could be obtained from agricultural uses? This would considerably help those smaller areas which cannot afford to install electricity for the small population of householders, simply because the load is not large enough. The point that troubles the farmers to-day with regard to electricity is simply that in many cases they are a considerable distance from the distributing line and the cost of the service to the farm is heavy. A farmer may have to lay the service 500 or 600 yards, and he cannot afford the first cost. There are scores of farmers who would use electricity if the cost of installation could be reduced. The author's suggestion of employing overhead instead of underground lines would meet the difficulty admirably. The application of electricity to farms, especially milk farms, would be of great service to the consuming population of this country, because nothing would conduce more to the supply of clean milk than a good light. I should like to impress on the urban districts the importance of assisting the rural districts, because if the farmer can be in any way helped at the outset they will find it a good paying proposition.

Mr. T. Wright: Rural areas are very scattered and, as Mr. Wadsworth said, services would be most costly to lay. In our locality there are many distributing lines, so perhaps every farmer will be able before long to obtain a supply at comparatively slight expense. If the first cost can be reduced, I am confident they will not hesitate to have a supply. Electricity will certainly be a great boon in a wet summer, and it will solve the problem of getting in the hay when the weather is bad. Hay dealt with in the way suggested does, I understand, produce a first-class milk, and that is what we require.

Mr. W. J. Medlyn: On the question of cost to the consumer the paper is a little disappointing; its value would be enhanced if the author could add some information as to the cost of this form of power as compared with other methods of meeting the working requirements. The paper gives a good idea of the economical advantages of using electricity, and in the course of his remarks the author has filled up some gaps in the paper. In a general way, of course, the growth of the system is an indication that the expansion is resulting in economic advantage to the consumers as well as to the supply undertakings. The lantern slides and cinematograph films have brought very clearly before us the fact that electricity is the only method of carrying out a good many of the operations in farm work. The paper leaves the impression that much still remains to be done in the way of standardizing materials and equipment. There are many important industries, not only in the United States but in this country also, where standardization has been developed to provide for the cheapening of supplies by mass production; and it seems clear that a further extension of this principle to rural electricity supply could not fail to prove advantageous alike to supply undertakings and to consumers. There appears to be an impression (which the author rather confirms in his remarks) that Post Office engineers are antagonistic to the extension of power supplies in rural areas. This is not so. Telephone exchanges require electrical power for their economical operation, and as the telephone services are being extended to meet the requirements of dwellers in country districts, the need for electrical power supply for Post Office purposes is growing. I hope that this statement will clear away some of the misapprehension which appears to exist. I think we ought to take a broad view in these matters. In all branches of the electrical industry we are all interdependent to a great extent, and the growth of one branch reacts to the common good and to the advantage of all. Further, growth can only take place when the supplies of the commodity prove to be an economic advantage and convenience to the community; and it is certainly to the advantage of

all of us to combine to produce this very desirable result. I suppose there will always be differences of opinion as to what is a proper apportionment of charges where different undertakers are concerned. A good deal has been said on the subject from time to time, one suggestion being that supply undertakers should have a free hand in the provision of distribution lines, and that the Post Office should take its own measures for the protection of its own plant. That sounds an excellent idea, from one point of view, but we might apply the same principle to the farmer who persists in loosing a savage dog at night and tells his neighbours that they should make their sheep safe by locking them up. The need for reasonably cheap methods of construction is a pressing one, but the question of finding the best solution is too involved to be dealt with in a casual way. After sifting the actual facts, the decision as to the precautionary measures which will be required will ultimately rest with the authorities who are vested with the necessary powers. With constructive suggestions and good will combined, I think the final solution ought to be fair to all the different interests concerned.

Mr. W. Fennell: I have been asked to speak as representing the supply side of the question, in what may be termed an agricultural area. Mr. Wright and Mr. Wadsworth have both emphasized the need for a rural supply of electricity, but the author says, I think, not quite correctly that we have not learned the proper way to tackle the problem. My view is that we are not allowed to. We have to construct overhead lines in this country under regulations which were made with the chief object of applying them to transmission lines designed to supply large quantities of power at a distance. Those regulations are quite unsuitable for dealing with a rural area. I realize the great field which is open to us in rural areas, and I have tried to do all that is possible under the existing regulations to reach the farmer in Mid-Cheshire. My company recently raised a considerable sum of money largely for this purpose. We did not underwrite the issue, which was over-subscribed, and this demonstrates the public belief in this development. We have encircled our area of 125 square miles with a 33 000-volt overhead line system. We have tapped these extra-high-pressure lines and have provided outdoor substations for stepping straight down from 33 000 volts to low pressure for use in large villages, using transformers of as low a capacity as 25 kVA, on a commercial basis, and I do not think this has been done before. We are prepared to run branch lines, and indeed have already run some of them miles into the country districts at about 3 000 volts, suitable for connecting transformers for hamlets and individual farms. We have no intention of charging the farmer large sums, or indeed anything, for getting to his farm. I do not think that in the last 10 years my company has taken from all its consumers more than a total of perhaps a couple of hundred pounds for service costs. In general we rely upon reasonable guarantees. We are in the position that we are ready with our main lines and substations, and we are prepared to go into the by-ways and the lanes; but we want help from the authorities and accommodation from the Post Office in order to carry out the rural portion of the scheme. I should like now to deal with some of the more pressing difficulties we have to face apart from the regulations. Both the author and Mr. Medlyn have said that the Post Office authorities are not antagonistic. I do not think they are; they are merely self-centred. The Post Office officials naturally think of the Post Office, and I do not blame them; but they should not carry it quite so far as to ask us to pay their costs for special construction when they decide in their wisdom to follow us. For instance, in the district of Cuddington they sent us a demand for special construction costs to enable their new line to cross ours in no less than six places in a ½ mile, although they could have chosen another route. We should certainly have chosen another route if we had been following them. We do not object to pay when we are second-comers; we recognize we must pay because we cannot expect the Post Office to alter their works for us at their own cost. Again, the guarding arrangements upon which they insist may be necessary under certain conditions, but along a country road they are superfluous. When the Post Office requests an undertaking to put up steel towers to support the line, with a steel net to hang under the line to catch it when it falls, and a double line wire connected to two sets of insulators, tied together at short intervals so that it cannot fall on to the guard, it is demanding rather too much. Each of those crossings costs £300, which sum would construct over a mile of country line, but I am very glad to say there are indications that a more reasonable spirit will be shown in this direction. There is another class of the community to whom we must look to help us to get to the farmer, and that is the farmer himself. The value of land seems to appreciate to an extraordinary degree when the farmer knows that an undertaking desires to erect a pole on it. The farmer, in general, will have to realize that electricity will benefit him, and therefore he must help us in every way, and not send in heavy claims for damages. A hedge seems to cost about £5 a yard to repair when a pole has been dropped on it or we have had to cut through it. I feel sure that the farmer, when he does realize the tremendous benefit he can obtain from electricity, will be more reasonable. With regard to overhead construction in general and the methods of construction of substations, it has been to me a most fascinating business designing new and cheap forms of tapping e.h.t. lines and dealing with manufacturers, persuading them to alter their designs to give us what we want and to leave out expensive things which are not required in rural work. With regard to the line construction itself, we have several cable companies and other highly organized firms who are second to none in the world for carrying out the heavy lines, and the smaller ones are carried out by our own staff very safely indeed, at the lowest cost we can achieve under existing regulations. Those of us who have rural districts included in their areas have a very great responsibility. There is every temptation to the supply engineer to keep to the towns and suburbs where the financial return is fairly sure and where he does not encounter such difficulties as arise in rural areas. This temptation must be resisted and we should be ready to go to a good deal

of trouble to meet the demands of the farmer so that we can put this country in a better position than it is in regard to agriculture. We have also to think of the country resident who is expecting a service for light, heat and power, which we alone can supply.

Mr. T. E. Herbert: I feel that it is incumbent on someone to issue a warning note on the development of electricity in agriculture. As electrical engineers we are naturally disposed to push our own industry without considering many of the larger problems involved. I think it would be a calamity if the public were allowed to believe that the supply of electrical energy to farmers would solve the whole of their difficulties. I admit, quite freely, that the supply of electrical energy is decidedly to be desired, but very serious injury will be done if extravagant claims are made as to the benefits to be derived from it. So far as I am able to judge, the question of encouraging and helping agriculture generally is engaging the attention of all the political parties. It is perfectly clear that the solution of the problem, so far as the farmer is concerned, is not simply the supplying of electrical energy. The guiding principle ought to be to secure the greatest economy of human effort, and I trust that the problem of greater efficiency in agriculture will not be obscured by any question of electrical development. With regard to the remarks of Mr. Fennell, I have always been under the curious misapprehension that the measure by which civilization advanced or is advancing could be correlated to the appreciation of the value of human life; and if, in order to provide cheap electrical energy on cheaply constructed open lines, those lines are going to take their toll of human life, well, all I can say is, frankly, that the electrification of farms does not appeal to me in the slightest. We have heard all about the sins of the Post Office—of course they are many—in protecting its plant, its operators, its subscribers and the members of the public, from the dangers caused by power circuits. Nobody appreciates more than I do the author's extremely valuable work in seeking to produce economy of human effort on the farms. He is right both theoretically and practically, but, after all, to supply electricity is merely to touch the fringe of the problem. The only opinion I venture to hazard is that it might be even more important that the small farmer should be in telephonic communication with the markets and the neighbouring farmers than that he should have a supply of electricity in bulk.

[The author's reply to this discussion will be published later.]

THE CAUSE AND ELIMINATION OF NIGHT ERRORS IN RADIO DIRECTION-FINDING.

By R. L. SMITH-ROSE, D.Sc., Ph.D., and R. H. BARFIELD, M.Sc., Associate Members.

[Communicated by permission of the Radio Research Board.]

(Paper first received 18*th February, and in final form* 29*th March; read before the* WIRELESS SECTION 5*th May,* 1926.)

SUMMARY.

The paper describes experiments which have been carried out with a view to obtaining more conclusive evidence as to the causes of the apparent variations in bearings observed under certain conditions on wireless direction-finders. In the course of the experiments the Adcock "four-aerial" direction-finder has been developed, and with its aid it has been shown that the actual deviation in azimuth of wireless waves is practically negligible. These experiments thus constitute a proof that the variable errors observed on closed-coil direction-finders at night are caused by downcoming waves arriving from the upper atmosphere and polarized with the electric force in a horizontal plane. The investigation also indicates the possibility of the Adcock system being developed into a practical direction-finder which is free from night errors, and those errors associated with observations on aircraft transmissions made at a ground direction-finding station.

(1) OBJECT OF THE PRESENT PAPER.

The object of a large proportion of the investigations carried out by the present authors for the Radio Research Board during the past few years has been to ascertain definitely the cause of the apparent variations in bearings experienced on closed-coil direction-finding apparatus during the "night" periods. Some of these investigations have led to the development of methods of distinguishing between the electric and magnetic components of wireless waves, and of the separate measurement of their intensity and direction. This portion of the work has recently led to a definite proof of the existence of downcoming waves at the earth's surface with components of suitable polarization and sufficient intensity to account for a large proportion of the night errors experienced.*

In this manner the theory originally advanced by T. L. Eckersley † in 1921 to account for the apparent variations in the direction of arrival of wireless waves has been adequately confirmed; and it is now evident that these variations are caused by the action of the horizontal components of electric force in the downcoming waves on the horizontal parts of the direction-finding loops. A good discussion of these effects and the associated phenomena is given in Keen's book on the subject of wireless direction-finding.‡

It is generally assumed that the downcoming waves have travelled via the upper regions of the earth's atmosphere without deviating laterally from the great-circle plane through the transmitter and receiver. This assumption has, however, not been sufficiently well justified in the past; and the presence of the downcoming waves has hitherto made it difficult to prove whether the direct waves travelling along the earth's surface have not also suffered any lateral deviation. Another portion of the authors' investigations has therefore been made to ascertain to what extent, if any, such lateral deviation exists. The problem is one of more than pure scientific interest; for it is evident that, if directional receiving apparatus can be devised which shows the absence of lateral deviation, we are at once provided with a direction-finder which is free from the variable night errors that place such a serious limitation on closed-coil direction-finders. The present paper describes the experiments which have been carried out with these objects during the past 18 months.

(2) SUGGESTIONS AND ATTEMPTS BY PREVIOUS WORKERS.

The problem involves essentially the production of an apparatus which will measure the horizontal component of the direction of arrival of wireless waves, irrespective of their angle of incidence at the earth's surface or their state of polarization.

Three methods of attacking this problem have previously been described. In a patent filed in 1919, F. Adcock * described a direction-finding arrangement in which the aerials were mounted and connected in such a manner as to ensure that only the vertical parts were acted upon by the arriving waves. In this way he proposed to eliminate the errors which are caused by the effect of the horizontal electric field on the receiving system. This arrangement consisted essentially of four vertical aerials spaced at the corners of a square; the aerials at the extremities of a diagonal formed a pair and were connected in opposition to the field coils of a radiogoniometer. Provided that the horizontal members of the system have no effective E.M.F. induced in them, it is clear that the current in the field coils is due entirely to the phase difference of the E.M.F.'s induced by the vertical component of the electric force of the arriving waves. This current will thus depend only on the horizontal direction of arrival of the waves relative to the system.

In the paper already mentioned,† T. L. Eckersley

† T. L. ECKERSLEY, loc. cit., p. 239.

suggested that any lateral deviation of wireless waves from the great-circle plane through transmitter and receiver could be measured by employing a receiver in which each of the ordinary closed loops of the Bellini-Tosi arrangement is replaced by two loops in the same plane connected together in series and so that their E.M.F.'s oppose each other. With such an arrangement the effective E.M.F. induced therein will be entirely due to the phase difference between the individual E.M.F.'s in the two loops resulting from their spacing. It is then evident that a wave arriving in a direction at right angles to the plane of the loops will produce no resultant E.M.F. in the circuit, whatever may be the angle of incidence or state of polarization of the arriving waves.

In 1921, G. M. Wright and S. B. Smith * published an account of experiments carried out with a direction-finder connected in such a manner as to give the heart-shaped polar diagram for reception. These experiments showed that, under conditions when large variations in apparent bearings were obtained on the ordinary direction-finder, the position of the heart-shape minimum remained constant although the actual shape of the polar reception curve altered considerably. The agreement of the experimental results with those predicted from Eckersley's theory served as a useful confirmation of this theory. The accuracy of such experiments, however, largely depends upon the purity of the minimum and, as Wright and Smith pointed out in their paper, the heart-shaped minimum only remains pure when the downcoming waves are arriving at a reasonably small angle to the horizontal (i.e. a large angle of incidence). In some of the authors' recent experiments, however, angles of incidence as small as 16° to the vertical have been measured,† and the behaviour of the heart-shaped diagram under such conditions is a matter for further investigation.

As far as the authors are aware, no account of the practical working of either of the above systems as direction-finders has yet been published, although the heart-shape circuit arrangement is now in common use for the determination of the "sense" of wireless bearings. Quite recently, however, a directional receiving system comprising two spaced loops mounted in a common vertical plane has been described by H. T. Friis.‡ This arrangement has been developed with a view to obtaining directional selectivity in ordinary wireless reception, and not as an application to direction-finding.

(3) Early Experiments at the Radio Research Board's Station, Slough.

(*a*) *Double loop method.*—In the first experiments, a modification of Eckersley's suggested method was employed. Instead of using two pairs of large double loops at right angles, a single pair of small loops was constructed and arranged in a vertical plane so as to be rotatable about a vertical axis.

The E.M.F. induced in such a system by a single wave is given by the expression :—

$$e = K \sin \frac{2\pi d \sin \theta}{\lambda} \cos \psi \, (\alpha \sin \psi + \beta \cos \psi) \quad . \quad (1)$$

where K is a constant for loops of a given area,
d = distance between the centres of the loops (assumed small compared with the wave-length λ),
ψ = angle between plane of loops and horizontal direction of waves,
θ = angle of incidence of the waves at the earth's surface,
α = horizontal component of magnetic field of waves in great-circle plane through transmitter and receiver,
β = horizontal component of magnetic field of wave perpendicular to α.

The above expression for the induced E.M.F. becomes zero when $\psi = 90°$, so that there is a zero or "minimum" position of the system when the plane of the coils is at

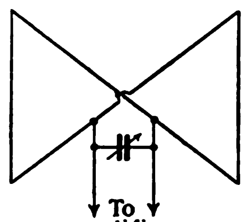

FIG. 1.

right angles to the horizontal direction of arrival of the waves, whatever may be their state of polarization or angle of incidence. It should be noted that this is not necessarily the only minimum which will be experienced in the rotation of the coil from 0° to 180°, since it is quite possible to have a second minimum at the value of ψ for which $\tan \psi = - \beta/\alpha$.

For simplicity of construction in the practical arrangement, the loops were made triangular in shape and consisted of a single winding in the form of a figure 8, as depicted in Fig. 1. These loops were erected in a hut which was suitably screened for the elimination of antenna effect, and the remainder of the receiving circuits and the amplifiers were adequately screened from the direct effects of the arriving waves. When the arrangement was tested it was found to work satisfactorily on near-by stations ; but owing to the fact that its reception factor is differential in nature, it was not sufficiently sensitive for operation on transmissions from the more distant stations. Hence it was not possible to use the apparatus under the conditions which give rise to the usual night phenomena in radio direction-finding. In the absence of a much more sensitive amplifier, the only methods of increasing the strength of the received signals would be either to increase the distance between the loops (d), or to adopt Eckersley's suggestion of employing large fixed loops on the Bellini-Tosi plan. In regard to the last alternative, it is seen from equation (1) that the E.M.F. is not propor-

* G. M. Wright and S. B. Smith : "The Heart-shaped Polar Diagram and its Behaviour under Night Variations," *Radio Review*, 1921, vol. 2, p. 394.
† R. L. Smith-Rose and R. H. Barfield, loc. cit., p. 612.
‡ H. T. Friis : "A New Directional Receiving System," *Proceedings of the Institute of Radio Engineers*, 1925 vol. 13, p. 685.

tional to cos ψ, and as the operation of the Bellini-Tosi radiogoniometer depends upon such a cosine law, this method cannot be adopted for the present case. Up to the present time no experiments have been made with loops separated by a greater distance, for, as will be seen below, the use of Adcock's method has been found to give more successful results.

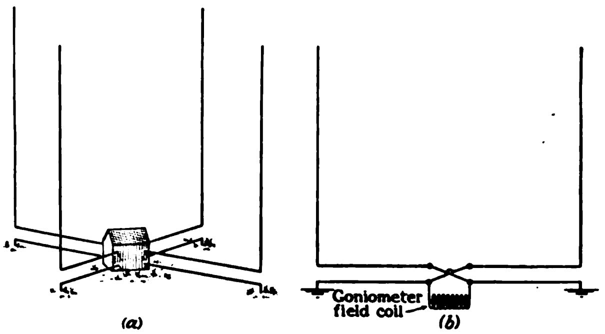

FIG. 2.

(a) Sketch of system. (b) Elevation of single pair of aerials.

(b) *Adcock's system.*—The simplest form which this system can take is probably that shown in Fig. 2 where each of the four aerials is earthed at a point vertically beneath it, but the earth lead is taken horizontally to the receiving hut at the centre of the system and back again. In Fig. 2 (b) only one pair of aerials is depicted to show the method of connecting the aerials in opposition through the field coil of the radiogoniometer. Such a mode of connection should have the effect of rendering any E.M.F.'s induced in the horizontal members of the system by the arriving waves equal and opposite with regard to the circuit "aerial-field-coil-earth," so that the net E.M.F. induced in this circuit is that due to the phase difference of the individual E.M.F.'s induced in the two vertical members. This E.M.F. is given by the equation

$$e = KZ\frac{2\pi d}{\lambda}\cos\psi \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where K is a constant for a given aerial system,

Z = vertical electric force,

d = distance between the aerials,

ψ = angle between direction of travel of the wave and the line joining the aerials.

Since the E.M.F. is proportional to cos ψ, it is clear that two pairs of such aerials may be used with a radiogoniometer in exactly the same manner that this instrument is used with the fixed loops of the Bellini-Tosi direction-finding system.

Experiments carried out with the above arrangement as in Fig. 2 showed that, due probably to stray capacities to earth, the horizontal E.M.F.'s induced in the system were not balanced out, and gave rise to serious errors.

(4) Attempted Improvement of Adcock's System.

With a view to overcoming the difficulty just mentioned, an attempt was next made to screen the whole of the horizontal portion of the system from the effects of the arriving waves. Previous experience had shown that in order to screen an aerial adequately, it was necessary for the screen to project beyond the aerial by a considerable length. The system finally adopted for the present case is depicted in Fig. 3, which shows one pair of aerials with the horizontal members contained within a screening trunk formed of a number of parallel wires. At their inner ends these wires were joined to the metallic lining of a screened hut which contained the whole of the receiving apparatus and the operator. Tests of the effectiveness of this screening arrangement were made by measuring the directional properties of the four individual aerials. These measurements unfortunately showed that the attempted screening of the horizontal portion of the aerials had been unsuccessful. The explanation of this result is probably that, whilst the screen effectively prevented any E.M.F. being induced directly in the horizontal members of the aerial system, the vertical component of the secondary electric field resulting from the currents in the screen itself, induced E.M.F.'s in the vertical portions of the

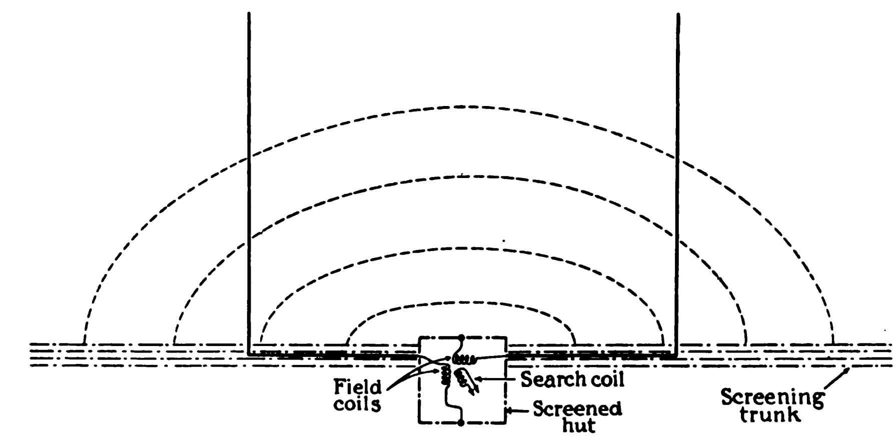

FIG. 3.

aerials (see Fig. 3). Since the currents in the screen are produced by the horizontal component of the electric force in the arriving wave, the condition that this component shall have no effect on the system is not fulfilled.

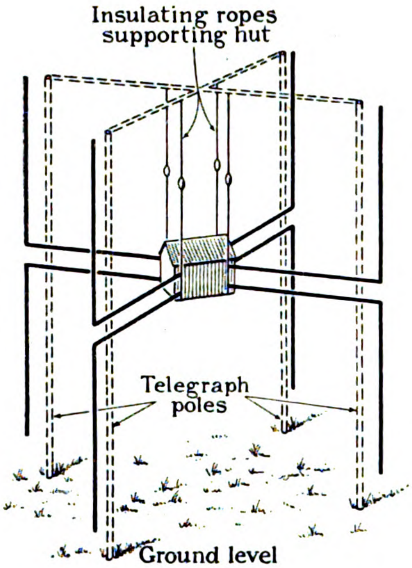

FIG. 4.

(5) FORM OF ADCOCK'S SYSTEM FINALLY ADOPTED.

It was now decided to revert to the alternative arrangement described by Adcock * in which the vertical aerials are comprised of complete Hertzian oscillators with leads taken horizontally from their mid-points to the receiving apparatus in the screened hut. In order

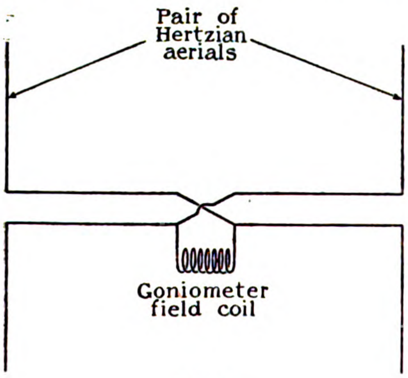

FIG. 5.

to maintain symmetry this of course necessitates the raising of the hut with the apparatus and operator to the level of the centre of the aerial system some 20 ft. above the ground. For the support of the aerial wires, four poles were available 44 ft. high, situated at the corners of a 20-ft. square. The receiving hut was placed at the centre of this system, being suspended by insulated steel ropes from cross beams attached to the poles, to reduce to a minimum its capacity to earth or to other structures.

* F. ADCOCK, loc. cit.

The arrangement is shown diagrammatically in Fig. 4, the circuit being as given in Fig. 5. By this reduction of the capacity to earth of the various parts of the system it was anticipated that the E.M.F.'s in the horizontal members would completely balance each other, and thus the system would be rendered free from the effects of any horizontal electric fields. The fulfilment of this condition was verified; first, by measuring the directional properties of the individual aerials as formerly; and secondly, by comparing the induced currents in the upper and lower halves of the same

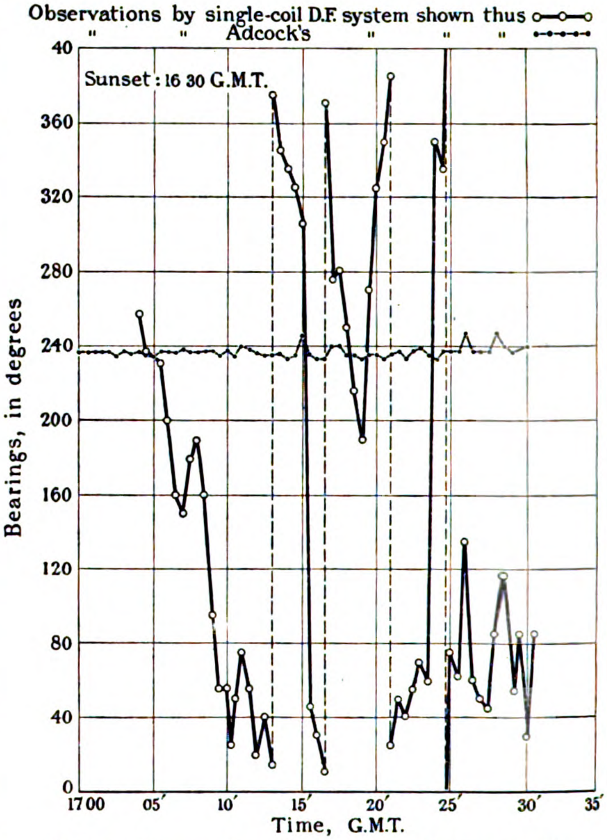

FIG. 6.—Observations of bearings on Bournemouth, 3 November, 1925 ($\lambda = 386$ m).

aerial. This last test brought to light a superiority of 2 or 3 per cent of the lower half over the upper half of each aerial, due probably to the difference in their capacities to earth. Although the error introduced by this asymmetry was very small, it could probably have been eliminated by suitably shortening the lower part of the aerial to make the two halves electrically equal. Since the whole method depends upon the assumption that the four receiving aerials are identical, it is important to observe that other tests showed that the receiving properties of the aerials was not materially influenced by slight differences or irregularities in the neighbouring supporting structures.

(6) CALIBRATION OF THE SYSTEM.

The apparatus was now calibrated for direction-finding by taking observations of the apparent bearings

of stations transmitting within the broadcasting band of wave-lengths, under conditions which gave freedom from night errors. In this manner it was found that the apparatus was subject to a permanent directional error of the same order as that experienced on the closed-coil direction-finders in use in the same field, due to the local surroundings.

(7) Determination of Lateral Deviation of Wireless Waves under Night Conditions.

In order to determine to what extent wireless waves can be laterally deviated from the great-circle plane connecting the transmitter and receiver, it was decided to make observations on some transmissions which were known to give rise to serious night variations on an ordinary direction-finder. Accordingly a series of tests was carried out in which the apparent bearing of a transmitting station was observed simultaneously on the above apparatus and on an ordinary single-coil direction-finder installed in another hut at about 100 yards' distance. In this manner observations were taken on the transmissions from Cardiff (353 m), London (365 m), Bournemouth (386 m), Newcastle (404 m), and Birmingham (475 m). The most serious night variations were obtained on Bournemouth and Cardiff, and Figs. 6 to 9 show graphically some of the results obtained in the simultaneous observations on these stations. Figs. 6 and 7 refer to the results obtained on Bournemouth on two different evenings; and these show very strikingly that the errors obtained on the Adcock system are almost negligible compared with those obtained on the single-coil direction-finder. Indeed, on several occasions, the latter system showed a rotation of the apparent bearing through more than 360°, whilst on the Adcock system the extreme variation in either of the tests was 14°. From the results on Cardiff plotted in Fig. 8 the same effect is observed, although the variations are less violent. On one occasion the bearing on the single-coil direction-finder rotated through 175°, whilst the extreme variation on the other system was about 7°. In the further observations on Cardiff plotted to a larger scale in Fig. 9, it is seen that when the normal direction-finding variation was comparatively small (14°) the extreme variation on the other set was 1°, which is of the same order as the limiting accuracy of the present apparatus.

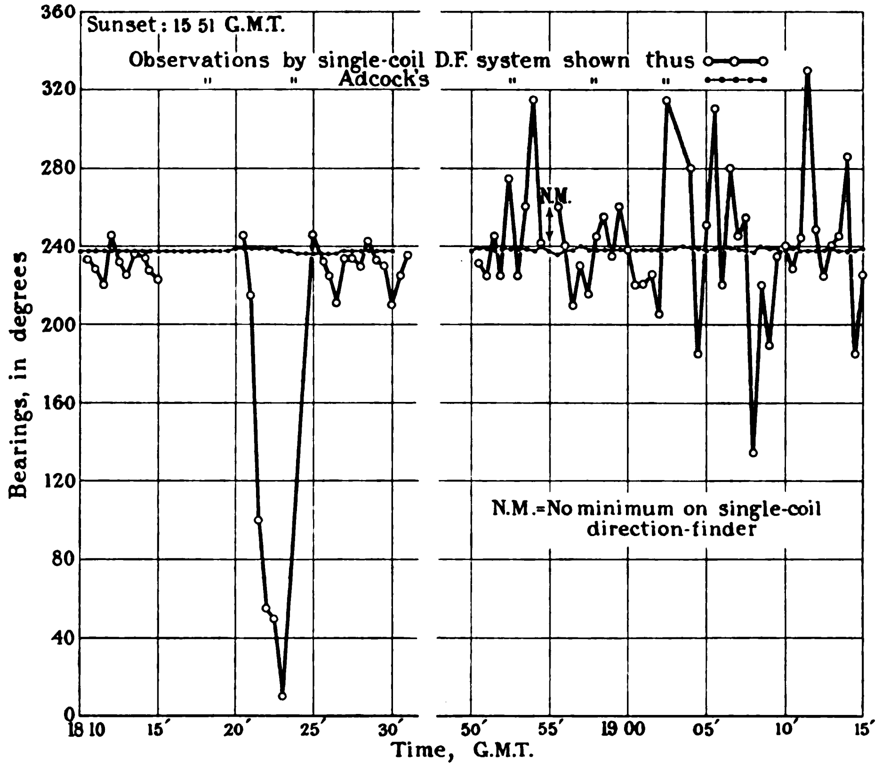

Fig. 7.—Observations of bearings on Bournemouth, 10 December, 1925 (λ = 386 m).

It is to be concluded from these results, therefore, that lateral deviation plays a negligible part in producing the large and variable errors in apparent bearings which are obtained at night on the present type of closed-coil direction-finding set; and that, therefore, these errors are entirely caused by the arrival of downcoming waves polarized with the electric force horizontal. We have, therefore, in this investigation a further proof of the existence of these downcoming waves which supplements and confirms those given in previous papers by Appleton and Barnett * and by the present authors.†

The slight residual variable errors noticed as having

* E. V. Appleton and M. A. F. Barnett: "On Some Direct Evidence for Downward Atmospheric Reflection of Electric Rays," *Proceedings of the Royal Society*, A, 1925, vol. 109, p. 621.

† R. L. Smith-Rose and R. H. Barfield, loc. cit.

been recorded on the "four aerial" system may, it will be seen, amount to $\pm$ 7°. These may be caused by a slight defect in the apparatus due to imperfect balancing by which the rotated downcoming wave is able to produce some slight current in the goniometer, or it may be actually a residual amount of lateral deviation. Before the point is settled by improvement of the apparatus it will be best to assume that it is due to the latter cause. The important point is, however, that

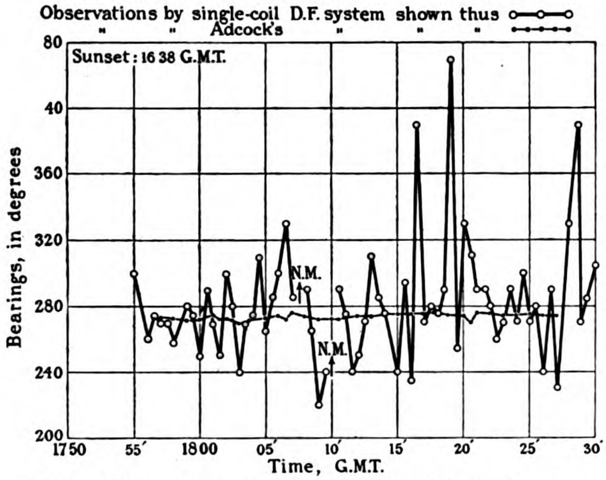

FIG. 8.—Observations of bearings on Cardiff, 26 January, 1926 ($\lambda = 353$ m).

even so, an error of $\pm$ 7° due to lateral deviation almost certainly does not imply that the waves are deviating to this extent from the great-circle path between transmitter and receiver, for it may be shown that, given two waves arriving with varying relative phase and with direction of travel in vertical planes separated by an angle ψ, the total maximum apparent variation in the resultant direction will greatly exceed ψ.* The conditions for this occurrence are simply that the two waves shall be approximately equal in amplitude and nearly 180° out of phase. It then appears extremely probable that the $\pm$ 7° apparent variation recorded is an indication of a much smaller real lateral deviation.

It may further be pointed out that a slight lateral difference in path between the horizontal and downcoming wave is almost certain to exist, for the horizontal wave on land is nearly always slightly deviated by local irregularities of the earth's surface (trees, etc.), whilst the downcoming wave on the other hand will not be influenced by these causes, at any rate to the same extent, and thus the two will probably not arrive exactly in the same vertical plane.

It is to be observed that, since there is no departure of the downcoming wave from the great-circle plane connecting tramsmitter and receiver, it is unlikely that the upper ionized layer, from which this wave is returned to the earth, is inclined to the horizontal. Such a tilt of the upper deflecting layer was suggested by Eckersley † as a possible cause of the downcoming wave having a

* See, for example, T. HEILIGTAG: "On the Causes of Error in Directional Reception," *Jahrbuch der drahtlosen Telegraphie und Telephonie*, 1923, vol. 21, p. 77.

† T. L. ECKERSLEY, loc. cit., p. 239.

component polarized with the electric force in the horizontal plane. Further, since it has previously been shown that directional errors are obtained on the transmissions from a vertical aerial,* it is evidently unnecessary for the horizontal electric force to be present in the radiation from the source. The investigations described in the present paper thus form a useful confirmation of the magneto-ionic theory of wave propagation which has been recently introduced by Appleton and Barnett † and by Nicholls and Schelleng,‡ in which the rotation of the plane of polarization of the downcoming waves is ascribed to the influence of

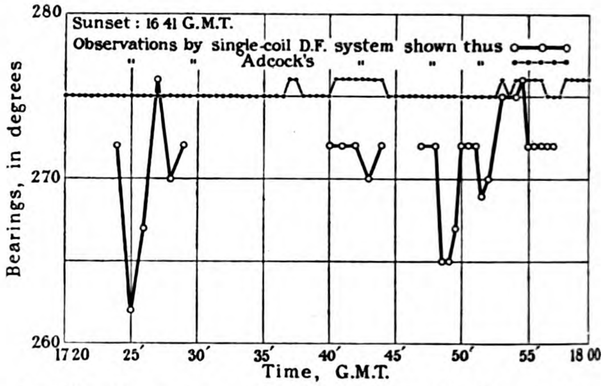

FIG. 9.—Observations of bearings on Cardiff, 28 January, 1926 ($\lambda = 353$ m).

the earth's magnetic field on the motions of the ions in the upper atmosphere.

(8) APPLICATION OF THE SYSTEM AS A DIRECTION-FINDER FREE FROM NIGHT ERRORS.

In the experiments described above it has been demonstrated that Adcock's four-aerial directional receiving system is successful in discriminating between laterally deviated waves and horizontally polarized downcoming waves. It is further shown that even during the times when the worst variations of bearings are obtained on the closed-loop direction-finding systems, the amount of actual lateral deviation of the arriving waves is very small. It therefore follows that such a system may be used as a direction-finder which gives the true direction of the great-circle plane of arrival of wireless waves whatever may be their state of polarization or their angle of incidence relative to the earth's surface. The system should, therefore, have important applications as an accurate direction-finder under night conditions, or for use in observing on aircraft at high angles of elevation, when the ordinary closed-loop direction-finder is subject to such large errors as to make it practically useless. For example, Baldus and Buchwald § have shown that the closed-coil direction-finder

* R. L. SMITH-ROSE: "The Effect of the Shape of the Transmitting Aerial upon Observed Bearings on a Radio Direction-finder," *Journal I.E.E.*, 1924, vol. 62, p. 957.

on the ground can give errors of as much as 60° in the bearings of aircraft.

In considering what will be the limiting accuracy of such a system it must be remembered that the variable error of $\pm 7°$ mentioned above was obtained under what are probably the worst conditions that can prevail in wireless direction-finding on medium wave-lengths. For it is worthy of note here that the variations of apparent bearing observed at Slough on the transmissions from Bournemouth are very much greater in both frequency and magnitude than any hitherto experienced by the authors during the past five years on all wave-lengths from 450 to 12 000 m. Under more favourable conditions, such as obtained in the case of the results taken on Cardiff, the maximum error experienced was only 2° or 3°, and it is considered that even this small amount can be reduced by a development of the system on a more favourable site. Also, on the longer wave-lengths allocated for commercial direction-finding the system will be subject to a still smaller error, and the instrumental difficulties will be somewhat decreased.

It is of course realized that in the practical development of the system it would be preferable to have the receiving apparatus, together with the operator, located on or near the ground and not at the centre of the aerial system as represented in Fig. 4. Several methods of overcoming the difficulties mentioned in Section 3 (*b*) have already occurred to the authors and these will be tested experimentally as soon as possible. A consideration of the case also shows that the system may be provided with the sense-finding modification, which is now a usual attachment to all direction-finders.

(9) Conclusion.

The experiments have shown that by paying careful attention to symmetry of construction, the system of direction-finding proposed by Adcock can be made to work with a considerable amount of success.

It has been employed as a means of discriminating between laterally deviated and horizontally polarized downcoming waves, demonstrating within the limits of experimental error that lateral deviation was non-existent and that, therefore, the latter type of wave was responsible, in all the cases examined, for the whole of the errors experienced at night in the closed-coil direction-finding system.

These experiments thus constitute an entirely self-contained proof that at night time there are waves arriving in a downward direction polarized with the electric force in a horizontal plane.

It has been shown that good reasons exist for the hope that this system may be successfully developed into a direction-finding system free from night errors and "aeroplane" effect.

These investigations were carried out for the Radio Research Board, established under the Department of Scientific and Industrial Research, and the authors desire to acknowledge their indebtedness to the Board for permission to publish the results. They also wish to thank Mr. R. Naismith for his assistance in the later portions of the experiments described in the paper.

APPENDIX.

Some Early Observations on Aircraft with the Four-Aerial Direction-finder.

By Frank Adcock, M.B.E., B.Sc.

It was suggested that as all the authors' observations were obtained on land transmitting stations it would be of interest for me to add an account of some experiments which were made with direction-finders on transmissions from aeroplanes in 1918. It was known at that time that bearings or directions obtained by means of the ordinary "closed loop" direction-finders were often quite inaccurate or indeterminable. Experiments with a Hertzian oscillator and with a small spark transmitting set fitted with two equal and symmetrically disposed aerials instead of the more usual aerial and earth arrangement confirmed the view that the vagaries of the ordinary direction-finders were due to the presence of a horizontal component in the electric force of the radiation emitted by an aeroplane in flight. Further, it was thought that this horizontal component

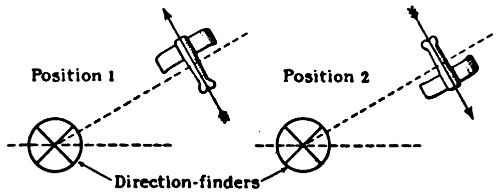

Fig. 10.

of the electric force of the radiation owed its existence to the two following independent causes :—

(1) An appreciable angle of incidence of the radiation in respect to the ground would cause the wave-front to lean forward.

(2) Owing to the drag of the aerial of an aeroplane in flight the axis of the "equivalent Hertzian oscillator" of the machine would depart considerably from the vertical. Under these conditions the horizontal electric component from this cause would be non-existent when the aeroplane was flying directly towards or away from the examination point, but would attain its maximum value when the machine was flying tangentially in respect to the observer.

The tests mentioned below were made with the aid of an aeroplane flying at a moderate altitude and at distances of 3 to 8 miles from the direction-finding installations, in which circumstances it was believed that any errors of direction would be associated almost entirely with the direction of flight of the machine. Two direction-finding installations were used for taking simultaneous observations on the aeroplane, one equipped with a revolving loop aerial, the other with the fixed experimental aerials devoid, as far as possible, of effective horizontal members. The two installations were erected close to one another but not so near as to cause

mutual interference. It was then arranged that the aeroplane fitted with a wireless transmitter should fly over a village in a direction at right angles to that of an imaginary line joining the village in question and the direction-finders. A return journey was then made over the same village, the aeroplane flying in the opposite direction. Wireless transmission took place when the machine was directly over the village, and the two positions of the aeroplane with respect to the direction-finders are shown in Fig. 10. The whole process was repeated over four villages situated at gradually increasing distances from the direction-finders, and the errors in the wireless bearings obtained in each case by both installations are indicated in the table above.

The results were meagre but it was clear that large and consistent errors were present in the bearings obtained with the revolving-loop direction-finder. On the other hand the apparatus fitted with the four vertical aerials gave errors in the bearings of only about one-fifth this magnitude. It was also of interest that the errors in the bearings taken with the revolving-loop direction-finder were reversed when the direction of flight of the transmitting aeroplane was reversed, and that these errors showed little tendency to diminish as the distance between the aeroplane and the direction-finder was increased.

TABLE.

Aeroplane flying over	Approximate distance of aeroplane from both direction-finders	Approximate true bearing of aeroplane from both direction-finders	Erorr of bearing on aeroplane as recorded by direction-finder with revolving-loop aerial		Error of bearing on aeroplane as recorded by direction-finder with four vertical aerials	
			Aeroplane in position No. 1 (Fig. 10)	Aeroplane in position No. 2 (Fig. 10)	Aeroplane in position No. 1 (Fig. 10)	Aeroplane in position No. 2 (Fig. 10)
	miles					
Village A	3	65°	—	− 21°	—	+ 1°
Village B	4	67°	+ 24°	− 33°	− 1°	− 6°
Village C	5½	66°	+ 31°	− 23°	− 3°	− 5°
Village D	8	63°	+ 40°	—	− 2°	+ 1°

The authors have made a very comprehensive examination of the wireless radiation from land stations under various conditions and if they can be induced to extend their investigations to a thorough examination of the radiations emitted from elevated sources, the publication of my own scanty observations will be justified.

DISCUSSION BEFORE THE WIRELESS SECTION, 5 MAY, 1926.

Mr. R. H. Barfield: I should like to point out one or two details which have occurred to Dr. Smith-Rose and myself since we wrote the paper, and also, perhaps, to forestall one or two of the more obvious criticisms to which the paper might otherwise be subjected. In the first place the system clearly has an application as an ordinary directional receiver, i.e. one in which its directional properties are made use of to minimize interference. Most of the established methods of directional reception work on the assumption that the waves are vertically polarized and they therefore break down when this is not the case. The present system has not this disadvantage and should therefore be an improvement as a method of reducing jamming or atmospherics at a receiver. For we now know that signal waves may often be circularly polarized and it is at least highly probable that atmospherics sometimes also are. There is certainly no evidence to the contrary. A criticism might well be raised that the Adcock direction-finding system could not possibly be worked in practical circumstances owing to the delicacy of the balancing required which might be upset by the presence of surrounding objects. Now for the successful working of the new system much the same conditions are required as for any other direction-finder. The two essentials are: (1) That the instrument shall be designed correctly to work in accordance with its theory, and (2) that a minimum space shall be provided round the system free from all conductors and of homogeneous or symmetrical dielectric properties, or, failing this, one in which all the electric properties remain constant. As regards the first of these I think we may now claim to have satisfactorily solved the problem of design. For the second, the dimensions of the minimum space will probably vary with the wave-length and the point remains to be investigated. So far, however, there is no evidence that the Adcock system requires any more space than any other direction-finding system; nor does there seem to be any particular reason why it should. In connection with the space occupied by the system, it has probably occurred to some that the arrangement we have described is not the most fundamental form which the system can take. The simplest arrangement would consist of a single pair of opposed aerials mounted rigidly on an arm so as to rotate about a vertical axis (see Fig. A), and which would take the form of a metal pipe down which the leads would be brought to a screened box on the ground. The circuit

diagram would be much the same as with the four-aerial system (Fig. B). The tuned circuit and the amplifier would be contained in a screened box forming the base of the apparatus. The advantage of this arrangement is that it might be made much smaller than the four-aerial system, to which it bears exactly the same relation as the closed-coil direction-finder bears to the Bellini-Tosi system. There does not seem to be any doubt that such a system as this will work satisfactorily, but we have not yet had time to try it. Returning finally to the four-aerial system, since the total signal strength obtained is the result of the small differential action of two identical aerials connected in opposition, and, further, since the aerials are not even directly tuned and are of dimensions too small to be efficient except for very short waves, it might well be questioned whether the apparatus had not attained its perfect directional properties by making too great a sacrifice of its range of working. As a matter of fact this is not at all the case. The daytime range obtained with the apparatus just described is over 200 miles to a standard B.B.C. station, but this is far from being a maximum range. This apparatus was not constructed from this point of view at all; not only could its aerial system be greatly

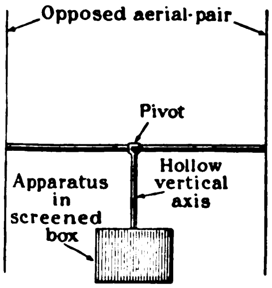

FIG. A.

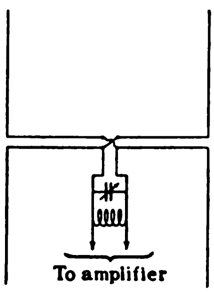

FIG. B.

improved in efficiency if necessary, but by the use of modern amplifying apparatus alone the range could without doubt be greatly increased. Thus the question of the range of the Adcock system in comparison with that of other systems is not likely to arise.

Admiral of the Fleet Sir H. B. Jackson: I should like to congratulate the authors on the results they have obtained after many years of labour in getting a directional system which may be free from night errors. I hope that they will be able to make of it a practical working instrument suitable for replacing the present Bellini-Tosi ones in places where they are erected. The Radio Research Board agrees with the results of these experiments. What the effect would be on the coil system on board ships it is difficult to foresee, but I think that if the night errors can be reduced to nil—they are not very great at present on the distances used at sea, it is true—it will be a great improvement and enable reliable bearings to be obtained at night at much greater distances than at present.

Mr. R. Keen: Although the paper is very interesting, I read it with mixed feelings. The authors make reference to the work of previous adherents to the Eckersley theory, but they fail, I think, to make clear that much of the confirmation which they bring forward had been produced in almost identical form by these earlier writers. Under the heading "Objects of the present paper" the authors say: "This portion of the work has recently led to a definite proof of the existence of downcoming waves at the earth's surface with components of suitable polarization and sufficient intensity to account for a large proportion of the night errors experienced." With regard to this, I think that Eckersley, in his original article in the *Radio Review* * gave very good proofs that the errors were caused by these downcoming waves with abnormal polarization, and, in addition, the article by Wright and Smith, to which the authors refer, afforded a number of examples of the 360° rotation of bearings similar to those now shown in connection with Bournemouth. In 1920 Wright and Smith were taking bearings at Chelmsford on Clifden which at that time was working on 6 000 m (C.W.) and also on Lyons on a 5 000-m arc transmission. One of the Clifden error curves shows that there was a tendency for the rotation to occur at intervals of approximately 20 minutes and this was the period which would be expected to elapse between two cycles of interference between the direct and reflected waves as the Heaviside layer was rising. The Bournemouth rotations on a much shorter wave-length appear to be at 4-minute intervals. Another instance of 360° errors is referred to briefly in my book † when dealing with the confirmation of the Eckersley theory. When the Marconi Co. originally started their wireless service to Paris, reception at this end was carried out on a Bellini-Tosi aerial with a figure-of-eight diagram, the wave-length being 2 300 m. Before the heart-shaped diagram was substituted for the figure-of-eight, complete rotations of the bearing of Paris were not unusual near the time of sunset, and on one evening in 1921 the apparent bearing of Paris made 3½ complete rotations within an interval of 15 minutes. On the assumption that these rotations are due to interference between the direct and reflected rays, then at the instant of maximum error there should be a drop in signal strength since the direct ray and the normally polarized component of the reflected ray are in phase opposition. Signal-strength measurements were accordingly made on Clifden by Wright and Smith, and the intensity was found to fall as the error increased, and in certain cases dropped almost to zero at the instant of 90° error. I do not wish to appear too critical, but I think it right to emphasize that these 360° rotations of bearing were well known 4 years ago, and I consider it hardly correct for the authors to say that "it is now evident that these variations are caused by the action of the horizontal components of electrical force in the downcoming waves," etc.; because many of us were convinced of this after the previous work on the subject was published. The results obtained with the Adcock aerial system are extraordinarily interesting, and the graph of Fig. 6 must surely be the first to be published showing such a complete conquest of night variations. If the system can be put into a more practical form, whilst retaining its accuracy, it should be of great commercial value. The Marconi Co. made

* T. L. ECKERSLEY: "The Effect of the Heaviside Layer on the Apparent Direction of Electromagnetic Waves," *Radio Review*, 1921, vol. 2, pp. 60 and 231.
† R. KEEN: "Direction and Position Finding by Wireless," 1922, p. 164.

some tests on the Adcock system some years ago using the arrangement shown in Fig. 2, but wave-lengths of several thousand metres were used. This made the whole operation rather more difficult, although trouble with the screening cage disappeared since underground cables could be used. The work had to be abandoned before any success was achieved approaching that now recorded by the authors. It would be interesting to know whether a capacity radiogoniometer has been tried in place of the inductive one. Since open aerials are being used, there might possibly be some advantage in doing so. Mr. Barfield has mentioned the use of the Adcock system for directional reception, as by its means a heart-shape minimum can be maintained under the worst night-effect conditions. It should certainly be very useful in this connection, but at the same time it is an uncommon thing in this country for the down-coming ray, on wave-lengths between 2 000 and 20 000 m, to be so steep as to upset the normal closed-coil heart-shape balance. At the Marconi receiving station at Brentwood there are 14 receivers employing heart-shape reception and it is only rarely necessary to alter adjustments due to this cause, although at some Continental stations where the district is mountainous a certain amount of trouble is experienced at sunset in maintaining the minimum for the elimination of jamming. It is mentioned on page 836 that: " The investigations . . . form a useful confirmation of the magneto-ionic theory of wave propagation which has recently been introduced by Appleton and Barnett and by Nicholls and Schelleng, in which the rotation of the plane of polarization of the downcoming waves is ascribed to the influence of the earth's magnetic field on the motions of the ions in the upper atmosphere." I think, however, that some credit for this should be given to Dr. Eccles who, in his Inaugural Address * to the Wireless Section in 1921, said that the action of the earth's field on free electrons in space would account for the rotation of the plane of polarization to this extent. I am glad that the authors have now experienced some of these violent variations on C.W. signals, because they will appreciate why it was that in discussions on their previous papers on night variations I have always insisted that errors were greater on C.W. than on spark. Having seen, on various occasions, the apparent bearing of a station move through 360°, makes one prejudiced against long-distance C.W. bearings with a closed-coil direction-finder. Lest this paper should, however, give the impression that all direction-finding is unreliable, it must be remembered that the authors were deliberately searching for bad night effect and that it has been proved by their previous tests that, up to 100 miles over sea, either spark or I.C.W. transmission will give all the reliability required for the navigation of ships.

Mr. J. M. Furnival: The authors refer to inaccuracies of bearings received by ground direction-finding stations from aircraft in flight. The tests mentioned in the Appendix were made with the aid of an aeroplane flying at a moderate altitude and at distances of 3 to 8 miles from the direction-finding installation. The tabulated data would appear to indicate considerable errors observed on a revolving-loop direction-finder, and it is furthermore stated that these errors showed little tendency to diminish as the distance between the aeroplane and the direction-finder was increased. It may be of interest to compare the results thus obtained experimentally under the conditions described with those achieved by the Bellini-Tosi ground direction-finding stations which have been in operation for the past 4 or 5 years in connection with the navigation of civil aircraft on the cross-Channel air routes. It may be explained that Bellini-Tosi direction-finding stations have been established for this purpose by the Air Ministry at Croydon, at Pulham in Norfolk, and lately at Lympne in Kent. Similar stations have also been arranged at various important air stations in Europe. The results of several years' experience show very definitely that during daylight hours an accuracy of within $1\frac{1}{2}°$ can be normally expected. Due to the speed of approach of the aircraft, which in any case makes the passing of bearings at close ranges an operation of some difficulty, any errors which may exist when the aeroplane is in close proximity to the station have not in practice been detrimental to the service to any appreciable extent. The great value of this service to aerial navigation is now well established, and this is borne out by the experience gained by pilots both in practice and also when flying in conditions of bad visibility. [The speaker here quoted extracts from numerous reports, by permission of the Air Ministry.]

Mr. F. Adcock: I am rather out of touch with " wireless " as applied to aircraft at the present time, and it is possible that a modern aeroplane carries a fairly heavy weight on its aerial, in which case the angle taken up by the aerial when unwound may be nearly vertical. That would have the effect of bringing the bearings much nearer the truth. In the actual tests that were made, we set out to obtain the largest possible errors (with the ordinary direction-finders) and the experiments were carried out in 1918 with that object in view. We did not use the Bellini-Tosi but the revolving-loop system. I take it that the Bellini-Tosi apparatus should be subject to similar errors.

Mr. E. H. Shaughnessy: Judging from the curves shown, although the Adcock direction-finder does vary, it does not seem to vary in the same way as the coil. Where there is a maximum deviation in the coil in one direction, the curve for the Adcock aerial seems to bend in the opposite direction. This seems to be common to all the curves. Is there any reason for this? The phenomenon can be clearly seen in Fig. 8 just after 18 20 G.M.T. and at 18 05 G.M.T. I take it that an error of 7° on a direction-finder is almost as bad as one of 50°. It seems, therefore, that unless the error can be reduced to, say, not more than 2°, the bearing cannot be relied upon and that the system is no better than the Bellini-Tosi. With regard to the day error, our practice with the Bellini-Tosi system shows we can get quite good results within 2°. Moreover, when we get these installations at shore stations calibrated by means of the ships the navigating officers say that they cannot get nearer than 2° in their calculation unless they have objects on land on which to take sights, which indicates that there is little to choose between compass bearings and wireless directional bearings.

* *Journal I.E.E.*, 1921, vol. 59, p. 83.

Lieut.-Col. H. P. T. Lefroy: The authors have not mentioned the subject of fading. If fading can be reduced by using the Adcock aerial, it might become a valuable form to use for broadcast reception. Referring to Fig. 5, would it be possible to get any compensation for asymmetry by sliding the connections of the lower antenna, leaving the upper connections fixed on the ends of the goniometer coil ?

Prof. J. T. MacGregor-Morris: Why does the bearing of the Bournemouth station show such excessive variations as compared with other stations which have been tested ? One speaker in the discussion has mentioned that it is not only a question of rather limited changes of wave-length, because he gave an example of a wave-length of 6 000 m where there was a revolution of this kind. Referring to Fig. 6, apparently the direction from which the received wave has come has undergone two complete revolutions and then has turned back through the same number of revolutions, as if it had to uncoil itself. Is this borne out by other observations ? The variations of bearing shown in this figure are very striking. They are taken, I understand, on the direction in which the waves appear to come from Bournemouth at Slough. If simultaneous observations were taken at Bournemouth when Slough was radiating, would the converse hold good ?

Major B. Binyon: I am very interested in what Mr. Barfield said with regard to future developments, because it seemed to me he was very confident on the sensitivity question. I should like to ask him if satisfactory signals could be received on an Adcock direction-finder having aerials of approximately the size of coil direction-finders as now used for ships. With regard to the disturbing effect of stray capacities in the original arrangement as shown in Fig. 2, in that sketch the two parallel horizontal leads are shown very far, apart; this may be only a matter of draughtsmanship, but it seems to me that the distance between the leads could be made absolutely negligible in comparison with their distance from the ground. This should reduce the asymmetry produced by capacity to earth. I presume that the $\pm$ 7° errors in bearings on Bournemouth, etc., were taken with the Hertzian oscillator apparatus. What would be the magnitude of the errors if the arrangement shown in Fig. 2 were used; would the horizontal effect be much worse ?

Dr. S. H. Long (*communicated*): I should first like to emphasize the valuable scientific contribution by the authors to the vexed question of the reflected polarized down ray and its resultant effect of producing "night-effect" errors in direction-finding work. The apparatus as designed and described certainly appears to offer immense possibilities for employment in cases where suitable care can be taken to ensure its being erected on a most favourable site where ample space and other facilities are available. It would then be of great importance to the safety of aerial and marine navigation, and it is for those purposes, I consider, that it appears to be specially adapted. I feel, however, that one should not overlook the present tendency in marine wireless direction-finding to install the apparatus on the ship rather than on the shore, and the ever-increasing number of radio beacon stations seems likely to encourage that tendency in the future. Now on board ship the conditions are very different from those on land. The apparatus has to be installed in a situation which is convenient to the general working of the vessel and which has in the majority of cases not been in any way selected for efficient wireless direction-finding. Further, the mere presence of the metal mass of the ship is an influence which may give results comparing unfavourably with those described by the authors. The space available for the installation is invariably limited, especially on cargo vessels where interference must not be caused to the working of cranes and cargo hoists. In the past it has been an unfortunate practice of navigators to demand a direction-finding bearing when night effect has been present and the wireless operator has taken, if minima were possible, one or two bearings and either cancelled them or sent them to the bridge marked "night-effect." Naturally in a large number of cases these results have caused wireless direction-finding apparatus to be regarded as unreliable for navigation purposes. Experience, however, shows that if a direction-finding set is designed to indicate the actual presence of night-effect, and the operator does not take one but a large number of bearings over a period of 5 mins., then the mean bearing is sufficiently accurate to be a valuable aid to navigation. The usual procedure now adopted when night-effect is present, on one large liner employing a single-coil direction-finding set with suitable compensating devices when making New York, is for the operator to submit a list of bearings on Nantucket at each sending period. All these bearings are submitted to the navigator, who can obtain a large degree of accuracy from the mean bearings. The following example is that obtained on such a liner when night effect was so bad that the shore station refused to give a bearing.

Time, G.M.T.	Maximum	Mean bearing	Difference against visual checks
15 20	272°	267·5°	+ 0·5
15 25	263°		
	272°	267·5°	+ 0·5
	263°		
15 30	272°		
	262°	267°	$\pm$ 0·0

Thus, in practice, provided bearings over a period of 5 mins. can be taken—and this is nearly always possible on direction-finding beacon stations—the "night-effect" does not become a really definite drawback. It is, of course, essential that both wireless operators and navigators should fully understand the problem. When examining Fig. 6 it appears at first glance that the night-effect difficulty with regard to the use of the direction-finder as an aid to marine navigation has been overcome, but on closer consideration it appears that there is a residual amount of lateral deviation which may amount to $\pm$ 7°. It seems doubtful whether, as

a point of practical navigation, it would not be preferable to continue to employ a direction-finder suitably designed so that unreliable bearings could be immediately recognized as unreliable, rather than a direction-finder which gives a definite reading which may or may not be subject to a deviation of $\pm 7°$ from the apparent bearing. I should like to ask the authors how the bearings given in the paper were actually taken. If they were taken on the carrier wave, by what method was the oscillator introduced into the single-frame and the Adcock systems? Moreover, what was the "arc of swing" in obtaining the bearings? With the increasing number of C.W. installations, and the desirability of obtaining accuracy on C.W. stations, I should think that the interaction of 5 frames as used by the authors (i.e. 2 main aerials, 2 field coils and 1 search coil) would render the system somewhat difficult to design for the accurate taking of C.W. bearings. Moreover, in "sense" determination—and this is essential in all modern direction-finding work—the phasing of the waves in the frame systems must be exceedingly complicated, and, as the whole sharp determination of "sense" is dependent on the accurate balancing of phasing in the systems, this problem does not appear capable of a simple solution such as can be obtained by the single-frame system.

Dr. R. L. Smith-Rose and **Mr. R. H. Barfield** (*in reply*): Mr. Keen has taken us to task for presuming to claim priority in the matter of the proof that night errors in direction-finding are due to the arrival of downcoming waves horizontally polarized. We would reply, however, that no such claim was intended. Full references are given in the paper to the work of all those mentioned by Mr. Keen, and, whilst we fully recognize the value of such work, others besides ourselves have considered that further confirmation was necessary. As a result of the research for such confirmation we think it will be agreed that our knowledge of the influence of the upper atmosphere on wireless transmission has been very materially enhanced. We must further emphasize that the present paper contains the first proof that wireless waves travelling around the earth, whether directly or via the upper atmosphere, suffer no appreciable lateral deviation from great-circle planes, a possibility to which attention was drawn in Mr. T. L. Eckersley's paper.* In final defence we would also remind Mr. Keen that there are still individuals, both within and outside this country, who are sceptical about the Heaviside layer.

On the question of the complete rotation through 360° of a signal minimum on a direction-finder, the following quotation may be given from a report † on an investigation on the variations of bearings of transmitting stations, both spark and continuous wave, operating at various distances on wave-lengths between 2 000 and 12 000 m. "The largest error recorded during the whole two years' observations was over 105°, but errors of this magnitude were extremely rare, and out of the 164 000 observations tabulated only in three cases was an error exceeding 90° experienced." In a later report * dealing with the continuation of the investigation on wave-lengths down to 450 m it was stated that "the maximum observed error on any station was 82·7°." This experience conflicts somewhat with that mentioned by Mr. Keen, and we must repeat that we still consider a rotation of bearing of more than 90° an exceptional occurrence. Even now we have only experienced a rotation of 360° in the case of Bournemouth's transmissions received at Slough, although observations have been made on several other of the British Broadcasting Co.'s stations on neighbouring wave-lengths. The condition for such rotations is evidently a critical one and depends upon getting the wave-length, the relative intensities of the direct and downcoming waves, and the polarization and angle of incidence of the latter, all of the right order. Owing to the fact that observations under identical conditions have not been made on damped-wave transmissions, we cannot agree with Mr. Keen that these results in any way affect the question of the relation between wave-damping and directional errors. All these points, however, would appear to be somewhat irrelevant to the main object of the paper, which, as Mr. Keen appreciates, has been to demonstrate the utility of the Adcock system in overcoming night errors in radio direction-finding.

From Mr. Furnival's remarks we gather that the only difficulty experienced in practice in the operation of ground direction-finding stations for observing the bearings of aircraft is in the matter of night errors. This would therefore seem to be a good case for the application of the Adcock system, which has the additional advantage that, *if necessary*, it can be used for accurate bearing observations at short ranges.

We think that the coincidence between the maximum deviations in opposite directions on the single coil and Adcock systems pointed out by Mr. Shaughnessy is accidental, for it does not always occur in the diagrams given in the paper (cf. Fig. 6 at 17 25–17 30). We do not consider that an error of 7° is quite as bad as one of 50°, but there seems to be every hope that the error of the Adcock system may be reduced to 2°, which is quite adequate for most navigation purposes at the present time.

In reply to Lieut.-Col. Lefroy, the fading of signals received on the Adcock aerial system should be of the same order as that experienced on any vertical aerial, since in both cases it is due to the variation in the intensity of the vertical electric force in the arriving waves. Since the Adcock system does not receive waves polarized with the electric force horizontal, the fading effects may not be quite the same as those experienced with an inverted L or a T aerial, but it is doubtful if any material advantage for broadcast reception is to be gained in this manner.

On the subject of the excessive variations in the bearings of the Bournemouth station, we would refer Prof. MacGregor-Morris to our reply to Mr. Keen above. The curious behaviour of the variations noted in Fig. 6 has not been confirmed by other observations. We regret that we have at present no data that will

enable us to answer the question as to the reciprocity of transmission between Bournemouth and Slough.

Major Binyon is correct in assuming that the horizontal leads in Fig. 2 are shown well separated for the purpose of clarity. In practice these leads should be as close together as is compatible with a small capacity between them. Having established the validity of the principles underlying the Adcock system and the fact that the lateral deviation of wireless waves is negligible, with the aid of apparatus represented diagrammatically in Figs. 4 and 5, we are now returning to the arrangement depicted in Fig. 2 with a view to removing the defects formerly experienced in its practical operation. While it may be difficult to reduce the dimensions of the system to that of a small frame coil, we see no reason why future development should not result in an Adcock direction-finder of suitable size for installation on board ship, and with adequate range for navigation purposes.

In reply to Dr. Long it would appear that on any direction-finding system which is subject to variable night errors the existence of these errors can be detected by taking successive observations over the space of several minutes. We agree entirely that the effect of a night error can be considerably reduced by taking the mean of such observations. On the medium wave-lengths employed for navigation purposes a period of 5 to 10 minutes will probably be sufficient for such a series of readings, but on the longer wave-lengths of from 2 000 to 20 000 m a night error may remain comparatively constant for $\frac{1}{2}$ hour at a time. It has been consistently pointed out, however, in previous publications * that over long periods the mean bearing at night is seldom more than 1° or 2° in error, although individual observations may be subject to errors up to 60°. Considering that the experiments described in the paper constitute the first systematic test of the Adcock system, we feel justified in assuming that an extreme error of 7° under the worst conditions for direction-finding is an extremely favourable beginning; and we feel confident that the system will in due course play its part in the application of direction-finding to navigation. All the bearings recorded in the paper were observed on the carrier wave of the broadcasting station concerned, a beat note being obtained by introducing oscillations from a local source. This source is adequately screened in a manner previously described.† A standard form of such screened oscillator has now been in use for continuous-wave direction-finding for several years and it has given every satisfaction for this purpose. We can assure Dr. Long that, provided correct precautions are taken with the apparatus by applying now well-known principles, there is no reason why direction-finding on continuous waves should not be quite as accurate as with damped waves (spark or interrupted continuous waves). Mr. Barfield has already drawn attention in this discussion to the possibility of the Adcock system being made quite as simple as the single-frame system, and this is one of the lines which future development will take.

THE ECONOMICS OF LAMP CHOICE.*

By D. J. BOLTON, B.Sc. (Eng.), Associate Member.

(*Paper first received 8th February, and in final form 18th March, 1926.*)

SUMMARY.

Lamps are first compared with other electrical apparatus as regards the possibility and the method of economic choice. Choice of type (carbon, metallic vacuum and gas-filled) is first considered, and then choice of rating for a given type, the latter being treated both graphically and algebraically. Simple formulæ are developed for the most economical rating, first with a fixed lamp and then with a fixed candle-power. These are applied to a number of different cases, and various courses of action are suggested for the manufacturer and the lamp user.

TABLE OF CONTENTS.

(1) INTRODUCTION.

In an earlier paper † it was pointed out that in dealing with any piece of apparatus or equipment in which a greater first cost would result in decreased running costs, the size of such apparatus can be determined in either of two ways, physical or economic. That is to say, the size may be the minimum required to perform the given service without risk of breakdown or damage, or it may be that size which will give minimum total costs over a number of years of service. With most apparatus it is the former which receives chief consideration, but with lamps the economic criteria are always the determining factor. Physical limits, such as the actual burning out of the filament, are never reached, and the working current is limited, not by the fear of immediate fusion, but with regard to length of life.

The rating of an incandescent lamp is therefore chosen on purely economic grounds, since any desired efficiency can be obtained by suitably over- or under-running, and the efficiency normally quoted is merely that which the lamp will attain when so run as to have a certain average length of life. This point of running, with the consequent length of life, is fixed by the lamp makers, usually at such a point that the lamps will have an average life of about 1 000 hours, but strictly it should vary according to the particular situation. For if energy is expensive it will clearly pay the consumer to over-run his lamps, getting a shorter life at a higher efficiency, and vice versa.

Lamps differ in two important respects from most other electrical apparatus. In the first place the life is reckoned in hours of burning rather than in hours of actual existence, i.e. the lamp is presumed not to depreciate except with use, and (barring mechanical vibration or long periods of idleness) this assumption is probably sufficiently accurate for the purpose. In the second place, lamp renewals are relatively so frequent that the interest charges can be neglected in comparison with the depreciation charges.* This obviates the difficulty of having to summate replacement charges dependent upon hours of burning, and interest charges dependent upon calendar hours.

Thus the economic calculations in connection with illumination are made on a basis of a service unit, e.g. lumen-hours, whereas most other economic comparisons are made on the basis of a time unit, e.g. annual costs or total capitalized costs.

(2) ECONOMIC CHOICE OF TYPE.

The problems which occur can be considered under two headings :—

(i) Choice of Type (usually between two or three alternatives).
(ii) Choice of Rating, i.e. voltage, and therefore efficiency (over a range of alternatives).

As an example of the former type of problem it will be sufficient to take a single case in which illumination is required in units having a mean horizontal candle-power of approximately 32 off a 220-volt circuit. It may be supposed that for this service there are available a 32-c.p. carbon lamp taking 110 watts and costing 1s. 9d., a 40-watt vacuum metal-filament lamp costing 2s. 6d., and a more efficient metal lamp, either vacuum or gas-filled, rated at 30 watts and costing 3s. 6d.† It is further assumed that they all give the same candle-power and that there is no qualitative difference between them for the purpose required.

Dividing the difference in price by the difference in watts, it will be seen that as between the carbon and the metal-filament vacuum lamp, energy will have to be less than 9d./70 = $\frac{1}{8}$d. per unit for the carbon lamp to be cheaper; whilst as between the two metal

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† *Journal I.E.E.*, 1926, vol. 64, p. 337.

* A single example will show this. A lamp which is burning for 3 hours a night and lasts 1 000 hours has to be renewed approximately once a year. With interest at 5 per cent the interest charge would be 1/20th of the depreciation or renewal charge, and can therefore be neglected in comparison.

† These figures are purely for illustration purposes to meet the case in which several makes or types of lamp are available for the same service, having different prices and corresponding efficiencies. On the larger sizes this often arises between the vacuum and the gas-filled types, but for the size mentioned the gas-filled lamp has little or no advantage.

lamps, energy will have to be more than 12/10 = 1·2d. per unit for the more efficient one to be cheaper. For any energy price between these two, the metal-filament vacuum lamp is the least expensive to employ.

The comparison would of course be more favourable to the carbon lamp if smaller lighting units were required, but however cheap the energy it is doubtful whether the carbon lamp would compete with a metal-filament lamp under-run in the manner described below, except under special circumstances such as severe vibration or extremely intermittent use.

(3) Choice of Rating (Graphical Treatment).

In considering problems concerned with the choice of rating over a range of alternatives, it is necessary first to fix on a criterion of rating. When a lamp which is intended by the makers to be used on a certain pressure is run on a different pressure, say a higher one, it may be said to be over-run, with results that can be summarized as (1) higher pressure, (2) higher efficiency, (3) higher candle-power, (4) lower life. The degree of over-running can therefore be expressed in the terms of the change in any one of these four quantities, and as the percentage efficiency change is very roughly twice the percentage pressure change, it will be convenient to define the degree of over- or under-running from the change either in efficiency or in applied pressure.

In what follows it will be best first to take a single instance, treating it graphically and approximately, before working out the more general case by an algebraic means, and for this purpose the following data will be employed :—

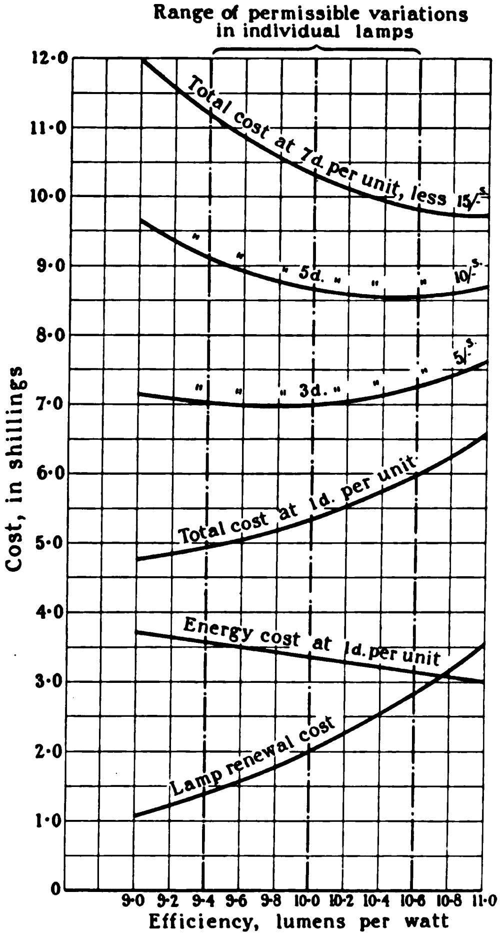
Size of illumination unit required—approx. 30 c.p.
Price of 100-volt lamp of this size—2s.
Normal rating—consumption 40 watts, efficiency 10 lumens per watt,* life 1 000 burning hours.

Table.

Col. 1	Col. 2	Col. 3	Col. 4	Col. 5	Col. 6
Efficiency (η) (Normal = 10)	Applied voltage necessary to obtain this with given lamp (Normal = 100)	Life (L) $\propto \left(\frac{1}{\eta}\right)^6$ (Normal = 1 000)	Per 400 000 lumen-hours' illumination		
			Cost of lamp renewals $\frac{1\,000}{L} \times 2s.$	Cost of energy at 3d. per unit $\frac{100}{\eta}$	Total cost
lumens/watt	volts	hours	shillings	shillings	shillings
9	95	1 885	1·06	11·11	12·17
9·2	96	1 650	1·21	10·87	12·08
9·4	97	1 450	1·38	10·64	12·02
9·6	98	1 277	1·57	10·42	11·99
9·8	99	1 129	1·77	10·20	11·97
10	100	1 000	2·00	10·0	12·0
10·2	101	888	2·254	9·804	12·06
10·4	102	791	2·53	9·61	12·14
10·6	103	705	2·838	9·434	12·27
10·8	104	630	3·17	9·26	12·43
11·0	105	563	3·55	9·09	12·64

* This figure is somewhat above present-day efficiencies for this size of lamp, but it will be convenient to have a round number for illustration purposes.

It is proposed to consider the effect of running the above lamps at various efficiencies ranging from 10 per cent below to 10 per cent above the normal (col. 1 of the above table), and this variation can be carried out in a number of ways. Thus a change in applied pressure of about half as much (say from 95 to 105 volts) will produce the required effect (col. 2), and the same result would be achieved by a change in filament diameter from 90 per cent to 110 per cent of the normal, or in filament length from 105 per cent to 95 per cent.*



Any one of these changes would affect also the candle-power of the lamp, but by changing the diameter and length simultaneously the desired efficiency can be obtained without altering the size of the illumination unit. It may be assumed that, whatever the means taken to vary the efficiency, the effect on the life will be the same; and most of the published figures give the life of a tungsten lamp as being inversely proportional to the efficiency raised to a power between 6 and 7. The value of this index is discussed later, but in this case it will be taken as having the value 6 † (col. 3).

Taking as a basis the cost per 1 000 hours of one

* These figures are approximate.
† "Dictionary of Physics," vol. 2, p. 383.

30-c.p. unit (i.e. per 400 000 lumen-hours) the cost of lamp renewals in shillings will be 2 000 ÷ (life in hours) (col. 4), assuming that the 2s. paid per lamp includes any costs incurred in putting it in. With regard to the power consumed, when the filament has been adjusted to give the same candle-power the watts will be 40 divided by the proportionate change in efficiency, and with energy at 3d. the cost for 1 000 hours will be $40 \times 10/\eta \times 3/12 = 100/\eta$ shillings (col. 5). Adding the last two columns gives the total cost for this quantity of illumination, and in the graph the total cost is plotted for energy prices from 1d. to 7d. per unit. By drawing a tangent to the lamp renewal curve through its mid-point the slope at this point is found to correspond to an energy price of 3½d., showing that with energy at this price the lamp is most economical at its rated voltage.

(4) Algebraic Solution.

In working out a general algebraic solution of the above problem it is desirable to know as accurately as possible how the various quantities, and particularly the life, vary with the change of rating. Unfortunately, there is considerable divergence in the published data and it would appear that the simple formula—

$$\text{Life} \propto (\text{Voltage})^{\text{CONSTANT}}$$

is not true for wide variations, nor is the constant the same for different starting temperatures.

This point is chiefly important when excessive over-running is proposed, as when the average life at normal pressure is estimated from a series of "forced" life-tests taken at considerably higher pressures. For economic purposes the degree of over- or under-running is much less than this, and any departure from the simple logarithmic form can probably be safely neglected in comparison with the very wide variations of the other items (cost of energy, etc.) in the problem.

The following symbols will be employed :—

$$\left.\begin{array}{l} V = \text{impressed voltage} \\ F = \text{luminous flux (in lumens)} \\ W = \text{watts consumed} \\ \eta = \text{efficiency (in lumens per watt)} \\ L = \text{life (in 1 000 hours)} \end{array}\right\} \begin{array}{l}\text{with suffix } n \\ \text{to denote the} \\ \text{normal values}\end{array}$$

$$\left.\begin{array}{l} C = \text{first cost of lamp} \\ P = \text{price of energy per kWh} \end{array}\right\} \text{in the same units}$$

It is assumed that all quantities vary according to some simple power of the impressed voltage, and if the latter is varied in the ratio R then

$$\frac{F}{F_n} = \left(\frac{V}{V_n}\right)^a = R^a;\ \frac{W}{W_n} = R^b;\ \frac{\eta}{\eta_n} = R^c \text{ and } \frac{L_n}{L} = R^d\,*$$

where a, b, c and d are fixed constants, provided R is restricted to a fairly small range (say from 0·9 to 1·1). Moreover, as $\eta = F/W$, it follows that c must equal $(a - b)$. In what follows the values will be taken as $a = 3{\cdot}6$, $b = 1{\cdot}5$, $c = 2{\cdot}1$ and $d = 14$ for vacuum tungsten lamps.

* This item is reversed because the life is inversely dependent upon the pressure, and it will be convenient to have all the indices positive.

At the normal rating, for an illumination of F_n lumens lasting 1 000 hours the number of lamps required $= 1/L_n$ and the lamp cost $= C/L_n$. The watts consumed $= W_n$ or F_n/η_n and the energy cost $= PF_n/\eta_n$. Hence the total cost for 1 000 F_n lumen-hours, $T = (C/L_n) + (PF_n/\eta_n)$. Or the total cost for 1 000 lumen-hours, $T' = (C/L_nF_n) + (P/\eta_n)$.

Case 1. *When the same lamps are used, the pressure being varied.*—When the pressure is varied in the ratio R, each lamp will give a flux $F = F_nR^a$ and will have an efficiency $\eta = \eta_nR^c$ and a life $L = L_nR^{-d}$. The total cost per 1 000 lumen-hours then becomes

$$T' = \frac{C}{LF} + \frac{P}{\eta} = \frac{C}{L_nR^{-d}F_nR^a} + \frac{P}{\eta_nR^c} = \frac{C}{L_nF_n}R^{d-a} + \frac{P}{\eta_n}R^{-c}$$

In order to find what ratio of voltage variation will give the minimum total cost, it is only necessary to differentiate T' with respect to R, giving

$$\frac{dT'}{dR} = (d - a)\left[\frac{C}{L_nF_n}R^{(d-a-1)}\right] - c\left[\frac{P}{\eta_n}R^{-(c+1)}\right]$$

This is zero when

$$R^{(d-a+c)} \text{ or } R^{(d-b)} = \frac{c}{d-a}\cdot\frac{P}{C}\cdot\frac{L_nF_n}{\eta_n} = \frac{c}{d-a}\cdot\frac{PL_nW_n}{C}$$

Putting in the above values for the constants, this becomes

$$R^{12\cdot5} = 0{\cdot}202\frac{PW_n}{C}$$

for lamps having a normal life of 1 000 hours.

It will be noted that the above case does not give a true economic comparison, because it results in the illumination being obtained in units of a new size. Thus if 30-watt lamps were proposed and the above calculation showed that the total illumination required would be most economically obtained by over-running the lamps, this might result in the flux per lamp equalling the normal output of a 40-watt lamp. But had it been known that the illumination could permissibly be carried out in the bigger units a saving could have been effected even without over-running, both because of the reduced number of lamps required of the 40-watt size and because of the intrinsically better efficiency of the larger unit.

Case 2. *With a fixed size of illumination unit (giving F_n lumens).*—In this case it will be best to work on the basis of 1 000 F_n lumen-hours, the total cost for which is given above as $T = (CL_n) + (PF_n/\eta_n)$ at the normal rating. When the rating is varied (to an extent equivalent to a pressure change of R) the filament dimensions are so altered that each lamp continues to give F_n lumens, and only the efficiency changes. The number of lamps required at any instant will be the same as before, so that the lamps required per 1 000 hours will still be the reciprocal of the life, and the total cost per 1 000 F_n lumen-hours

$$T = \frac{C}{L} + \frac{PF_n}{\eta} = \frac{CR^d}{L_n} + \frac{PF_n}{\eta_nR^c}$$

Differentiating, we get

$$\frac{dT}{dR} = d\left[\frac{C}{L_n}R^{d-1}\right] - c\left[\frac{PF_n}{\eta_n}R^{-(c+1)}\right]$$

This is zero when

$$R^{c+d} = \frac{c}{d}\cdot\frac{P}{C}\cdot\frac{F_nL_n}{\eta_n} \quad\text{or}\quad \frac{c}{d}\cdot\frac{P}{C}W_nL_n$$

Putting in the above values for the constants, this becomes

$$R^{16\cdot 1} = 0\cdot 15\frac{P}{C}W_nL_n = 0\cdot 15\frac{PW_n}{C}$$

for lamps having a normal life of 1 000 hours.

This formula can be explained as follows with reference to the curves already plotted. Maximum economy occurs when the slopes of the curves of energy cost and lamp cost are equal and opposite. If these are plotted to a base of rating measured in efficiency, the former will be a straight line and the latter a curve the shape of which depends on the efficiency/life index (c/d). The slopes will therefore depend upon the values of these indices and also on the multiplying constants—so that *at any one rating* maximum economy will occur when a particular ratio exists between the money normally spent on lamps ($\propto C/L_n$) and that spent on energy ($\propto PW_n$). This explains the appearance in the formula of items representing not only the energy and lamp prices but also the size of lamp.

(5) Application.

Taking the simplest form of the above, with constants for a vacuum tungsten lamp, namely $R^{16\cdot 1} = 0\cdot 15PW_n/C$, this can be applied to the case already considered of lamps costing 2s. each and having a normal rating of 40 watts. For a fixed size of illumination unit (which will be about 30 mean spherical candle-power for a 100-volt lamp) the most economical point at which to run will be given :—

With energy at 1d., by $R^{16\cdot 1} = \dfrac{0\cdot 15 \times 1 \times 40}{2 \times 12}$, whence $R = 0\cdot 917$, i.e. 91·7 per cent of normal pressure, or approx. 83·4 per cent normal efficiency.

With energy at 4d., by $R^{16\cdot 1} = 4/4$, whence $R =$ unity, i.e. 100 per cent of normal pressure, and efficiency.

With energy at 7d., by $R^{16\cdot 1} = 7/4$, whence $R = 1\cdot 035$, i.e. 103·5 per cent of normal pressure, or approx. 107 per cent normal efficiency.

These agree fairly closely with the graphical points, allowing for the fact that in the graphs the index c is taken as 2 and the ratio d/c as 6.*

Reference should here be made to the figures published by H. Bohle in his book "Electrical Photometry and Illumination" (1912, new edition recently published). Working on a curve connecting watts per candle-power and relative life, he considers a single size of tungsten lamp having a normal rating of 60 watts and costing 2s. 6d. He finds that when energy costs 4d. a unit this lamp is most economical on its normal rating, giving 1 000 hours' life and taking 1·2 watts per mean horizontal candle-power. When energy costs 6d. it is economical to over-run the lamp until it takes only 1·03 watts per mean spherical candle-power, whereas with energy at 2d. the specific consumption should be 1·35. As the size of the illumination unit is allowed to vary, these results must be compared with the first of the two formulæ developed above, and, allowing for slight differences in the indices employed, there is very general agreement.

In considering the conclusions to be drawn from the above formula, it should be noted in the first place that of the three variables, the lamp prices vary least, e.g. from about 2s. to 2s. 6d. for vacuum lamps, the lamp sizes vary more—say from 10 or 20 to 60 watts for these lamps—whilst the energy prices vary most, since they may range from 1d. to 8d. a unit or even more.

With regard to lamp size and price, it is clear that the larger or the less expensive the lamp, the more it should be over-run and the shorter should be the life aimed at. Thus, taking as a starting-point the 40-watt lamp costing 2s., which is economical on its present-day rating with energy at 4d. a unit, it is evident that with this energy price any lamp in which the lamp size in watts divided by the price in shillings exceeds 20 should be over-run. With a 60-watt lamp costing 2s. 3d., $R^{16\cdot 1}$ should equal $1\frac{1}{3}$, whence $R = 1\cdot 018$ and, as the life $L = L_nR^{-14}$, the best life will be $1\,000/1\cdot 018^{14}$ = 882 hours. On the other hand, with a 20-watt lamp costing, say, 2s. 6d., the most economical life (with energy at 4d.) will be 2 230 hours. If the lamp price were proportional to the size in watts these items would, of course, cancel out, but unfortunately the price varies little (and sometimes inversely) with the size, and it would certainly appear that manufacturers should make some attempt to rate their lamps accordingly, even though they take no account of variations in the price of energy.

Coming now to the third variable, viz. cost of energy, this is chiefly a problem for the consumer; but even here the manufacturers could help by grading their lamps for dear, medium and cheap energy, somewhat on the lines of the "three-voltage rating" suggested some years ago in competing with the carbon lamp for cheap energies.*

It will be noted that the B.E.S.A. Specification permits deviations in efficiency of about 6 per cent on either side of the specified normal—represented by the upright lines on the graph—and, when these variations occur, the consumer (on specially cheap or dear circuits) could be given the opportunity of choosing them in place of the normal lamps.

If no such help is forthcoming for the lamp user he must needs act for himself, and the difficulty of so doing is that whilst a considerable range of voltage

* With these values for the indices, the normal rating coincides with the most economical one for an energy price of 3½d., and for other energy prices the formula gives the most economical rating as follows :—

Energy at 1d.—Rating should be 91·2 per cent of normal pressure or 82·5 per cent of normal efficiency.
Energy at 3d.—Rating should be 98·7 per cent of normal pressure or 97·4 per cent of normal efficiency.
Energy at 5d.—Rating should be 102·6 per cent of normal pressure or 105·2 per cent of normal efficiency.
Energy at 7d.—Rating should be 104·7 per cent of normal pressure or 109·4 per cent of normal efficiency.

* See, especially, R. W. Hutchinson: "High-Efficiency Electric Illuminants."

atings is available, the number of sizes is very limited, and, unfortunately, re-rating by voltage alone alters the size of the illumination unit. Thus if the circuit voltage is 110 and lamps of about the 40-watt size are desired, the normal flux from such a lamp is 370 lumens. Assuming that 2s. is the price of the lamp, whatever the size or rating, the above calculation shows that with energy at 1d. a unit the most economical rating is that corresponding to 91·7 per cent of the normal voltage, or about 73 per cent of the normal candle-power. This can be exactly effected by fitting 120-volt lamps, but if, say, the 60-watt size is chosen, the lamp flux will be 415 lumens instead of 370.

Taking as the other extreme a circuit with energy at 8d. a unit, the calculation shows an economic rating of 104·4 per cent of the normal voltage. This requires lamps designed for a pressure of about 105 volts, and a 30-watt lamp of this type will then give 320 lumens when run on 110 volts. Such small changes in the size of the illumination unit are not necessarily disadvantageous, since there is no special virtue in the particular candle-powers associated with 30, 40 and 60 watts, and in any given case some intermediate values may be as good or better. It should be realized, however, that any such change will modify the economic calculation, since this is based on the assumption that lamps are available giving the original candle-power at the new rating.

Other Considerations.

So far, only initial conditions have been considered. As a lamp is used, its filament deteriorates to some extent, causing in the first place a loss in candle-power and secondly a loss in efficiency (since the filament is virtually smaller and therefore under-run). This deterioration is far less than it was with the older type of lamps, in which the life was frequently defined not as its life up to breaking point, but that up to when it gave 80 per cent of its initial candle-power. With the modern tungsten lamp it is rare for even an individual lamp to last until it becomes uneconomical on account of diminished efficiency, and the mean efficiency of a modern lamp should be over 90 per cent of the initial efficiency.

It is difficult to determine exactly what effect deterioration should have upon the economic calculation, without further data as to how the deterioration affects the values of the indices. It is safe to say, however, that in comparison with the wide range of the other variables entering into the problem, its effect on the economic position will be slight, and its chief result is a lowering of the mean size of the illumination unit.

When several energy prices rule—as when the first portion of the consumption is charged for at a higher rate—the economic choice should not be affected, since a change in efficiency will not affect the time distribution of the consumption. In such a case it is only necessary to employ in the formula the mean price paid per unit of lighting energy over the period in question.

Qualitative effects have been ignored throughout, but it is obvious that on a very cheap energy circuit it might pay to under-run lamps to such a point that the light became too red for satisfactory illumination. Other limits to under-running when energy is very cheap would be vibration (causing the lamp to break before its calculated life period) and interest on capital. The latter could not safely be neglected if excessive under-running (and long life) were proposed or if the service were highly intermittent. Its cost could be brought into the problem if the annual hours of service were fixed and known.

(7) Conclusions.

The purpose of the present paper has been not so much to arrive at any novel results as to emphasize facts not generally realized and to suggest possible courses of action by the manufacturer or the lamp user. The vital connection between rating and economy, and their sensitive dependence upon pressure, are at last being recognized, and Mr. C. W. Sully, speaking at the World Power Conference on behalf of the Electric Lamp Manufacturers Association of Great Britain, said: "It is therefore extremely important that lamps should be operated at their rated voltage. . . . It is equally necessary that supply voltages should be as definite and constant as possible, in order that lamp manufacturers may rate their lamps at the most economical efficiency." But the problem is regarded too statically, and of the many recent attempts at educating the public in the proper use of lamps there has hardly been one pointing out that the correct rating is not something fixed by nature or the lamp manufacturers but should depend on circumstances and, in particular, upon the energy price and the lamp size. To cite a particular case, until recently the author was paying 7d. a unit for all his lighting energy, whilst blocks of flats near by were buying their energy at a uniform price of 1d. Lamps which were economical for the one circuit would be quite unsuitable for the other, yet the same shop served them both, and there was nothing on the lamps or their wrappers to show that they were not suitable for the same voltage under all possible circumstances. In a similar way 20-watt and 60-watt lamps for the same circuit should be designed to have quite different lengths of life.

The energy price is admittedly the most difficult item in the problem, and the above suggestions make no pretence of exhausting the possibilities. But, however difficult, there can be no denying the importance of the problem, in view of the fact that the energy cost may frequently represent 90 per cent or more of the total cost of the illumination, and that the energy price may vary as much as from 1d. to 8d. a unit. In the absence of any more positive action or assistance for the consumer, it would appear that the least that could be done would be to stamp on the lamp or wrapper the particular energy price as well as the voltage for which the rating was determined.

INTERFERENCE BETWEEN CIRCUITS IN CONTINUOUSLY LOADED TELEPHONE CABLES.*†

By A. ROSEN, B.Sc. (Eng.), Ph.D., Associate Member.

(*Paper received 12th January, 1926.*)

SUMMARY.

This paper is concerned with the interference between circuits in homogeneous cables, and its reduction. The line is replaced by its equivalent network, and, in the case of a four-wire group as used in superimposed circuits, the network consists of six members. The relations between the induced and inducing currents and voltages are established, and a quantitative definition of interference is given. The effects of unbalances in the line constants are discussed, and the influence of distance and frequency is investigated. An account is given of methods of measurement and of the means of reducing interference in cables, and a method developed by the author for dealing with the difficulties introduced by the distributed inductance in continuous loading is described.

Z_t = impedance of telephone receiver.
Ψ = interference expressed in power ratio basis.
ψ = interference expressed in equivalent current ratio basis.

Section 1. INTRODUCTION.

Interference between circuits is of importance as being one of the factors which limit the distance over which satisfactory telephonic communication can be effected; since the introduction of thermionic valve repeaters its position in this respect has been emphasized.

If we consider a transmission system on two circuits of which two simultaneous conversations are taking place, we can imagine that at some particular instant there is a voltage V impressed on the near end of circuit 1, and at the same time an equal voltage V impressed on the distant end of circuit 2. At the near end of circuit 2, there will be a voltage kV due to the speech on that line, where k is a factor which depends on the attenuation of the line, and also a voltage $k'V$ due to the interference from circuit 1. Obviously k' must be much smaller than k, otherwise the interference would make the received speech on circuit 2 unintelligible; so that to a certain extent the lowest value of k is governed by the lowest value to which k' can be reduced. The use of amplifiers has made it possible to reduce k very considerably, the line losses being made good by the repeaters, but in order to take full advantage of this amplification the interference between circuits must be reduced in like proportion. This is perhaps most important in the case of a long submarine cable where, on account of the limitations of weight, the size is restricted; it is desired to obtain the largest number of circuits, and this entails working with the maximum value of attenuation that the repeaters will allow. This can only be done if the interference is kept small.

Again, it is undesirable that any appreciable volume of speech should be overheard from another circuit, as this would do away with the secrecy of the individual line, which is regarded as one of the advantages of line telephony as compared, for example, with radio telephony in its present stage of advancement.

The form of the attenuation factor and its dependence on the constants of the line are well known. In this paper the interference factor is discussed and its relation to the other properties of the line investigated.

The subject has received considerable attention during recent years, notably in Germany, where important contributions have been published.*

In this paper the problem has been attacked from a new view-point, and the results obtained are expressed in a form in which they can be applied to practical working. Methods of measurement are described, and the means of reducing interference discussed, in particular a system which the author has developed to deal with cases in which the methods at present in use break down.

Section 2. GENERAL CONSIDERATIONS.

(i) *Phantom circuit.*—The arrangements for obtaining the superimposed or phantom circuit are shown diagrammatically in Fig. 1.

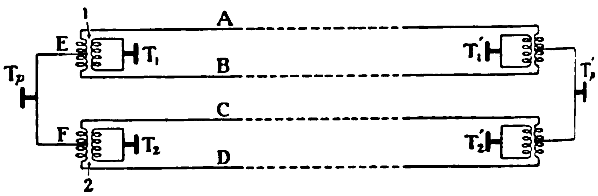

FIG. 1.—Phantom circuit.

The loops AB, CD, commonly known as the "side circuits," are terminated by transformers at both ends. Telephones T_1, T_2, are connected to the primary windings; the secondary windings are divided into carefully balanced halves, the mid-points being joined by the telephones T_p.

The following is an elementary explanation of the action of the phantom circuit; the fuller mathematical treatment is given later. When speaking into T_p, the current into transformer secondary 1 divides, having the choice of two paths, along A returning via CD, and along B returning via CD. If these paths offer equal impedance, the currents will be equal, consequently there will be no resultant magnetic field in the core of the transformer, and no current in the telephone T_1. Similarly there will be no current in T_2 if the impedances of the paths C/AB and D/AB are equal. When speaking on T_1, the transformer 1 will function in the normal way and points A and B will be at opposite

* LICHTENSTEIN: *Elektrotechnische Zeitschrift*, 1920, vol. 41, p. 188; BREISIG: *ibid.*, 1921, vol. 42, p. 933: DOHMEN and KÜPFMÜLLER: *ibid.*, 1924, vol. 45, p. 266, and KÜPFMÜLLER: *Archiv für Elektrotechnik*, 1923, vol. 12, p. 160.

potentials with regard to circuit CD. Here again, if the impedances A/CD and B/CD are equal, these potentials will be equal and opposite; consequently there will be no P.D. between the mid-point E and CD, and no current in the telephone T_p.

The super-phantom circuit is obtained by an extension of this principle. A, B, C, D (Fig. 2) represent one group of four wires, and H, I, J, K a second group of four wires. The mid-points of the transformers 1, 2, 3, 4, are connected to two further transformers, 5, 6, the mid-points of which are joined through the telephones T_{pp}. T_1, T_2, T_3, T_4 serve the side circuits,

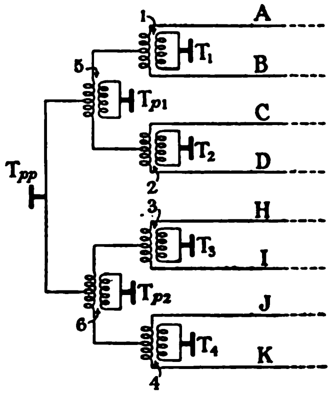

FIG. 2.—Super-phantom circuit.

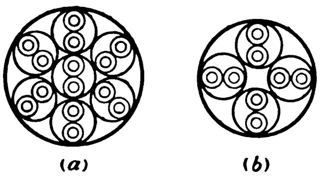
T_{p1} and T_{p2} the phantom circuits, and T_{pp} the super-phantom circuit. In the phantom circuit A and B function in parallel as a single wire, and similarly the pairs CD, HI, JK. In the super-phantom circuit A, B, C, D function in parallel as a single wire, as do H, I, J, K.

(ii) *Forms of cable construction.*—It will be seen that the use of the phantom circuit entails the grouping of the wires in fours, in such a way that the characteristics of each individual within that group are the same.



(*a*) (*b*)

FIG. 3.—Twin cables.

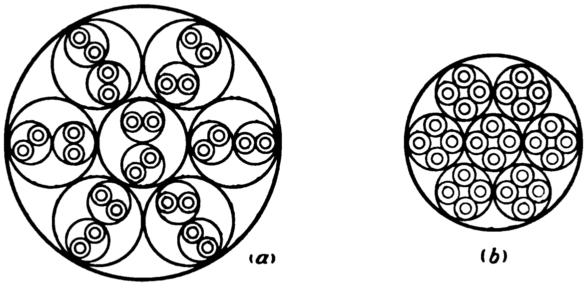
This has led to the development of the four-wire grouping in cables intended for superimposed working.

The principal forms of construction of telephone cables are (1) with the pair as unit, (2) with a group of four wires or quad as unit.

(1) In this class the cable is built up of pairs stranded together in one or more layers; it is not suitable for superimposing except in the special case of four pairs, where the diagonally opposite pairs constitute the phantom circuits (Figs. 3*a* and 3*b*).

(2) The quads may be built up in two ways, (*a*) star form, in which the four wires are laid up together, (*b*) multiple twin form in which two pairs are laid up together. The quads are then stranded into layers in the usual way. The multiple twin (Fig. 4*a*) has inherently a better balance in its capacity characteristics and is the type generally adopted for trunk lines. The star form, however, occupies a smaller space, and is used for submarine cables, where this is an important consideration (Fig. 4*b*).

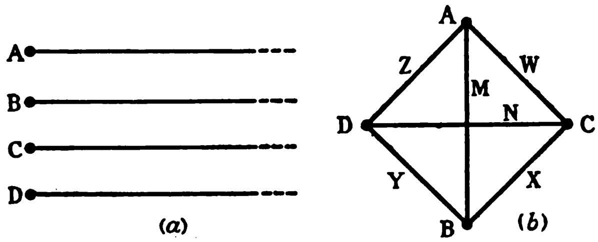
(iii) *The equivalent network.*—There are two methods of approaching the problems of interference between circuits; in the first (which is the usual one adopted) the line is considered along its length; in the second the circuits are regarded from one end and, so to speak, a cross-sectional view is taken. The author has found the latter aspect of great assistance and it has been adopted generally in the discussions which follow.



(*a*) (*b*)

FIG. 4.—Q lead cables, (*a*) 7-quad multiple twin, (*b*) 7-quad star.

G. A. Campbell gives the following theorem in his paper on "Cisoidal Oscillations": * "If we retain a group of terminals as the only accessible part, any network may be replaced either by a set of direct impedances connecting the terminals in pairs, or by a set of mutual impedances between branches radiating from a common point and terminating one at each of the terminals. In the first case all mutual impedances



(*a*) (*b*)

FIG. 5.—Line and equivalent network.

are avoided; in the second case all self-impedances are avoided." Consequently, if we have a transmission line containing a number of wires which terminate at the end nearer us at points A, B, C . . . etc. we may, as regards the effect on external apparatus at this end, replace the line by a system of conductors joining every pair of the points A, B, C . . . etc. In particular the quad ABCD in Fig. 5 (*a*) may be replaced by the six-member network AC, CB, BD, DA, AB, CD, in Fig. 5 (*b*). The values of the members will depend on the nature of the line and how it is terminated.

For all the theoretical work the values, unless other-

* *Transactions of the American I.E.E.*, 1911, vol. 30, p. 890.

wise indicated, are admittance operators, these being generally the better to work with. In practical work, however, impedance operators are usually considered, and the formulæ, where necessary, are given also in that form. When there is a possibility of doubt, y or z respectively will be used as a distinguishing suffix.

(iv) *Quad composed of two symmetrical pairs* AB, CD.—Each pair is symmetrical with regard to all the other wires in the cable and earth. Hence AB is symmetrical about the axis CD, i.e. $W = X$ and $Z = Y$; also CD is symmetrical about the axis AB, i.e. $W = Z$ and $X = Y$. Thus $W = X = Y = Z = \overline{W}$.

Admittance of the side-circuit AB,

$$Y_1 = \overline{W} + M \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Admittance of the side-circuit CD,

$$Y_2 = \overline{W} + N \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Admittance of the phantom circuit,

$$Y_p = 4\overline{W} \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

In any practical case these three admittances, Y_1, Y_2 and Y_p, are easily measured or calculated, and thus the values of our equivalent network members are known.

From these values it is possible to calculate the effective admittance of the quad under various conditions. For example :—

(1) Between AC and BD. By inspection, the admittance is

$$2\overline{W} + M + N = Y_1 + Y_2 \quad . \quad . \quad . \quad (4)$$

(2) Between ABC and D. By inspection, the admittance is

$$2\overline{W} + N = \tfrac{1}{4}Y_p + Y_2 \quad . \quad . \quad . \quad (5)$$

(3) Between A and C, B and D being free.

First transform the star AB, CB, DB into the mesh ADC,* the new values being shown in Fig. 6. From this triangle the admittance between AC is easily calculated, the value being

$$Y_{ac} = \frac{4\overline{W}(\overline{W} + M)(\overline{W} + N)}{(2\overline{W} + M)(2\overline{W} + N) - \overline{W}^2}$$

$$= \frac{Y_p Y_1 Y_2}{Y_1 Y_2 + \frac{1}{4}Y_p(Y_1 + Y_2)} \quad . \quad . \quad . \quad (6y)$$

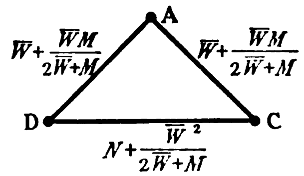


FIG. 6.—Point B eliminated.

Expressing this in impedances, we get the following simple result :—

$$Z_{ac} = Z_p + \tfrac{1}{4}(Z_1 + Z_2) \quad . \quad . \quad . \quad (6z)$$

(v) *Practical confirmation.*—These results provide a ready means of testing the validity of the application of Campbell's network theorem to the telephone transmission line.

* See Appendix I.

ω = 5 000 radians per second.

Tests were carried out on a length of continuously loaded cable using an angular frequency of $\omega = 5\,000$. The impedance of a quad was measured with various arrangements of connections of the cores. Two sets of readings were taken, first with the distant end open, and secondly with the distant end short-circuited. The bridge used is illustrated in Fig. 7. R_1, R_2 are equal non-inductive resistances of 1 000 ohms each, r a variable non-inductive resistance, C a variable condenser; C is connected across arm CD or BC according

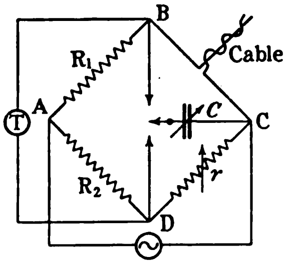

FIG. 7.—Bridge for measuring impedance.

as the angle of the admittance measured is positive or negative. The admittance of the cable is $1/r \pm j\omega C$, where r is in ohms and C in farads, $\omega = 2\pi \times$ frequency; expressed as an impedance the result is

$$\frac{r(1 \mp j\omega Cr)}{1 + \omega^2 C^2 r^2}$$

It will be seen that formulæ (4), (5) and (6z) above are simple additions of vectors. For the first two the result is required in admittance form, and for the last as an impedance.

The results given in Table 1 show a close agreement between the calculated and the measured values, and prove that a telephone line consisting of a number of

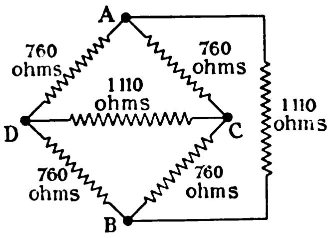

FIG. 8.—Resistance network.

conductors can be treated as a network of impedances joining the terminals at one end. The slight discrepancies shown in the table may be attributed to the small unbalances between the cores, and also to the following facts:—The inductance of a continuously loaded cable varies somewhat with the current, as the permeability of the iron alters with the strength of field; and the distribution of current in the conductors would have to be the same for all the different ways of connections if the relations are to be rigidly fulfilled.

(vi) *The infinite line and terminating networks.*—When the line is infinitely long, Y_1, Y_2, Y_p become Y_{01}, Y_{02}, Y_{0p}, the characteristic admittance of the two side and phantom circuits respectively. The corresponding six-member network will represent the infinite line in every respect. Hence if a finite line having these characteristic admittances be terminated by such a network, it will behave in every way as if it were itself infinitely long. In the following discussion, when a line is terminated by a network equivalent to the infinite line it will be spoken of as "terminated."

Generally, the characteristic impedance of a loaded line is a vector having a small angle, and in practice it is approximated to by a plain resistance. The terminating network for a loaded line can thus consist of

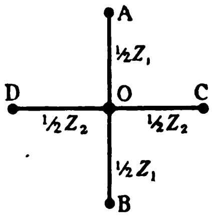

FIG. 9.—Star network.

six suitably chosen resistances. For one cable the following figures were obtained:—

Characteristic impedance of side circuits = 480 ohms.
Characteristic impedance of phantom circuit = 190 ohms.

In the corresponding terminating network (Fig. 8)

$$\begin{aligned} AD = BD = AC &= BC \\ &= 4 \times 190 = 760 \text{ ohms} \\ AB = CD &= \frac{760 \times 480}{760 + 480} = 1\,110 \text{ ohms} \end{aligned}$$

Further, with a loaded line, the value of the characteristic impedance does not alter greatly with frequency, so that a network chosen on the values at a mean frequency (e.g. $\omega = 5\,000$) will represent the infinite line for actual speech.

In the case where the phantom impedance is half

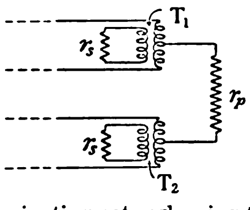

FIG. 10.—Terminating network using transformers.

the mean of the impedances of the side circuits, the six-member network may be reduced to the simple star form (Fig. 9) with $OA = OB = \frac{1}{2}Z_1$ and $OC = OD = \frac{1}{2}Z_2$.

(vii) *Other types of terminating network.*—That used by the British Post Office is shown in Fig. 10. T_1, T_2 are transformers similar to those at the sending end. The primaries are closed through resistances r_s, the mid-points of the secondaries being joined by a resistance r_p. If r is the resistance of one half of each transformer winding, the resistances are chosen so that

$$\left.\begin{aligned} r_s + 4r &= Z_s \\ r_p + r &= Z_p \end{aligned}\right\} \quad \ldots \ldots \quad (7)$$

The arrangement shown in Fig. 11 is used in American practice, choke coils C_1, C_2, being employed instead of transformers. The values of the resistances are :—

$$\left.\begin{aligned} r_s &= Z_s \\ r_p + r &= Z_p \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \quad (8)$$

Section 3. THE INTERFERENCE PROBLEM.

(i) *Definitions.*—In English, a certain confusion exists regarding the use of terms, e.g. the word "cross-talk" is applied to all classes of interference and also to one particular kind. The author uses "interference" in this paper to designate the general phenomenon, this corresponding to the German word "nebensprechen." Interference between circuits may be divided into two classes, (*a*) "cross-talk" between circuits which are physically separate, (*b*) "overhearing" between circuits which have a common metallic path.

Cross-talk includes interference between :—

(i) Side circuit and side circuit in the same quad,
(ii) Side circuit and side circuit in another quad,
(iii) Side circuit and phantom circuit on another quad,
(iv) Phantom circuit and phantom circuit on another quad.

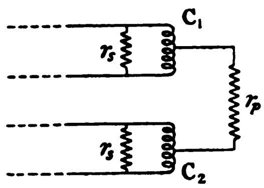

FIG. 11.—Terminating network using choke coils.

Overhearing includes interference between :—

(i) Side circuit and phantom circuit on the same quad,
(ii) Side circuit and super-phantom circuit on the same quad,
(iii) Phantom circuit and super-phantom circuit on the same quad.

Cross-talk corresponds to the German word "übersprechen" and overhearing to the German "mitsprechen."

Interference may be defined quantitatively as the ratio of the power in the disturbed to that in the disturbing circuit. Obviously this ratio will depend on the circuit conditions, and in the case of uniform transmission lines it is desirable to define these explicitly. Before this is done, however, the relations between the currents and voltages in the general case will be obtained.

We have so far considered the components of each pair of wires to be perfectly symmetrical. In practice unbalances occur, and these give rise to interference between the circuits.

Fig. 12 represents the equivalent network of a quad ABCD, the values being admittances.

Let
$$\begin{aligned} W - X &= P \\ Z - Y &= Q \\ W - Z &= R \\ X - Y &= S \\ W + X + Y + Z &= 4\overline{W} \end{aligned}$$

It is assumed that the unbalances are not so great as seriously to upset the symmetry of the pairs, i.e. P, Q, R, S are small compared with $\overline{W}$.

Further, let
$$\begin{aligned} P - Q = R - S &= F \\ P + Q &= G \\ R + S &= H \end{aligned}$$

F, G, H are proportional to the interference coeffi-

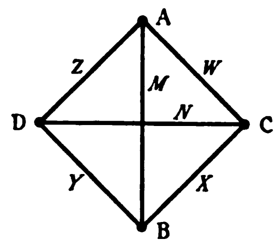

FIG. 12.—Generalized network.

cients, and will always be expressed as admittance vectors.

The network can be regarded as a Wheatstone bridge, and we shall first determine the relation between the voltages in this type of network.

(ii) *Wheatstone network.*—In Fig. 13 (*a*), A, B, C, D represent the four corners of the bridge, the supply of P.D. = V_1 being across AB; to determine the P.D. across the detector arm CD.

Let B be at zero potential, and let the potential of

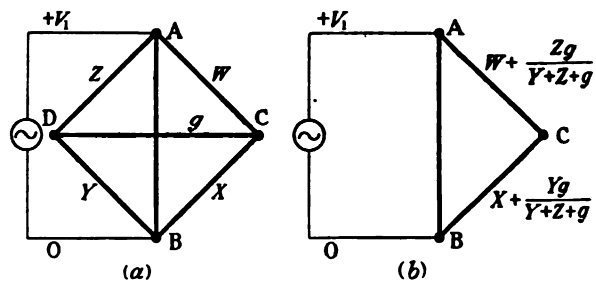

FIG. 13.—Wheatstone network.

A be $+V_1$. Transform star AD, CD, BD (Fig. 13*a*) into mesh AC, BC, AB (Fig. 13*b*).

Then
$$\mathrm{AC} = W + \frac{Zg}{Y + Z + g}$$
$$\mathrm{BC} = X + \frac{Yg}{Y + Z + g}$$

$$\text{Potential of C} = \frac{\mathrm{AC}}{\mathrm{AC} + \mathrm{BC}} V_1$$
$$= \frac{W(Y + Z + g) + Zg}{(W + X)(Y + Z + g) + (Y + Z)g} V_1$$

By symmetry,
$$\text{potential of D} = \frac{Z(W + X + g) + Wg}{(Y + Z)(W + X + g) + (W + X)g} V_1$$

$\therefore$ P.D. across CD, V_2 = potential of C − potential of D

$$= \frac{WY - XZ}{(W + X + Y + Z)g + (W + X)(Y + Z)} V_1 \quad (9)$$

(iii) *Cross-talk.*

(*a*) *Supply* $= V_1$ *volts, and telephone of admittance* Y_t *connected directly to the cable.*

Case (*i*). *Source on* AB, *listening on* CD, (AB/CD).—Let the voltage on CD $= V_2$.

Then from (9)

$$\frac{V_2}{V_1} = \frac{WY - XZ}{4\overline{W}(N + Y_t) + (W + X)(Y + Z)}$$

It is easy to show by direct substitution that

$$WY - XZ = (P - Q)\overline{W} - \tfrac{1}{4}(P + Q)(R + S)$$

Also $$(W + X)(Y + Z) \simeq 4\overline{W}^2$$

$$\therefore \frac{V_2}{V_1} = \frac{F - (GH/4\overline{W})}{4(\overline{W} + N + Y_t)} \quad . \quad . \quad . \quad (10)$$

Generally $GH/4\overline{W}$ is negligibly small compared with F; also $W + N = Y_2$, the admittance of circuit CD.

$$\therefore \frac{V_2}{V_1} = \frac{F}{4(Y_2 + Y_t)} \quad . \quad . \quad . \quad (11y)$$

Expressed in impedances,

$$V_2 = \frac{Z_2 Z_t}{Z_2 + Z_t} \cdot \frac{F}{4} V_1 \quad . \quad . \quad . \quad (11z)$$

Current in telephones,

$$I_t = \frac{Z_2}{Z_2 + Z_t} \cdot \frac{F}{4} V_1 \quad . \quad . \quad . \quad (12z)$$

Case (*ii*). *Source on* CD, *listening on* AB, (CD/AB).—Let the voltage on AB $= V_2$.

Then $$\frac{V_2}{V_1} = \frac{F}{4(Y_1 + Z_t)} \quad . \quad . \quad . \quad . \quad (13y)$$

etc.

(*b*) *The supply and telephone connected to the cable through transformers of* 1 : 1 *ratio, the primary and secondary being divided.*

Let r_z = impedance of each half of primary or secondary. For side-circuit currents, the impedance $= 4r_z$ + impedance in secondary circuit; for superimposed currents, impedance $= \frac{1}{2}r_z$ per transformer.

Case (*i*). *Source on* AB, *listening on* CD (AB/CD).—Due to the transformer on CD, $4r_z$ has to be added to Z_t in equations (11*z*) and (12*z*); further, due to the transformer on AB, the voltage across the cable is less than that applied, in the ratio $Z_1/(Z_1 + 4r_z)$.

Therefore, expressed in impedances,

$$\frac{V_2}{V_1} = \frac{Z_1 Z_2 (Z_t + 4r)}{(Z_1 + 4r)(Z_2 + Z_t + 4r)} \cdot \frac{F}{4} \quad . \quad (14z)$$

and current in telephones

$$I_t = \frac{Z_1 Z_2}{(Z_1 + 4r)(Z_2 + Z_t + 4r)} \cdot \frac{F}{4} V_1 \quad . \quad (15z)$$

Case (*ii*). *Source on* CD, *listening on* AB, (CD/AB).—The equations for V_2 and I_t are the same as (14*z*) and (15*z*), but Z_1 and Z_2 are interchanged.

(iv) *Overhearing.*

(*a*) Let us first consider the more direct case in which equal ratio arms are used to obtain the super-

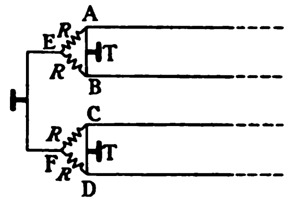

FIG. 14.—Phantom circuit employing resistances.

imposing effect (Fig. 14). Fig. 15 shows the equivalent network at the sending end, all the values being admittances. Whether the source is on AB and the detector on EF (phantom) or vice versa, it is evident from Fig. 15 that since W, X, Y and Z are all approxi-

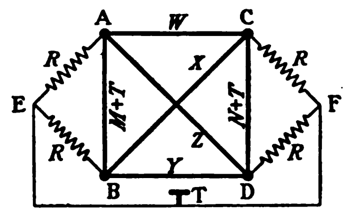

FIG. 15.—Network equivalent to Fig. 14.

mately equal, the points C and D will be at practically the same potential, and therefore the admittance across CD may be neglected. This enables us to simplify the diagram (Fig. 15) in one operation by converting the three-ray stars AC, BC, FC and AD, BD, FD into

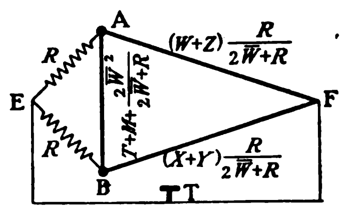

FIG. 16.—Result of eliminating points C and D.

the mesh ABF. The resulting system is shown in Fig. 16.

$$\mathrm{AF} = \frac{(W + Z)R}{2\overline{W} + R}$$

$$\mathrm{BF} = \frac{(X + Y)R}{2\overline{W} + R}$$

$$\mathrm{AB} = M + T + \frac{2\overline{W}^2}{2\overline{W} + R}$$

(The same result can be obtained without neglecting CD, but this involves three stages of transformation.)

Case (*i*). *Supply on phantom* EF, *listening on side* AB, (+/AB).—From equation (9),

$$\frac{V_2}{V_1} = \frac{(X + Y - W - Z)R^2/(2\overline{W} + R)}{[2R + 4\overline{W}R/(2\overline{W} + R)]\,[M + T + 2\overline{W}^2/(2\overline{W} + R)] + [R + 2\overline{W}R/(2\overline{W} + R)]^2}$$

$$= \frac{-(P + Q)}{[1 + (4\overline{W}/R)]\,(2\overline{W} + 2M + R + 2T)}$$

$$= \frac{-G}{2Y_1[1 + Y_p/R]\,[1 + R/(2Y_1) + T/Y_1]} \quad \ldots \quad (16y)$$

Expressed in impedances,

$$\frac{V_2}{V_1} = \frac{-Z_1G}{2[1 + R_z/Z_p]\,[1 + Z_1/(2R_z) + Z_1/T_z]} \quad (16z)$$

Case (*ii*). *Supply on side* AB, *listening on phantom* EF, (AB/+).—From equation (9),

$$\frac{V_2}{V_1} = \frac{(X + Y - W - Z)R^2/(2\overline{W} + R)}{[2R + 4\overline{W}R/(2\overline{W} + R)]T + 2R\,.\,2\overline{W}R/(2\overline{W} + R)}$$

$$= \frac{-(P + Q)}{(8\overline{W} + 2R)T/R + 8\overline{W}}$$

$$= \frac{-G}{2Y_p[1 + T/Y_p + T/R]} \quad \ldots \quad (17y)$$

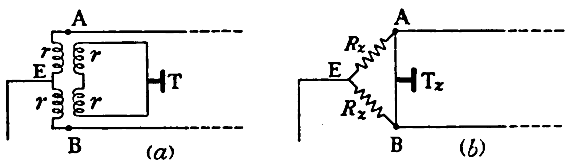

FIG. 17.—Transformer and equivalent resistances.

Case (*iii*). *Supply on phantom, listening on* CD, (+/CD).—By similarity,

$$\frac{V_2}{V_1} = \frac{-H}{2Y_2[1 + Y_p/R]\,[1 + R/(2Y_2) + T/Y_2]} \quad (18y)$$

Case (*iv*). *Supply on* CD, *listening on phantom*, (CD/+).

$$\frac{V_2}{V_1} = \frac{-H}{2Y_p[1 + T/Y_p + T/R]} \quad \ldots \quad (19y)$$

(*b*) When transformers are used, Fig. 17 (*a*) is equivalent to Fig. 17 (*b*).

Equating impedance to phantom currents,

$$\tfrac{1}{2}R_z = \tfrac{1}{2}r$$

Therefore $$R_z = r \quad \ldots \quad (20)$$

Equating impedance to side-circuit currents,

$$\frac{1}{2R_z} + \frac{1}{T_z} = \frac{1}{4r + Z_t} \quad \ldots \quad (21)$$

Case (*i*). *Supply on phantom, listening on* AB, (+/AB).—Substituting (20) and (21) in equation (16*z*),

$$\frac{V_2}{V_1} = \frac{-Z_1G}{2[1 + r/Z_p]\,[1 + Z_1/(4r + Z_t)]} \quad . \quad (22z)$$

Current in telephone,

$$I_t = \frac{V_2}{4r + Z_t}$$

$$\therefore\ I_t = \frac{-Z_1Z_p}{(Z_p + r)\,(Z_1 + 4r + Z_t)} \cdot \frac{G}{2}V_1 \quad . \quad (23z)$$

Case (*ii*). *Supply on side* AB, *listening on phantom*, (AB/+).—The voltage across the cable is less than that applied in the ratio $Z_1/(Z_1 + 4r)$, due to the drop in the transformer.

Equation (17) becomes, in impedances,

$$V_2 = \frac{-Z_p}{\left(1 + \dfrac{Z_p}{Z_t} + \dfrac{r}{Z_t}\right)} \cdot \frac{Z_1}{Z_1 + 4r} \cdot \frac{G}{2} \quad . \quad (24z)$$

Current in telephones,

$$I_t = \frac{V_2}{Z_t}$$

$$= \frac{-Z_1Z_p}{(Z_p + r + Z_t)\,(Z_1 + 4r)} \cdot \frac{G}{2}V_1 \quad . \quad (25z)$$

Cases (*iii*) *and* (*iv*).—The equations for +/CD and CD/+ are the same as (22) to (25), but H is written for G and Z_2 for Z_1.

(v) *Deductions from equations.*

(*a*) The interference between the physical circuits AB and CD is directly proportional to $\tfrac{1}{4}F$; $\tfrac{1}{4}F$ will be called the cross-talk coefficient of the quad ABCD.

(*b*) The interference between the phantom and the side circuits AB, CD is directly proportional to $-\tfrac{1}{2}G$ and $-\tfrac{1}{2}H$ respectively; $-\tfrac{1}{2}G$ and $-\tfrac{1}{2}H$ will be called the relevant overhearing coefficients of the AB and CD pairs, respectively.

(*c*) The formulæ given apply whether the distant end be open, closed or terminated in any manner; the required modifications are obtained by inserting the appropriate values of Y_s and Y_p or Z_s and Z_p.

(*d*) The formulæ can be extended to interference between quads by considering each group of wires acting in parallel as a single wire.

(*e*) The induced currents and voltages depend not only on the values of the interference coefficients and the circuit impedances, which are properties of the line, but also on the impedances of the transformers and telephones, i.e. on the external apparatus. This fact is often forgotten in making comparisons between the figures for different cables, and misleading deductions may be drawn.

(vi) *Quantitative definition of interference.*—In order to eliminate the effect of the external apparatus, we may define the interference Ψ as the ratio of the

power in the disturbed to that in the disturbing circuit, when the lines are closed by ideal transformers having no losses, and the impedance of the telephone is equal to that of the disturbed circuit.

Writing J for the general interference coefficient ($+\frac{1}{2}F$, $-\frac{1}{2}G$ or $-\frac{1}{2}H$) we see that all the equations reduce to the form

$$\frac{I_2}{I_1} = \frac{JZ_1}{2}$$

$$\frac{V_2}{V_1} = \frac{JZ_2}{2}$$

the suffixes 2 and 1 referring to the disturbed and disturbing circuits respectively. Therefore the interference

$$\Psi = \frac{P_2}{P_1} = \frac{J^2Z_1Z_2}{4} \quad . \quad . \quad . \quad . \quad (26)$$

It is often more convenient to use a ratio of currents (or voltages) to measure interference. To obtain a consistent result, we may write

$$\psi = (\sqrt{\Psi} = \tfrac{1}{2}J\sqrt{(Z_1Z_2)} \quad . \quad . \quad . \quad (27)$$

Here ψ is the interference expressed on a current (or voltage) ratio basis.

(vii) *Units.*—There are a number of systems of units in use at present in which interference is expressed.

(a) The one which appertains logically to the definition given above is the new transmission unit (T.U.) * which is based on a power ratio and is defined by

$$\text{T.U.} = 10 \log_{10} P_1/P_2$$

Thus

$$\text{T.U.} = 10 \log_{10} \frac{1}{\Psi} = 10 \log_{10} \frac{4}{J^2Z_1Z_2} \quad . \quad (28)$$

(b) The βl unit, which is expressed by the relation

$$\beta l = \log_e \frac{I_1}{I_2}$$

Thus

$$\beta l = \log_e \frac{1}{\psi} = \log_e \frac{2}{J\sqrt{(Z_1Z_2)}} \quad . \quad . \quad (29)$$

(c) The mile of standard cable (M.S.C.), given by

$$\text{M.S.C.} = \frac{1}{0{\cdot}1065} \log_e \frac{I_1}{I_2}$$

Thus

$$\text{M.S.C.} = 9{\cdot}38 \log_e \frac{1}{\psi} = 9{\cdot}38 \log_e \frac{2}{J\sqrt{(Z_1Z_2)}} \quad (30)$$

(d) The cross-talk meter unit, which is the ratio of induced to inducing current in millionths, i.e. if n is the cross-talk meter reading,

$$n = \frac{I_2}{I_1} \times 10^6$$

Thus $\quad n = \psi \times 10^6 = \frac{1}{2}J_1\sqrt{(Z_1Z_2)} \times 10^6$

As it is generally used, the cross-talk meter does not give this value directly; the question is more fully discussed in a later Section.

* R. V. L. HARTLEY: *Electrician*, 1925, vol. 94, pp. 55, 58 and 93.

Section 4. RELATION BETWEEN UNBALANCES IN THE LINE CONSTANTS AND THE INTERFERENCE COEFFICIENTS.

The equations obtained in the previous Section enable us to calculate the value of the individual currents and voltages when the interference coefficients are known. We must now investigate how the interference coefficients depend on the original causes, viz. the unbalances in the constants of the line, and we shall consider capacity, leakance, self-inductance, resistance and mutual inductance. The problem falls into two parts, viz. when the unbalance is very close to the measuring end, and when it is at a distance.

(A) *When the unbalance is very close to the measuring end.*

(i) *Unbalanced capacity.*—Since the unbalances are very close to the end, it follows from the definition of the interference coefficients that their relation to the unbalanced capacity is the same however the line is terminated; we can therefore consider the case of the

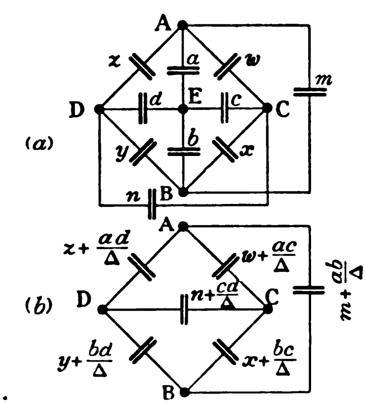

FIG. 18.—Capacity unbalance.

short length in which the distant end is free, and represent the capacity system by a network of condensers. Fig. 18 (a) shows a quad ABCD, and E represents the sheath which is earthed. By means of the four-ray star-mesh transformation, the point E can be eliminated, the resulting system being shown in Fig. 18 (b).

Then

$$P = j\omega\left\{w - x + \frac{c}{\Delta}(a - b)\right\}$$

$$Q = j\omega\left\{z - y + \frac{d}{\Delta}(a - b)\right\}$$

$$R = j\omega\left\{w - z + \frac{a}{\Delta}(c - d)\right\}$$

$$S = j\omega\left\{x - y + \frac{b}{\Delta}(c - d)\right\}$$

where $\quad \Delta = a + b + c + d$

Writing

$$w - x = p\,; \quad x - y = s$$
$$z - y = q\,; \quad a - b = u$$
$$w - z = r\,; \quad c - d = v$$

we obtain

$$F = j\omega\left(p - q + \frac{uv}{\Delta}\right) \quad . \quad . \quad . \quad (32)$$

$$G = j\omega\left(p + q + \frac{c+d}{\Delta}u\right) . \quad . \quad . \quad (33)$$

$$H = j\omega\left(r + s + \frac{a+b}{\Delta}v\right) . \quad . \quad . \quad (34)$$

Generally uv/Δ can be neglected compared with $p - q$, and $\frac{c+d}{\Delta} \simeq \frac{a+b}{\Delta} \simeq \frac{1}{2}$.

Therefore

$$F = j\omega(p - q) \quad . \quad . \quad . \quad . \quad (35)$$

$$G = j\omega(p + q + \tfrac{1}{2}u) . \quad . \quad . \quad . \quad (36)$$

$$H = j\omega(r + s + \tfrac{1}{2}v) . \quad . \quad . \quad . \quad (37)$$

$2(p + q) + u$ and $2(r + s) + v$ are known as the composite values of the AB and CD loops respectively.

(ii) *Unbalanced leakance.*—The system of leakances of a quad is the same as that of the capacities, and the corresponding equations are of a similar form. The

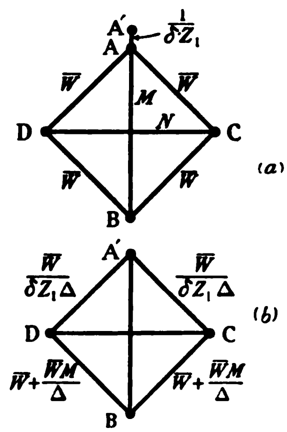

FIG. 19.—Impedance unbalance.

normal leakance of a telephone cable is of the order $G/(\omega C) = 1/250$, and thus the interference due to unbalanced leakance is, on the whole, only 1/250th of that due to capacity and in practice is negligibly small.

(iii) *Unbalanced self-inductance and resistance.*—Considering the AB pair, let the unbalance be in the A wire and equal in impedance to $\delta Z_1 = \delta r_1 + j\omega\delta l_1$. Since it is very close to the measuring end it must of necessity be small and can be represented by AA′ in Fig. 19 (*a*), the rest of the quad being shown by the equivalent network in the usual way. As we are dealing with admittances, $AA' = 1/(\delta Z_1)$. Transforming the four-ray star A′A, CA, BA, DA, we obtain Fig. 19 (*b*).

Then

$$A'C = \frac{\overline{W}}{\delta Z_1 \Delta}$$

$$BC = \overline{W} + \frac{\overline{W}M}{\Delta}$$

$$BD = \overline{W} + \frac{\overline{W}M}{\Delta}$$

$$A'D = \frac{\overline{W}}{\delta Z_1 \Delta}$$

where $\Delta = 2\overline{W} + M + 1/(\delta Z_1)$

Then

$$F = 0 \quad . \quad . \quad . \quad . \quad . \quad . \quad (38)$$

$$H = 0 \quad . \quad . \quad . \quad . \quad . \quad . \quad (39)$$

$$G = \frac{2\overline{W}}{\delta Z_1 \Delta} - 2\left(\overline{W} + \frac{\overline{W}M}{\Delta}\right)$$

$$= \frac{2\overline{W}}{\Delta}\left(\frac{1}{\delta Z_1} - \Delta - M\right)$$

$$= \frac{-4\overline{W}(\overline{W} + M)\delta Z_1}{1 + \delta Z_1(2\overline{W} + M)}$$

Since δZ_1 is very small, $\delta Z_1(2\overline{W} + M)$ can be neglected compared with unity. Substituting Y_p for $4\overline{W}$ and Y_1 for $\overline{W} + M$, we obtain

$$G = -Y_p Y_1 \delta Z_1 \quad . \quad . \quad . \quad . \quad (40)$$

Similarly if there is an unbalance δZ_2 in the CD pair,

$$H = -Y_p Y_2 \delta Z_2 \quad . \quad . \quad . \quad . \quad (41)$$

In a loaded cable with the distant end terminated Y_p, Y_1 and Y_2 are vectors with a small angle and are approximately independent of frequency.

If $\qquad G = g_1 + j\omega c_1$

then

$$g_1 = -Y_p Y_1 \delta r_1 \quad . \quad . \quad . \quad . \quad (42)$$

$$c_1 = -Y_p Y_1 \delta l_1 \quad . \quad . \quad . \quad . \quad (43)$$

these relations being approximately true for all frequencies. Similar equations apply to the CD pair.

We conclude from these equations that unbalanced

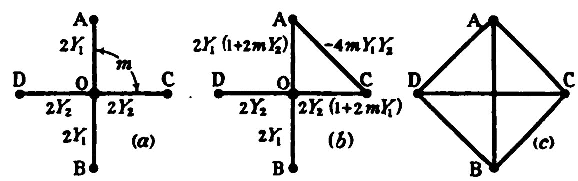

FIG. 20.—Mutual impedance unbalance.

self-impedance has no direct influence in causing cross-talk, and that it affects the overhearing only in the pair in which it occurs. In a loaded cable, provided the line is long or is suitably terminated, unbalanced series resistance and inductance are approximately equivalent to and can be compensated by shunt leakance and capacity respectively.

Example.—If $Y_s = 1/450$ mho, $Y_p = 1/190$ mho.

$$Y_p Y_s = 11 \cdot 7 \times 10^{-6}$$

Then $\qquad g = 11 \cdot 7$ micro-mhos per ohm

$$c = -11 \cdot 7 \ \mu\mu\text{F per } \mu\text{H}$$

(iv) *Unbalanced mutual inductance.*—In practice, mutual inductance unbalance is ignored and it would appear that its effect is very small. It is, nevertheless, desirable to see if this supposition is correct, and we shall take the case in which the phantom impedance is half the mean of the side circuits, so that the equivalent network is a four-ray star. Let there be an unbalanced mutual impedance between arms OA, OC equal to m, Fig. 20 (*a*). This can be transformed into Fig. 20 (*b*)

(see Appendix II), and then as a four-ray star into Fig. 20 (*c*).

In Fig. 20 (*a*), if Y_1, Y_2 are the admittances of the AB and CD loops respectively, then

$$\mathrm{OA} = \mathrm{OB} = 2Y_1 \quad \text{and} \quad \mathrm{OC} = \mathrm{OD} = 2Y_2$$

In Fig. 20 (*b*)

$$\mathrm{OA} = 2Y_1(1 + 2mY_2)$$
$$\mathrm{OC} = 2Y_2(1 + 2mY_1)$$
$$\mathrm{AC} = -\,4mY_1Y_2$$

and OB, OD are unaltered.

In Fig. 20 (*c*)

$$\mathrm{AC} = -\,4mY_1Y_2 + \frac{4Y_1Y_2(1 + 2mY_1)\,(1 + 2mY_2)}{\Delta}$$

where $\Delta = 4Y_1 + 4Y_2 + 8mY_1Y_2$

i.e. $$\mathrm{AC} = \frac{4Y_1Y_2}{\Delta}(1 - 2mY_1 - 2mY_2 - 4m^2Y_1Y_2)$$

$$\mathrm{BC} = \frac{4Y_1Y_2}{\Delta}(1 + 2mY_1)$$

$$\mathrm{AD} = \frac{4Y_1Y_2}{\Delta}(1 + 2mY_2)$$

$$\mathrm{BD} = \frac{4Y_1Y_2}{\Delta}$$

$$\therefore P = \frac{-\,4Y_1Y_2}{\Delta}(4mY_1 + 2mY_2 + 4m^2Y_1Y_2)$$

$$Q = \frac{4Y_1Y_2}{\Delta}2mY_2$$

$$R = \frac{-\,4Y_1Y_2}{\Delta}(2mY_1 + 4mY_2 + 4m^2Y_1Y_2)$$

$$S = \frac{4Y_1Y_2}{\Delta}2mY_1$$

Since the unbalance is all located at the near end of the line, it must be very small, and thus m^2 can be neglected compared with m, and $\Delta = 4Y_1 + 4Y_2$.

$$\therefore F = \frac{-\,4Y_1Y_2}{4Y_1 + 4Y_2}(4mY_1 + 4mY_2)$$
$$= -\,4Y_1Y_2m \quad . \quad . \quad . \quad . \quad . \quad . \quad (44)$$

$$G = \frac{-\,4Y_1Y_2}{4Y_1 + 4Y_2}4mY_1$$
$$= -\,Y_1Y_pm \quad . \quad . \quad . \quad . \quad . \quad . \quad (45)$$

$$H = -\,Y_2Y_pm \quad . \quad . \quad . \quad . \quad . \quad . \quad (46)$$

If the mutual inductance $= M$, then $m = j\omega M$, i.e.

$$F = -\,4j\omega Y_1Y_2M \quad . \quad . \quad . \quad . \quad (47)$$

etc.

As with self-inductance, if the cable is loaded and the line is terminated, Y_1, Y_2 and Y_p are vectors of small angle, and approximately independent of frequency.

Thus
$$\left.\begin{aligned} c &= -\,4Y_1Y_2M \\ c_1 &= -\,Y_1Y_2M \\ c_2 &= -\,Y_1Y_pM \end{aligned}\right\} \quad . \quad . \quad . \quad (48)$$

where c, c_1, c_2 are the capacity components of F, G and H respectively.

Therefore, in a long loaded line, mutual inductance is equivalent to, and can be compensated by, shunt capacity.

That mutual inductance does not appear to have any effect on interference is due to a variety of reasons. In a cable with unloaded cores it depends on the geometrical disposition of the conductors in the same way as does the capacity, if the dielectric be uniform, so that when the capacity is balanced by crossing the cores (q.v.) the unbalanced mutual inductance is reduced at the same time. In a continuously loaded cable, as regards overhearing, the form of the equations is the same as for self-inductance unbalance, and where the latter is measured and compensated the unbalanced mutual inductance will be included. As regards cross-talk, it can be shown that the effect due to mutual inductance is but little dependent on normal variations in the thickness or permeability of the iron covering the conductors; e.g. if core A has a higher permeability, it will increase both M_{ac} and M_{ad}, and the effect on the cross-talk, which is due to the difference between these increases, will be small. Consequently, unbalanced mutual inductance, as affecting cross-talk, depends mainly on the geometrical arrangement of the cores and will be balanced out with the capacity. Where, however, there is no direct capacity between the cores owing to the presence of a conducting screen between them, we may expect mutual inductance to be noticeable; this is the case with a submarine cable having gutta-percha as dielectric, as the water has access to the spaces between the cores. In a recent example, the author found that there was a certain amount of cross-talk, although, as was to be expected, capacity unbalance measurements on short lengths with the distant end open showed that this was not due to electrostatic interference. When, however, the ends of these sections were terminated, and measurements were made with the bridge described in Section 6 (iii), the cross-talk coefficient was found to be appreciable, and steps had to be taken to reduce this as well as the overhearing coefficients.

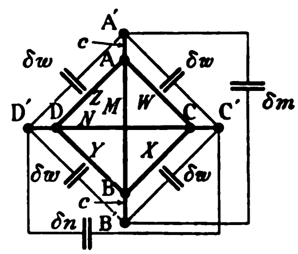

FIG. 21.

(B) *When the unbalance is some distance from the measuring end.*—We have now to determine how the interference coefficients are modified when the unbalance exists some distance from the measuring end.

Let ABCD (Fig. 21) represent a quad, the equivalent network having the values marked; and AA′, BB′, CC′, DD′ represent a further small section of similar line, free from unbalances, of length δl, placed in front of ABCD. Since this added length is very short, the distributed capacities and leakances may be replaced

by leaky condensers at the near end of the added portion, as shown in the diagram.

Let the interference coefficients of ABCD measured at ABCD be $\frac{1}{4}F$, $-\frac{1}{2}G$, $-\frac{1}{2}H$ respectively. We have to determine the change when measured at A′, B′, C′, D′ caused by the presence of the conductors AA′, BB′, CC′, DD′ each of admittance c; the admittances δw will obviously not alter the values of the coefficients. This can conveniently be done in two stages, AA′, BB′ being added first and CC′, DD′ later.

To eliminate points AB from the network in Fig. 22 (*a*), first the four-ray star A′A, CA, BA, DA is transformed into the corresponding mesh.

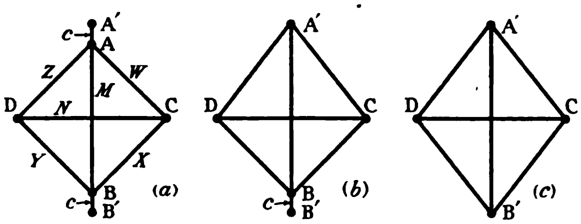

FIG. 22.

Let $W + M + Z + c = \Delta_1$.

Then in Fig. 22 (*b*),

$$A'C = \frac{Wc}{\Delta_1}$$

$$A'D = \frac{Zc}{\Delta_1}$$

$$A'B = \frac{Mc}{\Delta_1}$$

$$CD = M + \frac{WZ}{\Delta_1}$$

$$BC = X + \frac{WM}{\Delta_1}$$

$$BD = Y + \frac{ZM}{\Delta_1}$$

Secondly, the four-ray star B′B, CB, A′B, DB is transformed into the corresponding mesh.

Let $X + M + Y + c = \Delta_2$.

Then in Fig. 22 (*c*)

$$B'C = \frac{c(X + WM/\Delta_1)}{(M/\Delta_1)(W + Z + c) + X + Y + c}$$

$$= \frac{c(\Delta_1 X + WM)}{M(\Delta_1 - M) + \Delta_1(\Delta_2 - M)}$$

i.e.
$$B'C = \frac{c}{\Delta_1\Delta_2 - M^2}(\Delta_1 X + WM)$$

By symmetry

$$B'D = \frac{c}{\Delta_1\Delta_2 - M^2}(\Delta_1 Y + ZM)$$

$$A'C = \frac{c}{\Delta_1\Delta_2 - M^2}(\Delta_2 W + XM)$$

$$A'D = \frac{c}{\Delta_1\Delta_2 - M^2}(\Delta_2 Z + YM)$$

Since the conductors AA′, BB′ are short, the admittance c will be great; further $W \simeq X \simeq Y \simeq Z$.

Therefore we may write $\Delta_1 = \Delta_2 = \Delta$

where
$$\Delta = 2\overline{W} + M + c$$

Now

$$P' = A'C - B'C = \frac{c}{\Delta^2 - M^2}\{\Delta(W - X) + M(X - W)\}$$

$$= \frac{c}{\Delta^2 - M^2}(\Delta - M)P = \frac{c}{\Delta + M}P$$

$$Q' = A'D - B'D = \frac{c}{\Delta^2 - M^2}\{\Delta(Z - Y) + M(Y - Z)\}$$

$$= \frac{c}{\Delta + M}Q$$

$$R' = A'C - A'D = \frac{c}{\Delta^2 - M^2}\{\Delta(W - Z) + M(X - Y)\}$$

$$= \frac{c}{\Delta^2 - M^2}(\Delta R + MS)$$

$$S' = B'C - B'D = \frac{c}{\Delta^2 - M^2}\{\Delta(X - Y) + M(W - Z)\}$$

$$= \frac{c}{\Delta^2 - M^2}(\Delta S + MR)$$

$$\left.\begin{aligned} F' &= P' - Q' = \frac{c}{\Delta + M}F \\ G' &= P' + Q' = \frac{c}{\Delta + M}G \\ H' &= R' + S' = \frac{c}{\Delta - M}H \end{aligned}\right\} \quad . \quad . \quad (49)$$

Here we may notice that if a line have the following constants :—

Resistance, R ohms per unit length
Inductance, L henrys per unit length
Capacity, C farads per unit length
Leakance, G mhos per unit length

the line impedance $\quad Z = R + j\omega L$

the line admittance $\quad Y = G + j\omega C$

characteristic admittance $\quad Y_0 = \sqrt{\dfrac{Y}{Z}}$

propagation constant $\quad \gamma = \sqrt{(ZY)}$

Therefore $\quad \gamma = Y_0 Z$

For a length l $\quad \gamma l = Y_0 Z l$

Zl may be called the line impedance of the length l.

Reverting to the main argument

$$\frac{c}{\Delta + M} = \frac{c}{2\overline{W} + 2M + c} = \frac{1}{1 + 2Y_1/c}$$

If the quad considered be terminated, Y_1 becomes Y_{01}, the characteristic admittance of side circuit AB.

Further, $2/c$ is the line impedance of the side circuit AA′, BB′.

Therefore $\quad 2Y_{01}/c = \gamma_1 \delta l$

where γ_1 is the propagation constant per unit length of the side circuit AB.

Similarly $\dfrac{c}{\Delta - M} = \dfrac{c}{2\overline{W} + c} = \dfrac{1}{1 + Y_p/(2c)}$

$1/(2c)$ is the line impedance of the phantom circuit AA′, BB′ and, as the quad is terminated, Y_p becomes Y_{0p}.

Therefore $\qquad Y_{0p}/(2c) = \gamma_p \delta l$

where γ_p is the propagation constant per unit length of the phantom circuit.

Therefore
$$F' = \frac{1}{1 + \gamma_1 \delta l} F$$
$$G' = \frac{1}{1 + \gamma_1 \delta l} G$$
$$H' = \frac{1}{1 + \gamma_p \delta l} H$$

Adding the short conductors CC′, DD′, the corresponding factors will be :—

for F', $\qquad \dfrac{1}{1 + \gamma_2 \delta l}$

for G', $\qquad \dfrac{1}{1 + \gamma_p \delta l}$

for H', $\qquad \dfrac{1}{1 + \gamma_2 \delta l}$

Thus, when the four wires are added, the combined result is

$$\left.\begin{aligned} F' &= \left(\frac{1}{1 + \gamma_1 \delta l}\right)\left(\frac{1}{1 + \gamma_2 \delta l}\right) F \\ G' &= \left(\frac{1}{1 + \gamma_1 \delta l}\right)\left(\frac{1}{1 + \gamma_p \delta l}\right) G \\ H' &= \left(\frac{1}{1 + \gamma_2 \delta l}\right)\left(\frac{1}{1 + \gamma_p \delta l}\right) H \end{aligned}\right\} \quad . \quad . \quad (50)$$

Now, if the added section be of any length l, let it be divided into n small parts, where n is a large number. Then

$$F' = \left\{\frac{1}{1 + \gamma_1 (l/n)}\right\}^n \left\{\frac{1}{1 + \gamma_2 (l/n)}\right\}^n F$$

When n becomes infinitely great,

$$\left\{\frac{1}{1 + \gamma_1 (l/n)}\right\}^n \text{ becomes } e^{-\gamma_1}$$

where e is the base of natural logarithms.

i.e. $$F' = e^{-(\gamma_1 + \gamma_2)l} F \quad . \quad . \quad . \quad . \quad (51)$$

Similarly $$G' = e^{-(\gamma_1 + \gamma_p)l} G \quad . \quad . \quad . \quad . \quad (52)$$

$$H' = e^{-(\gamma_2 + \gamma_p)l} H \quad . \quad . \quad . \quad . \quad (53)$$

We can obtain an idea of the physical meaning of these equations by considering Fig. 23, in which the line is looked at along its length. The source at AB sends a wave of current along circuit 1, which when it has travelled a distance l has been attenuated by a factor $e^{-\gamma_1 l}$. At this point there is an unbalance which gives rise to an induced voltage in circuit 2, and the wave of induced current in travelling back to the detector at CD is attenuated by a further factor $e^{-\gamma_2 l}$. This aspect, however, is complicated by, among other things, the impedance of the receiver. The method of equivalent networks introduces no assumptions in that respect, and as the interference coefficients are, by definition, admittance operators, they are independent of the apparatus external to the sending end of the line and are the same however measured.

In the foregoing discussion it was stated that the section of line placed in front of ABCD was free from unbalances. If, however, it itself possesses interference coefficients $\frac{1}{4}F_1$, $-\frac{1}{2}G_1$, $-\frac{1}{2}H_1$, when measured from A′B′C′D′ and terminated at its distant end, these may be regarded as being produced by small admittances parallel with the arms A′C′, C′B′, B′D′, D′A′, and thus the effective interference coefficients are the result of

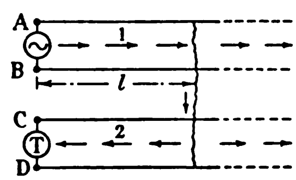

FIG. 23.

admittances in parallel and are added algebraically. In this case,

$$F' = F_1 + Fe^{-(\gamma_1+\gamma_2)l} \quad . \quad . \quad . \quad (54)$$
$$G' = G_1 + Ge^{-(\gamma_1+\gamma_p)l} \quad . \quad . \quad . \quad (55)$$
$$H' = H_1 + He^{-(\gamma_2+\gamma_p)l} \quad . \quad . \quad . \quad (56)$$

We may generalize this in the following statement :—

If we have a number of sections of similar line, 1, 2, 3, . . . connected in series in that order, each of which when measured at its nearer end and terminated at its further end has interference coefficients $\frac{1}{4}F_1$, $-\frac{1}{2}G_1$, $-\frac{1}{2}H_1$; $\frac{1}{4}F_2$, $-\frac{1}{2}G_2$, $-\frac{1}{2}H_2$; $\frac{1}{4}F_3$, $-\frac{1}{2}G_3$, $-\frac{1}{2}H_3$; . . . respectively, and if the beginnings of the sections are at distances $l_1 (= 0)$, l_2, l_3, . . . respectively from the near end of the line, the resultant interference coefficients $\frac{1}{2}F'$, $-\frac{1}{2}G'$, $-\frac{1}{2}H'$ measured at this near end with the distant end terminated will be such that :—

$$F' = F_1 + F_2 e^{-(\gamma_1+\gamma_2)l_2} + F_3 e^{-(\gamma_1+\gamma_2)l_3} + \; . \quad (57)$$
$$G' = G_1 + G_2 e^{-(\gamma_1+\gamma_p)l_2} + G_3 e^{-(\gamma_1+\gamma_p)l_3} + \; . \quad (58)$$
$$H' = H_1 + H_2 e^{-(\gamma_2+\gamma_p)l_2} + H_3 e^{-(\gamma_2+\gamma_p)l_3} + \; . \quad (59)$$

Section 5. VARIATION OF THE INTERFERENCE COEFFICIENTS WITH FREQUENCY.

(i) *When the unbalance is close to the measuring end.*—It has been shown that as regards unbalances on a long loaded line, mutual and self-inductance are equivalent to capacity, and resistance to leakance.

The effective leakance component of an interference coefficient consists of :—

(i) True leakance, which varies approximately as the

first power of the frequency; this is generally negligibly small.

(ii) Resistance, viz. (*a*) d.c. resistance, which is independent of frequency, (*b*) a.c. losses consisting of eddy-current losses which vary as the square of the frequency, and, in a loaded line, hysteresis losses which vary as the first power of the frequency.

Generally the effective leakance component is comparatively small in a loaded line. (An exception may arise when there is a high-resistance joint in a conductor, in which case there will be a large d.c. unbalance independent of frequency.) In the cross-talk coefficient it is in any case negligible, being due only to true leakance.

The effective capacity component may be due to (i) true capacity, (ii) mutual inductance, (iii) self-inductance, all three of which are independent of frequency. In the cross-talk coefficient only capacity and mutual inductance play a part.

Summing up, the capacity component, which is the principal, is independent of frequency; the leakance component in cross-talk is negligibly small, in over-hearing it is also small and is independent of frequency if due to d.c. resistance, and varies as some power between the first and second if due to a.c. losses.

(ii) *When the unbalance is some distance from the measuring end.*—As equations (57), (58) and (59) are of the same type, they may be written in the general form:—

$$J' = \Sigma(J_n e^{-2\gamma l_n}) \quad . \quad . \quad . \quad . \quad (60)$$

where J_n is the value of the interference coefficient of the nth section as measured from its nearer end with its further end terminated,

J' is the interference coefficient as measured at the near end of the line, with the distant end terminated,

l_n is the distance of the beginning of the nth section from the near end of the line,

γ is the average of the propagation constants of the two circuits,

β is the average of the attenuation constants,

and α is the average of the wave-length constants.

Then $$J' = \Sigma(J_n e^{-2\beta l_n}) \overline{\rfloor 2\alpha l_n} \quad . \quad . \quad . \quad (61)$$

i.e. each term is reduced by its appropriate factor $e^{-2\beta l_n}$ and its phase is shifted backwards by the angle $2\alpha l_n$.

Writing $J_n = g_n + j\omega c_n$, and $J' = g' + j\omega c'$, we have

$$J' = \Sigma\{(g_n + j\omega c_n)e^{-2(\beta + j\alpha)l_n}\}$$

i.e.

$$g' + j\omega c' = \Sigma\{(g_n + j\omega c_n)(\cos 2\alpha l_n - j \sin 2\alpha l_n)e^{-2\beta l_n}\}$$

$$\therefore g' = \Sigma\{(g_n \cos 2\alpha l_n + \omega c_n \sin 2\alpha l_n)e^{-2\beta l_n}\} \quad (62)$$

and $$c' = \Sigma\{(\omega c_n \cos 2\alpha l_n - g_n \sin 2\alpha l_n)e^{-2\beta l_n}\}. \quad (63)$$

If the terms g_n are small enough to be neglected,

$$g' = \omega\Sigma(c_n \sin 2\alpha l_n e^{-2\beta l_n}) \quad . \quad . \quad . \quad (64)$$

$$\omega c' = \omega\Sigma(c_n \cos 2\alpha l_n e^{-2\beta l_n}) \quad . \quad . \quad . \quad (65)$$

In a loaded line, $\alpha = \frac{1}{2}\omega\{\sqrt{(C_1 L_1)} + \sqrt{(C_2 L_2)}\}$ approx. $= \omega k$, where C_1, C_2 and L_1, L_2 are the capacities and inductances per unit length of the two circuits respectively.

Therefore

$$g' = \omega\Sigma(c_n e^{-2\beta l_n} \sin 2\omega k l_n) \quad . \quad . \quad . \quad (66)$$

$$\omega c' = \omega\Sigma(c_n e^{-2\beta l_n} \cos 2\omega k l_n) \quad . \quad . \quad (67)$$

i.e. $$c' = \Sigma(c_n e^{-2\beta l_n} \cos 2\omega k l_n) \quad . \quad . \quad . \quad (68)$$

Thus each unbalance gives rise to a term periodic in ω, the value between successive peaks being $\omega = \pi/(kl_n)$ or

$$f = \frac{1}{2kl_n}$$

The further away the seat of the unbalance the closer together are the peaks in the frequency curve.

The resultant of several unbalances along the line will consist of the sum of a number of such curves, each of which has a different period in ω, and thus will present a complex appearance. The amplitudes of the total value $(g' + j\omega c')$ and also of g' will tend to increase with frequency on account of the term ω outside the bracket, while c' will tend to decrease slightly with frequency on account of the attenuation factors $e^{-\beta l_n}$, the terms c_n, as shown in the preceding Section, being independent of frequency.

If there be a particularly large unbalance at some point, the corresponding periodic curve will be well marked on plotting the interference coefficient against frequency, and this affords a means of locating its position. The factor k is easily obtained and thus the distance of the disturbance from the measuring end is

$$l = \frac{1}{2fk} \quad . \quad . \quad . \quad . \quad . \quad (69)$$

where f is the frequency interval in cycles per second between the peaks in the periodic curve.*

(iii) *Example.*—To illustrate how the interference coefficients vary with frequency, we may consider the cross-talk between two similar circuits; for simplicity the attenuation constant β for each circuit is taken as being 0·02 per mile for all frequencies, and the wave-length constant $\alpha = \omega/20\,000$. Let there be unbalances whose capacity components are $-300\ \mu\mu$F at the measuring end, $-1\,000\ \mu\mu$F at a distance of 5 miles and $+1\,000\ \mu\mu$F at a distance of 10 miles, the leakance components being zero. Equations (64) and (65) become

$$g = g_1 + g_2 + g_3 \quad . \quad . \quad . \quad . \quad (70)$$

where
$$g_1 = 0$$
$$g_2 = -1\,000e^{-0\cdot 2} \sin(\omega/2\,000)\omega$$
$$g_3 = +1\,000e^{-0\cdot 4} \sin(\omega/1\,000)\omega$$

and $$c = c_1 + c_2 + c_3 \quad . \quad . \quad . \quad . \quad (71)$$

where
$$c_1 = -300$$
$$c_2 = -1\,000e^{-0\cdot 2} \cos(\omega/2\,000)$$
$$c_3 = +1\,000e^{-0\cdot 4} \cos(\omega/1\,000)$$

In Fig. 24, the capacity components are plotted, c_1, c_2 and c_3 in broken lines, the total, c, in a full line; in Fig. 25 the leakance components are similarly treated.

* FERRIS and McCURDY: "Telephone Circuit Unbalances," *Journal of the American I.E.E.* 1924, vol. 43, p. 1133.

In Fig. 26 the modulus of the resultant [$= \sqrt{(g^2 + \omega^2 c^2)}$] is shown.

(iv) *Deductions.*—The equations obtained in this and the preceding Section show to what extent interference

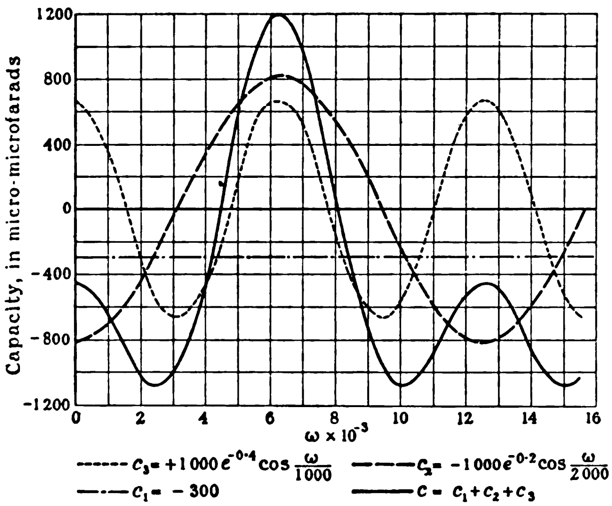

FIG. 24.—Variation of unbalance with frequency. Capacity component.

is caused by various factors and enable us to judge the effectiveness of the methods of reducing it.

Where no attempt is made to control them, the unbalances will occur in an arbitrary manner and, speaking generally, one would expect that, in a long line, for every unbalance there is somewhere along the length a similar unbalance of opposite sign. The extent

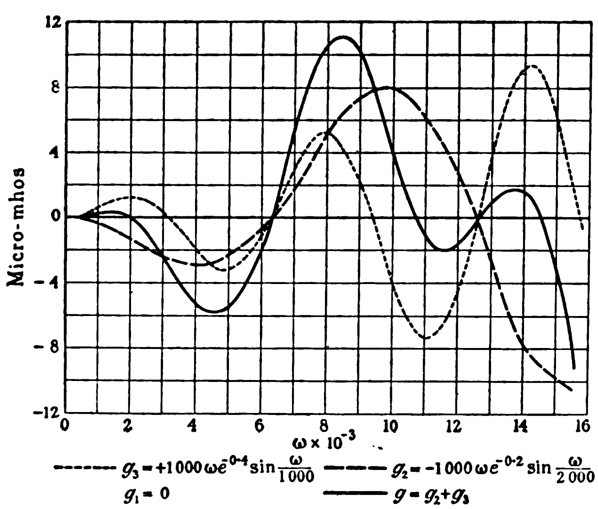

FIG. 25.—Variation of unbalance with frequency. Leakance component.

to which these will neutralize each other depends on the distance between them, the wave-length constant and, to a lesser degree, the attenuation constant. In the example given, the unbalances of + 1 000 and − 1 000 $\mu\mu$F separated by 5 miles do not cancel each other, in fact in the most important region of frequencies they add up. Where the inductance is high, interference would be increased, as not only would the inductance unbalances be higher, but the wave-length constant is large and the attenuation constant small. Thus one would expect interference to give more trouble on a loaded line, and this is a point in favour of lighter loading.

The equations also throw a light on the difficulties

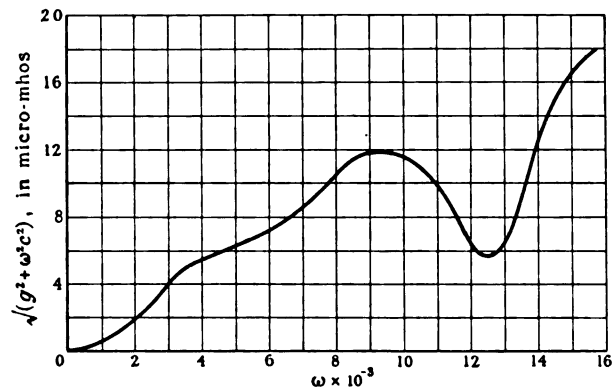

FIG. 26.—Variation of unbalance with frequency. Modulus of resultant.

in the measurement of interference, which forms the subject of the next Section.

Section 6. METHODS OF MEASUREMENT.

This subject as applied to interference is in itself a wide one, and for the most part only the outlines can be considered.

(i) *Unbalanced capacity.*—This is taken on sections short compared with the wave-length, with the distant end open, so that the distributed capacities may be regarded as replaced by lumped condensers of the same value.

P.O. double bridge.—The method developed by the British Post Office is illustrated in Fig. 27. R_1, R_2 are equal non-reactive resistances of 1 000 ohms each; K_1, K_2, variable air condensers having a maximum value of 1 200 $\mu\mu$F each; k_1, k_2, fixed air condensers each of value 600 $\mu\mu$F. Alternating current of frequency about 1 000 cycles per sec. is supplied through a screened

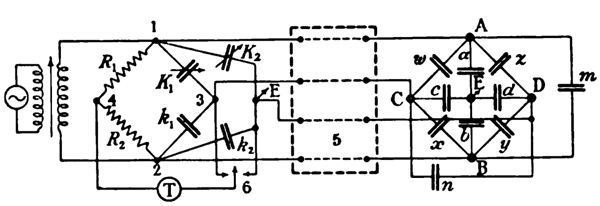

FIG. 27.—Unbalanced capacity bridge.

and balanced transformer to the corners 1, 2. The quad is connected to the bridge through a switch 5 (not shown in detail) which has 4 positions. In the first, or " P " position, A is joined to 1, B to 2, C to 3 and D to earth (E). By means of switch 6, the telephone is connected between 4 and C, and the wire-

to-wire condenser K_1 is varied until silence is obtained. Switch 6 is then thrown over so that the telephone is connected between 4 and E and the wire-to-earth condenser, K_2, adjusted for balance. On switching back to C, K_1 is re-adjusted and the cycle is repeated, each time coming closer to the true balance until finally silence is obtained in both positions. In these circumstances

$$K_1 + w = k_1 + x$$

i.e.
$$k_1 - K_1 = w - x = p \quad . \quad . \quad . \quad (72)$$

and
$$K_2 + z + a = k_2 + y + b$$

i.e.
$$\begin{aligned} k_2 - K_2 &= z - y + a - b \\ &= u + q = p_e \quad . \quad . \quad . \quad (73) \end{aligned}$$

The variable condensers are calibrated from + 600 to − 600 $\mu\mu$F so as to read $k_1 - K_1$ and $k_2 - K_2$ directly. On changing the switch 5 to the "Q" position, D is connected to 3 and C to E, A and B remaining unaltered. The readings of the wire-to-wire and wire-to-earth condensers after balance has been obtained give q and $q_e = u + p$ respectively. In the third or "R" position, C is joined to 1, D to 2, A to 3 and B to E, and one obtains r and $r_e = v + s$. Finally in

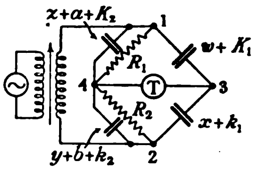

Fig. 28.

the "S" position, B is connected to 3 and A to E, C and D remaining unaltered, and the condenser readings give s and $s_e = v + r$, respectively. From these eight readings one obtains

$$p - q = r - s,$$
$$p + q, \quad r + s,$$
$$p_e - q = q_e - p = u,$$
$$r_e - s = s_e - r = v.$$

The duplications provided by the cross-talk and the earth figures afford an immediate check on the accuracy of the readings.

A considerable saving of time is effected if, when the switch 6 is in the "wire-to-wire" position, i.e. connecting the telephone between 4 and 3, the point 4 is put to earth. The resulting bridge network for the "P" position is shown in Fig. 28, the capacities shunting the source and detector being omitted. The conditions for balance are

$$\left.\begin{aligned} K_1 + w &= k_1 + x \\ \text{and} \quad K_2 + z + a &= k_2 + b + y \end{aligned}\right\} \quad . \quad . \quad (74)$$

The second condition is affected by the leakance of the cable and is not reliable; the first, however, gives the required setting of the wire-to-wire condenser in one operation and the corresponding wire-to-earth balance is then obtained as previously, necessitating only one further operation.

Other methods have been developed, notably by the Western Electric Co. (British Patent, Specification No. 203870), and a single-bridge arrangement is described by E. A. Beavis in an article on "Trunk Telephone Cables." [*]

(ii) *Unbalanced inductance and resistance.*—This is likewise taken on sections short compared with the wave-length; the distant end is short-circuited, so that the cores can be represented by lumped inductances and resistances. A form of bridge suitable for measuring these unbalances is shown in Fig. 29. R_1 and R_2 are equal non-reactive resistances of 100 or 1 000 ohms each; L_1 and L are variable and fixed inductances

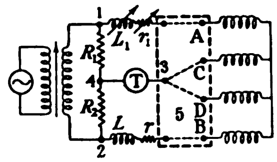

Fig. 29.

respectively, r_1 and r, variable and fixed resistances respectively. The current is supplied through a screened and balanced transformer to the points 1, 2, the telephone being connected between 3 and 4. The quad is connected to the bridge through the switch 5 which has two positions. In the first A is connected to the variable arm, B to the fixed arm, C and D to 3. When L_1 and r_1 are adjusted for balance,

$$r_1 + j\omega L_1 + r_a + j\omega L_a = r + j\omega L + r_b + j\omega L_b$$

$$\left.\begin{aligned} \text{i.e.} \quad r - r_1 &= r_a - r_b = r_{ab} \\ \text{and} \quad L - L_1 &= L_a - L_b = l_{ab} \end{aligned}\right\} \quad . \quad . \quad . \quad (75)$$

The adjustable resistance and inductance are calibrated to read $r - r_1$ and $L - L_1$ respectively. In

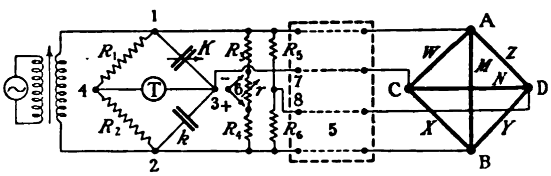

Fig. 30.—Measurement of interference coefficients.

the second position of 5, C is connected to the variable arm, D to the fixed arm, A and B to 3, and the unbalanced resistance and inductance of the CD pair are obtained.

(iii) *Measurement of interference coefficients.* — The interference coefficients as defined in Section 3 are admittance operators, and can be taken on a bridge which measures both unbalanced capacity and unbalanced leakance. The form used by the author [†] is shown in Fig. 30.

R_1 and R_2 are equal non-reactive resistances of 1 000 ohms each, K a variable air condenser of maximum value 1 200 $\mu\mu$F, k a fixed air condenser of 600 $\mu\mu$F, R_3 and R_4 equal non-reactive resistances of 10 000 ohms

[*] *Electrician*, 1924, vol. 92, p. 318.
[†] British Patent Specification No. 241972.

each, r a 3-dial variable non-reactive resistance of maximum value 1 000 ohms, R_5 and R_6 equal non-reactive resistances of 100 ohms each. R_3 and R_4 are in parallel with K, k respectively, and, by means of switch 6, r is put in series with either R_3 or R_4. Switch 5 is a "PQRS" switch as described in Sub-section (i), and connects the quad ABCD, which is here represented by its equivalent network, to the bridge.

Neglecting for the time being the resistances R_5 and R_6, the conditions for balance (in the "P" position) may be obtained as follows:—Transform the star AD, CD, BD into its mesh. Then AC becomes

$$W + \frac{NZ}{Z + Y + N} = W + \lambda_1 Z$$

and BC becomes

$$X + \frac{NY}{Z + Y + N} = X + \lambda_1 Y$$

where $$\lambda_1 = \frac{N}{Z + Y + N}$$

Assuming that switch 6 is the + position, i.e. r is in series with R_3,

$$\frac{1}{r + R_3} + j\omega K + W + \lambda_1 Z = \frac{1}{R_4} + j\omega k + X + \lambda_1 Y$$

i.e. $$\frac{r}{10\,000\,(10\,000 + r)} + j\omega(k - K) = P + \lambda_1 Q$$

If r is small, it may be neglected compared with 10 000 ohms; also the variable condenser is calibrated to read $k - K = c$ directly. Thus we may write

$$10^{-8} r_p + j\omega c_p = P + \lambda_1 Q \quad . \quad . \quad . \quad (76)$$

the p suffix denoting readings in the "P" position. Similarly, in the "Q" position

$$10^{-8} r_q + j\omega c_q = Q + \lambda_2 P \quad . \quad . \quad . \quad (77)$$

where $$\lambda_2 = \frac{N}{W + X + N}$$

Now $\lambda_1 \simeq \lambda_2 \simeq \lambda$, where $\lambda = N/(2\overline{W} + N)$

$$\therefore\ (r_p - r_q)10^{-8} + j\omega(c_p - c_q) = (1 - \lambda)\,(P - Q) = (1 - \lambda)F \quad . \quad (78)$$

and

$$(r_p + r_q)10^{-8} + j\omega(c_p + c_q) = (1 + \lambda)\,(P + Q) = (1 + \lambda)G \quad . \quad (79)$$

From the "R" and "S" positions, we obtain

$$(r_r + r_s)10^{-8} + j\omega(c_r + c_s) = (1 + \lambda')H \quad . \quad (80)$$

and $$(r_r - r_s)10^{-8} + j\omega(c_r - c_s) = (1 - \lambda')F \quad . \quad (81)$$

where $$\lambda' = M/(2\overline{W} + M)$$

Nearly always the quad is a symmetrical one, i.e. the pairs AB and CD are alike; then $\lambda = \lambda'$, and equation (81) gives a check on the accuracy of the readings.

The effect of the 100-ohm resistance is to reduce λ to $\dfrac{\overline{M}}{2\overline{W} + \overline{M} + (2/100)}$, and thus variations in λ_1, λ_2 are of less account. For example, if $\overline{M} = 1/1\,100$ mho, $\overline{W} = 1/760$ mho, without the 100-ohm resistances $\lambda = 0{\cdot}257$, whereas with the 100-ohm resistances $\lambda = 0{\cdot}039$.

If only the overhearing coefficients are required, points 7 and 8 are joined, the 100-ohm resistances being omitted. The "P" (or "Q") position gives G directly, and the "R" (or "S") position gives H directly.

Series inductance method.—It has been shown that, as regards overhearing, series inductance and resistance are equivalent to shunt capacity and leakance respectively. Hence the bridge described in Sub-section (ii) for measuring inductance and resistance unbalances can be used for obtaining the overhearing coefficients, the relations being

$$\left.\begin{aligned} G &= -\,Y_1 Y_p(r_{ab} + j\omega l_{ab}) \\ H &= -\,Y_2 Y_p(r_{cd} + j\omega l_{cd}) \end{aligned}\right\} \quad . \quad . \quad . \quad (82)$$

The series method is of advantage where the impedance of the line is low, e.g. a fairly short length

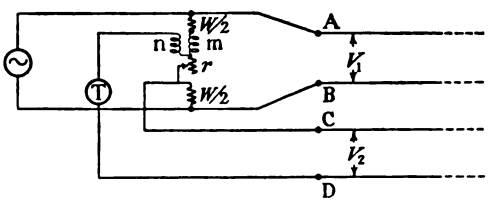

FIG. 31.—Measurement of induced voltage.

with the distant end short-circuited, but it does not give the cross-talk coefficient. This type of bridge has been used by Ferris and McCurdy for locating irregularities in transmission lines, as described in Section 5 (ii).

(iv) *Measurement of the induced voltage.*—Messrs. Felton and Guilleaume have described in British Patent No. 8243/22 a method of measuring the ratio of the induced to the inducing voltage, both in magnitude and phase. In Fig. 31, $W/2$, $W/2$ are fixed resistances, each of 25 000 ohms, m the fixed coil, and n the moving coil of a variometer, r a small variable resistance. In taking a test, r and n are adjusted until silence is obtained in the telephone T. Then the current in the branch circuit, $I_a = V_1/W$ approx.

Voltage across $r = rI_a$.

Voltage across coil n $= MI_a$, where M is the mutual inductance between the coils.

Total voltage $= (r + j\omega M)I_a$ and this is equal and opposite to the induced voltage V_2.

$$\therefore\ \frac{V_2}{V_1} = \frac{r + j\omega M}{W} \quad . \quad . \quad . \quad . \quad (83)$$

Since the balancing circuit does not carry any current the induced line behaves as if it were insulated. In practice, both the supply and the telephone must be connected through screened transformers to avoid capacity effects, and a reversing switch is provided on the listening pair to obtain the correct phase relationship.

It is to be noted that the ratio V_2/V_1 as measured in this way is not the same as occurs in practice, where the impedance of the listening instrument considerably alters the value; this is shown in equation (14z) *et seq.*

(v) *Measurement of interference with speech.*—The methods discussed so far all necessitate the use of a single-frequency current, and while it is true that such tests taken over a range of frequencies supply far more information about the line than does a single test with speech, in the present stage of development of the art the speech test is the ultimate criterion.

From a preceding Section we see that the interference coefficients are vector quantities which vary both in magnitude and direction with frequency. Consequently the induced current will alter in intensity and phase with frequency, and, inasmuch as this variation may be quite irregular, no measurement at a single periodicity can be taken as being representative of the behaviour over the whole range of frequencies in speech. This is different from the measurement of the transmitting qualities of a line, in which case the attenuation varies in a regular manner with frequency, and $\omega = 5\,000$ is taken as the mean speech frequency.

The principle of speech tests is to compare the volume of the induced current with the corresponding volume obtained through an adjustable network or "artificial cable," the input current and/or voltage being the same

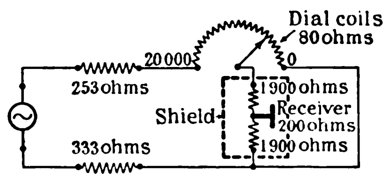

FIG. 32.—Cross-talk meter.

in both cases. By means of a switch a telephone is placed alternately in the listening circuit in the cable and on the output terminals of the network; the latter is varied until the intensity of sound is the same in both positions.

The "artificial line" can be used either in parallel or in series with the cable. In the first case the impressed voltages are equal, and in the second the currents entering are equal. When the meter has the same impedance as the cable, both conditions are fulfilled, but otherwise it is necessary, in giving results, to state the method of connection.

(vi) *The standard cable.*—The earliest method adopted was the use of the standard cable as the adjustable network, arising out of its employment for the measurement of attenuation. It is constructed of condensers and resistances, and is made to approximate to a line having the following constants per mile loop:— $R = 88$ ohms, $L = 1$ mH, $C = 0\cdot054\ \mu$F, $G = 1$ micromho, attenuation $= 0\cdot1065$. The equivalent length of the artificial cable is varied by means of switches, and the instrument is calibrated to read in miles of standard cable.

(vii) *The Western Electric cross-talk meter.*—This is probably the most widely used instrument in this country, and has been adopted by the British Post Office. It consists essentially of a form of universal shunt (Fig. 32) by which a known fraction of the total current passes through the telephone, and additional resistances are inserted so that the resistance of the combination is practically constant for all positions of the switch arm; the value is 666 ohms, using a 60-ohm Bell receiver of the ordinary type. The instrument is calibrated to express the current in the telephone as a fraction in millionths of the total current passing through the meter. If V_m = the voltage on the terminals of the meter, and I_m = the current passing through it, then $I_m = V_m/666$; if n is the reading then the current in the telephone,

$$I_t = \frac{nV_m}{666 \times 10^6} \quad . \quad . \quad . \quad . \quad . \quad (84)$$

The cross-talk meter can be used with a source of alternating current of adjustable frequency to obtain the variation of current in the telephone with frequency. Such a curve will correspond approximately to the variation of the modulus of the interference coefficient, but will be modified owing to the alteration in the impedance of the telephone receiver and transformers. Further, the source of alternating current must be a pure sine wave, as the presence of harmonics may give misleading results. (It is to be noticed that harmonics do not cause error in the null methods, but only make the balancing somewhat more difficult.)

Meter in parallel.

(*a*) *Cross-talk.*

AB/CD.

Equation (15*z*) gives

$$I_t = \frac{Z_1Z_2}{(Z_1 + 4r)(Z_2 + Z_t + 4r)} \cdot \frac{F}{4}V_1$$

Since the meter is in parallel, $V_m = V_1$.

$$\therefore\ n = \frac{666 \times 10^6 Z_1Z_2}{(Z_1 + 4r)(Z_2 + Z_t + 4r)} \cdot \frac{F}{4} \quad . \quad (85)$$

The equation for CD/AB is similar, Z_1 and Z_2 being interchanged.

(*b*) *Overhearing.*

(i) +/AB.

Equation (23*z*) gives

$$I_t = \frac{-Z_1Z_p}{(Z_p + r)(Z_1 + 4r + Z_t)} \cdot \frac{G}{2}V_1$$

$$\therefore\ n = \frac{666 \times 10^6 Z_1Z_p}{(Z_p + r)(Z_1 + 4r + Z_t)} \cdot \frac{G}{2} \quad . \quad . \quad (86)$$

(ii) AB/+.

Equation (25*z*) gives

$$I_t = \frac{-Z_1Z_p}{(Z_p + r + Z_t)(Z_1 + 4r)} \cdot \frac{G}{2}V_1$$

$$\therefore\ n = \frac{666 \times 10^6 Z_1Z_p}{(Z_p + r + Z_t)(Z_1 + 4r)} \cdot \frac{G}{2} \quad . \quad . \quad (87)$$

The corresponding equations for +/CD and CD/+ are obtained from equations (86) and (87) respectively, by writing Z_2 for Z_1 and H for G.

Meter in series.

(*a*) *Cross-talk*, AB/CD.—If I_1 is the input current into the cable, then $I_1 = V/Z_1$.

$$\therefore \text{ From (15}z\text{)},\quad I_t = \frac{Z_1^2Z_2}{(Z_1 + 4r)(Z_2 + Z_t + 4r)} \cdot \frac{F}{4}I_1$$

For the meter, $I_t = nI_m/10^6$ and, since the meter is in series with the cable, $I_m = I_1$.

$$\therefore n = \frac{10^6 Z_1^2 Z_2}{(Z_1 + 4r)(Z_2 + Z_t + 4r)} \cdot \frac{F}{4} \quad . \quad . \quad (88)$$

(*b*) *Overhearing*, +/AB.—In a similar way we find

$$n = \frac{10^6 Z_p^2 Z_1}{(Z_p + r)\ (Z_1 + 4r + Z_t)} \cdot \frac{G}{2} \quad . \quad . \quad (89)$$

$$\text{AB}/+,\ n = \frac{10^6 Z_1^2 Z_p}{(Z_p + r + Z_t)\ (Z_1 + 4r)} \cdot \frac{G}{2} \quad . \quad . \quad (90)$$

etc.

The equations for the cross-talk meter are given in enable proper comparison to be made between lines of different characteristics.

(viii) *Correction of cross-talk meter readings.*—Equation (31) gives as the true value of the interference in millionths, $n = \frac{1}{2}J\sqrt{(Z_1Z_2)} \times 10^6$, where $J = \frac{1}{4}F$ for cross-talk, and $-\frac{1}{2}G$ or $-\frac{1}{2}H$ for overhearing. Combining this with the equations in the previous Section, we can obtain the correction factor k by which it is necessary to divide the meter readings to allow for the effect of the external apparatus and for the difference in impedance between the disturbed and the disturbing circuits. The values for k are given in Table 2.

Using "4006A" repeating coils, r is 35 ohms, and for a 60-ohm Bell receiver Z_t is approximately 200 ohms. In Fig. 33, k is plotted against various values of the side-circuit impedance; for the overhearing two cases

TABLE 2.

	Side/side	Phantom/side	Side/phantom
Meter in parallel	$\dfrac{2 \times 666\sqrt{(Z_1Z_2)}}{(Z_1 + 4r)(Z_2 + 4r + Z_t)}$	$\dfrac{2 \times 666\sqrt{(Z_sZ_p)}}{(Z_p + r)(Z_s + 4r + Z_t)}$	$\dfrac{2 \times 666\sqrt{(Z_sZ_p)}}{(Z_s + 4r)(Z_p + r + Z_t)}$
Meter in series	$\dfrac{2Z_1\sqrt{(Z_1Z_2)}}{(Z_1 + 4r)(Z_2 + 4r + Z_t)}$	$\dfrac{2Z_p\sqrt{(Z_sZ_p)}}{(Z_p + r)(Z_s + 4r + Z_t)}$	$\dfrac{2Z_s\sqrt{(Z_sZ_p)}}{(Z_s + 4r)(Z_p + r + Z_t)}$

some detail, as it is the practice of the British Post Office to test with the meter both in parallel and in series. It is seen that the differences between results obtained for +/AB and AB/+, and for meter in parallel are given (i) $Z_p = 0{\cdot}5Z_s$ shown in full lines, and (ii) $Z_p = 0{\cdot}4Z_s$ shown in broken lines.

It will be seen that unless they are corrected, the readings may be very misleading, particularly for cables

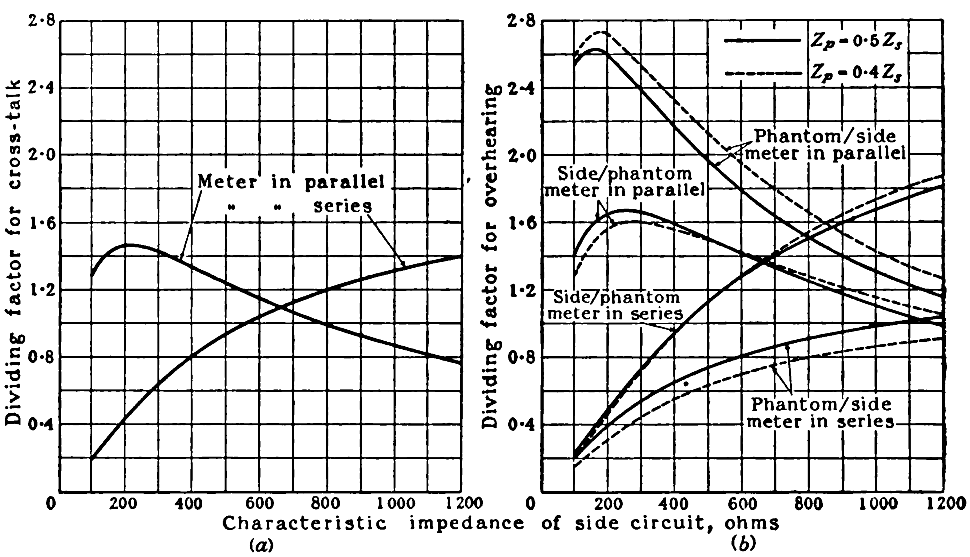

FIG. 33.—Correction factor for cross-talk meter readings.

and in series depend on the external apparatus. It is highly desirable that a standard of measurement be adopted which will be independent of the external apparatus and the method of connections, and depend on the cable only. This will simplify the testing and of small impedance, e.g. those with light loading. For $Z_s = 250$ ohms, the highest overhearing readings are given by the phantom/side connections with the meter in parallel; here $k = 2{\cdot}5$ when $Z_p = 0{\cdot}5Z_s$, so that a reading of 2 000 millionths really corresponds to a

value of 800 millionths. Particular caution therefore is necessary in comparing cross-talk meter figures with those obtained by different methods in a different system of units.*

(ix) *Difficulties of speech measurements.*—The measurement of interference with actual speech is one of the least satisfactory of the measurements in telephony. The ratio of the induced to the inducing current in the real cable varies irregularly, but generally increases as the frequency increases; on the other hand, the corresponding variation in the standard cable is in the reverse direction, the ratio decreasing with increasing frequency, whilst in the cross-talk meter the ratio is constant and independent of frequency. The real and the artificial cables behave differently towards the various harmonics in the speech current, and in consequence the observer has to attempt to equate by their sound in the telephone two currents of entirely different wave-form. In these circumstances the readings can vary widely with the conditions of test. It is difficult for the human ear to judge a complex sound by its intensity alone, without giving undue weight to some particular harmonic. The sensitivity of the ear varies for sounds of different pitch, it being most receptive to frequencies from 1 000 to 2 000 cycles per sec.; moreover, this variation is affected by the actual strength, for in louder sounds the lower tones have a certain "masking" effect. Thus the readings are affected by the strength of the current from the transmitter, by the presence of external noise, and by the position in which the receiver is held, whether tightly up to the ear or away from it. The results also vary considerably with the voice of the speaker, e.g. with the pitch, intensity and timbre, and again with the nature of the speech, e.g. the language, as determining the proportion of vowels and consonants. One possible solution is to arrange that the impedance/frequency curve of the artificial cable rises with increasing frequency.†

(x) *Relation between the interference with actual speech and at various frequencies.*—Let the angular frequencies of the components of the currents with actual speech be $\omega_1, \omega_2, \omega_3 \ldots$ and let the proportions of the total power at these frequencies be $k_1, k_2, k_3 \ldots$ etc., respectively; further let the values for the interference be Ψ_1 at ω_1, Ψ_2 at ω_2, etc.

The power in the disturbing circuit,

$$P_1 = k_1 P_1 + k_2 P_1 + \ldots$$

The power in the disturbed circuit

$$P_2 = k_1 \Psi_1 P_1 + k_2 \Psi_2 P_1 + \ldots$$

$$\therefore \Psi_{\text{speech}} = P_2/P_1 = k_1 \Psi_1 + k_2 \Psi_2 + \ldots \qquad (91)$$

Section 7.—Reduction of Interference.

The problem has been attacked in two ways, (*a*) by reduction all along the length of the cable, e.g. the method of cross-jointing as used in England and America, and the method of inserting small fixed condensers as used in Germany, and (*b*) by the use of apparatus at the ends only.

(i) *Cross-jointing.*—This method, as applied to the reduction of capacity unbalances in underground trunk cables (coil-loaded) was developed by the P.O. Research Department * in England and independently by the Western Electric Co.† in America.

From a consideration of Section 4 A (i), we can see that if the wires A and B are interchanged, the signs of $p - q$, $p + q$, and u are reversed, leaving $r + s$ and v unaltered; if C and D are interchanged, then the signs of $p - q$, $r + s$ and v are reversed, leaving $p + q$ and u unaltered; if A and B as well as C and D are interchanged, then all the characteristics change sign except $p - q$. Again, if the pairs are interchanged, the relevant overhearing characteristics are interchanged as well.

In the multiple-twin form of construction, one quad can be jointed to another in one of eight ways:—

(1) With the pairs straight:

(*a*) AB straight and CD straight.
(*b*) AB straight and CD crossed.
(*c*) AB crossed and CD straight.
(*d*) AB crossed and CD crossed.

(2) With the pairs crossed:

(*a*) AB straight and CD straight.
(*b*) AB straight and CD crossed.
(*c*) AB crossed and CD straight.
(*d*) AB crossed and CD crossed.

When a number of lengths are joined together, the resultant capacities are the algebraic sums of the corresponding capacities in the separate sections, provided the total length is short, and the joints can generally be designed by suitable crosses to reduce all the characteristics. The length of cable between loading coils in trunk mains ($1\frac{1}{3}$ to $2\frac{1}{2}$ miles) fulfils this condition very nearly, as the wave-length of the unloaded cable is considerable, and therefore balancing on the plain summation principle is permissible. Each section of cable between loading points is treated as a separate unit, and in English practice the characteristics are balanced out so that the following values are not exceeded:—

$$\begin{array}{rl} p - q & 80\ \mu\mu\text{F} \\ \left.\begin{array}{r} 2(p+q)+u \\ 2(r+s)+v \end{array}\right\} & 110\ \mu\mu\text{F} \\ \left.\begin{array}{r} u \\ v \end{array}\right\} & 200\ \mu\mu\text{F} \end{array}$$

This method can be applied to continuously loaded cables, but on account of the higher distributed inductance the wave-length is less than for an unloaded cable and the sections have to be considerably shorter. The inductance and resistance unbalances have to be reduced at the same time and this complicates the balancing. If capacity and inductance are balanced out

† British Patent Nos. 2009 and 2508 of 1913.

separately in different stages, it is necessary to work in yet shorter lengths. This is undesirable as adding to the number of joints and multiplying the testing and clerical work.

The author has extended the crossing method to apply to the general case where the unbalances are complex quantities and the propagation effect has to be taken into account; it has been developed to deal more particularly with continuously loaded cables.

(ii) *Procedure in the author's method.**—The results of crossing are similar to those in the simpler case, viz. interchanging the wires of a pair reverses the sign of its relevant overhearing coefficient; the sign of the cross-talk coefficient is altered if one pair is crossed and is the same if both are crossed; the magnitudes are unaffected. The corresponding terms in the summation formulæ are altered in the same way.

Briefly, the interference coefficients of each section of cable are measured by means of the bridge described in Section 6 (iii). In order that the behaviour of every part shall be the same as when it forms a portion of the completed line, all measurements are taken with the distant end terminated. The sections are grouped together, and the effective coefficients of each quad are calculated by means of equations (62) and (63) to obtain the value when measured from the end of its group. The joints between sections are arranged by suitable crosses so that the total value of each interference coefficient is reduced below some predetermined value. The groups are tested to check the calculated figures, and the process is repeated in connecting up the groups.

It is evident from the equations that a balance for one particular frequency does not hold good for all others, in fact, under certain conditions, the arrangement that will be the best for one frequency is the worst for another. It is impossible to cancel an unbalance by any other unbalance situated at a distance from it, so that the resultant is zero for all frequencies; but the smaller the distance separating the two, the wider the range of frequencies over which the cancellation is effective. The first principle in selection therefore is that every large unbalance must be neutralized by an unbalance of the same order of magnitude, located as close to it as possible. If the cable contains a large number of quads, and if the quads can be crossed indiscriminately in the joints, then this condition can generally be met. The difficulties arise when the number of cores is limited, and especially when the manner of jointing is restricted. In submarine cables it is desirable to avoid mechanical discontinuities, and the size of the joint must be the same as the rest of the cable; consequently crossing over of quads is not practicable, and when the joint in one quad of a layer is determined the remaining quads have to follow in their normal positions. This severely limits the possibility of reducing the characteristics to small values. On the other hand, if the order of the sections is not fixed, they can be arranged so as to help to reduce the unbalances, and in the case of a submarine cable where the joints are made in the factory this is of considerable assistance.

* British Patent No. 241972.

The second principle is to arrange that the band of frequencies over which the coefficients are reduced, covers the region of the most important harmonics in speech. Generally the interference/frequency curve rises more or less regularly with frequency. The effect of balancing at one definite frequency is to cause a

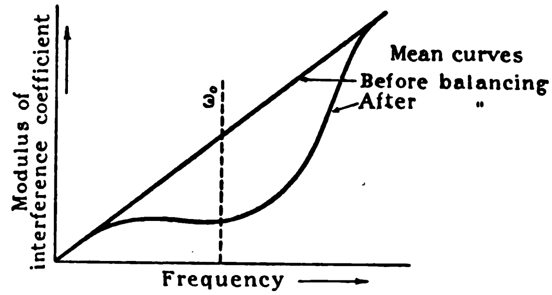

FIG. 34.—Effect of balancing at a single frequency, ω_0.

depression in the curve over a region of which that frequency is the centre. The result is shown in Fig. 34; the curve is first approximately level and then rises steeply. In transmission tests it is found that $\omega = 5\,000$ represents the mean speech frequency, and we may take the region $\omega = 3\,000$ to $\omega = 10\,000$ as containing the most important frequencies. The author has found that balacing at $\omega = 7\,000$ gives good results on total

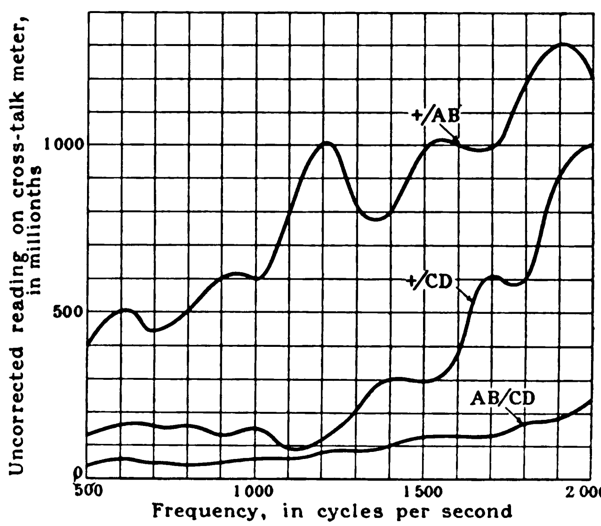

FIG. 35.—Variation of interference with frequency on a continuously loaded cable. $Z_s = 480$ ohms; $Z_p = 190$ ohms.

lengths up to $\alpha l = 1 \cdot 0$. Fig. 35 shows some typical curves, the cross-talk meter readings, which are approximately proportional to the modulus of the interference coefficient, being plotted against frequency.

In the joining up of groups to form longer lengths a difficulty arises if the same frequency be used. Where the resultant has been reduced to a low value at $\omega = 7\,000$, it no longer bears any relation to the rest of the interference/frequency curve, and balancing on these figures may give worse results. The procedure then is to use a different frequency for each stage of

the balancing, e.g. $\omega = 7\,000$ for forming the initial groups, and $\omega = 5\,000$ for joining these, or if three stages are required, then $\omega = 10\,000$, $7\,000$ and $5\,000$ respectively would be suitable.

A point to be noticed is that the interference has to be reduced at both ends, and for a short cable this means that every section has to be tested from both ends and the groups balanced from both ends; on a long cable it would suffice to balance each half from one end only, and join up so that these are the ends in the total length.

In applying equations (62) and (63), the labour is much reduced by constructing charts so that the effective values of the interference coefficients can be read off. For this purpose, the author works from the bridge readings as they stand rather than from the actual interference coefficients. The equations for this case can be written :—

$$g' = (g \cos 2al + \omega c \sin 2al) e^{-2\beta l} \quad . \quad . \quad (92)$$

$$c' = (c \cos 2al - (g/\omega) \sin 2al) e^{-2\beta l} \quad . \quad . \quad (93)$$

If the bridge figures are r ohms and c $\mu\mu$F, then

$$\frac{r'}{10^8} = \left(\frac{r}{10^8} \cos 2al + \frac{\omega c}{10^{12}} \sin 2al\right) e^{-2\beta l} \quad . \quad . \quad (94)$$

$$\frac{c'}{10^{12}} = \left(\frac{c}{10^{12}} \cos 2al - \frac{r}{\omega \times 10^8} \sin 2al\right) e^{-2\beta l}. \quad (95)$$

For $\omega = 7\,000$, these become :—

$$r' = (r \cos 2al + 0{\cdot}7c \sin 2al) e^{-2\beta l} \quad . \quad . \quad (96)$$

$$c' = \left(c \cos 2al - \frac{r}{0{\cdot}7} \sin 2al\right) e^{-2\beta l} \quad . \quad . \quad (97)$$

For a given length $\cos 2al$, $\sin 2al$, $e^{-2\beta l}$ are constants, and the equations are of the form :—

$$r' = Ar + Bc \quad . \quad . \quad . \quad . \quad . \quad . \quad (98)$$

$$c' = Ac - Cr \quad . \quad . \quad . \quad . \quad . \quad . \quad (99)$$

where A, B and C are constants. The corresponding graphs are straight lines and enable the effective values to be read off quite simply. Examples are shown in Figs. 36 and 37. A chart has to be constructed corresponding to each distance, i.e. if five sections are joined to form a group, four charts are required for the cross-talk and four for the overhearing.

An example will help to make the foregoing clearer. The group to be joined up consists of five sections, and we shall consider one quad in each section. The test-results on the sections at $\omega = 7\,000$ are shown in Table 3.

From the known constants of the cable, the following values are calculated :—

Cross-talk, βl per section length $= 0{\cdot}0097$
al per section length $= 0{\cdot}1528$

Overhearing, βl per section length $= 0{\cdot}0114$
al per section length $= 0{\cdot}1786$

TABLE 3.

Section	F		G		H	
	c	r	c	r	c	r

3	− 415	− 70	+ 200	+ 150	+ 210	− 90
4	− 480	− 45	+ 120	− 40	+ 620	+ 190
5	+ 445	+ 80	+ 110	+ 100	+ 80	+ 90

Length of sections $= \frac{1}{2}$ mile.

The equations for obtaining the effective interference coefficients are :—

(a) *Cross-talk.*

(1) Distance $= \frac{1}{2}$ mile (one section length)
$c' = 0{\cdot}930c - 0{\cdot}422r$; $r' = 0{\cdot}930r + 0{\cdot}207c$

(2) Distance $= 1$ mile (two section lengths)
$c' = 0{\cdot}779\,c - 0{\cdot}737r$; $r' = 0{\cdot}779r + 0{\cdot}386c$

(3) Distance $= 1\frac{1}{2}$ miles (three section lengths)
$c' = 0{\cdot}562r - 1{\cdot}062r$; $r' = 0{\cdot}562r + 0{\cdot}520c$

(4) Distance $= 2$ miles (four section lengths)
$c' = 0{\cdot}303c - 1{\cdot}225r$; $r' = 0{\cdot}303r + 0{\cdot}600c$

(b) *Overhearing.*

(1) Distance $= \frac{1}{2}$ mile (one section length)
$c' = 0{\cdot}921c - 0{\cdot}456r$; $r' = 0{\cdot}921r + 0{\cdot}224c$

(2) Distance $= 1$ mile (two section lengths)
$c' = 0{\cdot}746c - 0{\cdot}841r$; $r' = 0{\cdot}746r + 0{\cdot}412c$

(3) Distance $= 1\frac{1}{2}$ miles (three section lengths)
$c' = 0{\cdot}500c - 1{\cdot}117r$; $r' = 0{\cdot}500r + 0{\cdot}547c$

(4) Distance $= 2$ miles (four section lengths)
$c' = 0{\cdot}210c - 1{\cdot}255r$; $r' = 0{\cdot}210r + 0{\cdot}615c$

The charts corresponding to "cross-talk, distance $= \frac{1}{2}$ mile," and "overhearing, distance $= 2$ miles" are

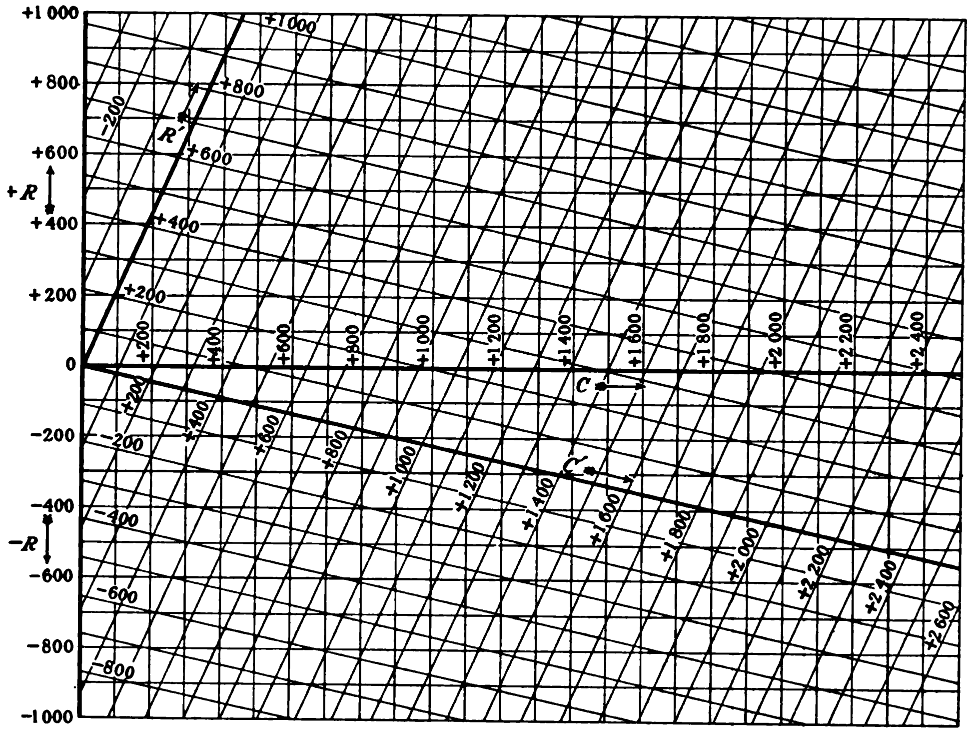

FIG. 36.—Cross-talk. Distance = ½ mile.

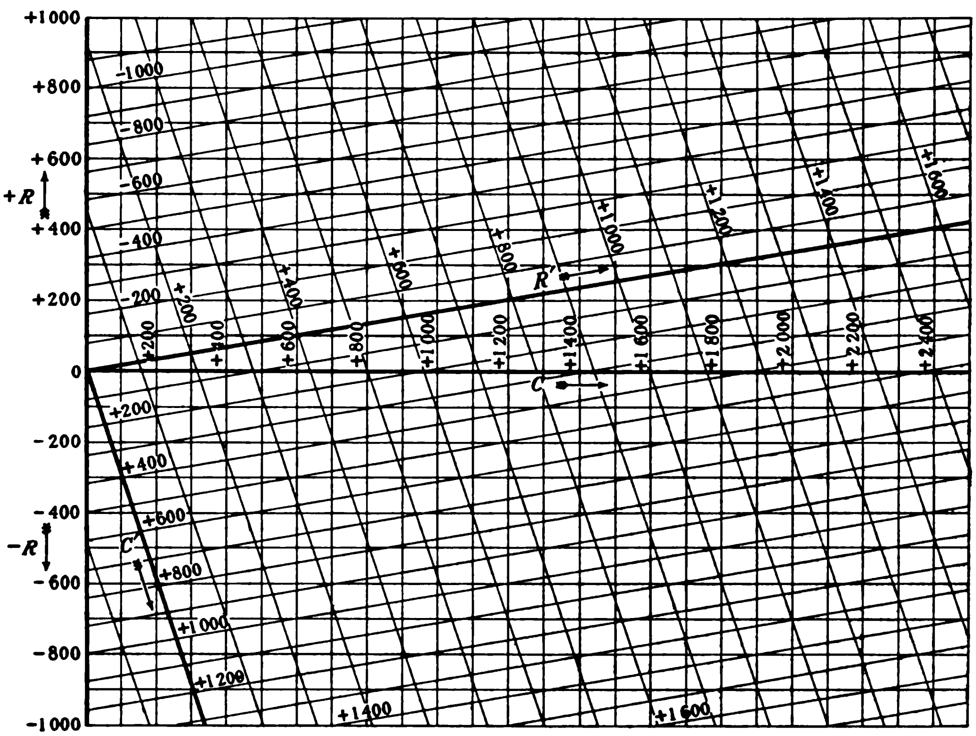

FIG. 37.—Overhearing. Distance = 2 miles.

those given in Figs. 36 and 37. The order of joining up the sections and the crosses in the cores is shown in Table 4, together with the effective values and the resultant totals.

(iii) *Balancing before laying-up*.—The efficacy of the crossing method depends upon the freedom of choice in selecting the quads which are to go together. Before the quads are laid up this choice is much wider, and balancing can be carried out up to the longest length which can be handled by the stranding machine. No difficulty is experienced as regards inductance and resistance unbalances (in a continuously loaded cable). In the case of a cable with paper dielectric, the lead sheath is not put on until after the quads are laid up. Consequently the capacity unbalances cannot be measured in the usual way on the quads before stranding, and, moreover, owing to the damp condition of the paper, ordinary capacity measurements are not possible. The author has found that by using a bridge in which the leakance as well as the capacity are balanced, as described in Section 6 (iii), results are obtained which are comparable with the capacity unbalances after laying up and casing in lead; the extent of agreement depends on the dampness of the dielectric and the amount of crushing the quad receives in the stranding and lead-sheathing processes. The figures, particularly those for the cross-talk, are sufficiently reliable to be used for a preliminary balance, and the method has proved of considerable value.*

(iv) *Balancing by condensers*.—This method has been developed by the firm of Siemens and Halske † in Germany and has been largely used on the coil-loaded cables in that country. In each quad three fixed condensers are connected between the cores so as to equalize the partial capacities, each loading-coil section being treated as a unit. Referring to Section 4A (i), let $p - q = f$, $p + q + \frac{1}{2}u = g$, and $r + s + \frac{1}{2}v = h$. If equal capacities be added between BC and AD, the cross-talk will be altered without affecting the overhearing; if added equally to BC and BD, only g is altered, and if to BD and AD, only h is altered. The required values to be added are the totals as shown in Table 5. It is understood that where the totals are negative, the condensers are inserted in the opposite arms.

The condensers are made up with paper insulation and are sealed into glass tubes; they are placed either in a separate pot or in an enlarged lead sleeve over the joint. Out-of-balance resistance is compensated by inserting small portions of high-resistance wire.

The author is not aware if the condenser method has been used on continuously loaded cables. On account of the shorter wave-length of the loaded core it would require that the condensers be inserted at more frequent intervals if the same degree of compensation is required. As explained in Section 4, on a loaded cable, provided it is suitably terminated, shunt capacity will compensate approximately the self and mutual unbalances as well as the capacity unbalances. The required values for the balancing condensers can be ascertained by measuring each section, not with the distant end free in the usual way, but terminated by a network equivalent to the infinite line.

(v) *Balancing at the ends of the line*.—Both the crossing and the condenser methods involve a considerable amount of work, especially on a long cable, and if the unbalances could be compensated easily by apparatus at the ends only, it would simplify and cheapen the manufacture and laying.

At any particular frequency the unbalance consists of a capacity and leakance. The capacity can be easily compensated, but the leakance is more difficult,

as it is of the order of hundreds of megohms. The main obstacle, however, is that the unbalance varies irregularly with frequency, and thus it is necessary to design a network in which both the capacity and the leakance components vary in some predetermined, irregular way. Networks composed of a series of resonant circuits, each corresponding to a hump in the frequency curve,* have met with partial success, but the reduction in interference is not nearly so complete as can be obtained by balancing along the length of the line. Another objection is that such networks cannot be designed to introduce only just the required out-of-balance impedance; their impedance is commensurate with that of the line, and when placed in shunt across it they lower the transmission efficiency. The same applies to balancing networks in series with the line, with the additional objection that these cannot compensate cross-talk, but only overhearing.

The author desires to express his thanks to the management of Messrs. Siemens Bros. & Co., Ltd., Woolwich, for permission to present this paper.

APPENDIX I.

Star-mesh Conversion.†

In any network, a star of n rays $OA = a$, $OB = b$, $OC = c \ldots ON = n$ (Fig. 38), may be replaced by a

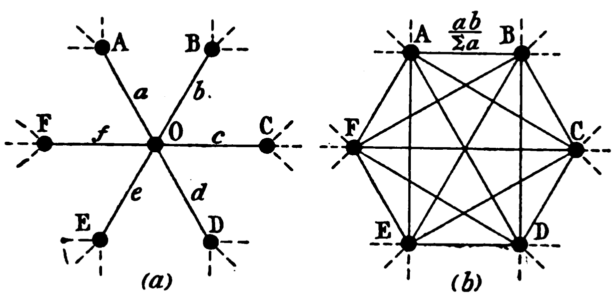

Fig. 38.—Star-mesh transformation.

mesh of $\frac{1}{2}n(n-1)$ conductors joining every pair of the points A, B, C . . . N (O being eliminated) without affecting the rest of the network; then for conductance operators,

$$AB = \frac{ab}{\Sigma a}, \quad BC = \frac{bc}{\Sigma a}, \text{ etc.} \quad . \quad . \quad (100)$$

where $\Sigma a = a + b + c + \ldots n$.

For impedance operators,

$$AB = ab\Sigma\left(\frac{1}{a}\right), \quad BC = bc\Sigma\left(\frac{1}{a}\right), \text{ etc.} \quad . \quad (101)$$

where $$\Sigma\left(\frac{1}{a}\right) = \frac{1}{a} + \frac{1}{b} + \frac{1}{c} + \ldots \frac{1}{n}$$

APPENDIX II.

Transformation of Mutual Impedance.

In Fig. 39 (a) the arms OA, OB are of self-impedance Z_a, Z_b, and there is a mutual impedance m between them. They can be transformed into a star free from mutual impedance * [Fig. 39 (b)] in which the arms are $OC = -m$, $AC = Z_a + m$, $BC = Z_b + m$. This star can again be transformed into a mesh [Fig. 39 (c)] using equation (101).

Then

$$OA = Z_a[1 - (m/Z_b)]$$
$$OB = Z_b[1 - (m/Z_a)]$$
$$AB = Z_a + Z_b + 2m - (Z_a + m)(Z_b + m)/m$$

In terms of admittances, if the arms in Fig. 38 (a) are Y_a and Y_b, then

$$OA = \frac{Y_a}{1 - mY_b}$$
$$OB = \frac{Y_b}{1 - mY_a}$$
$$AB = \frac{mY_aY_b}{m^2Y_aY_b - 1}$$

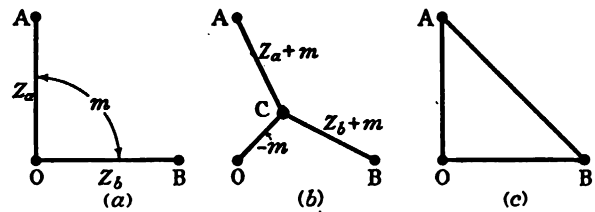

Fig. 39.—Transformation of mutual impedance.

If mY_a, mY_b are small so that their squares can be neglected compared with unity, then

$$\left.\begin{aligned} OA &= Y_a(1 + mY_b) \\ OB &= Y_b(1 + mY_a) \\ AB &= -mY_aY_b \end{aligned}\right\} \quad . \quad . \quad . \quad (102)$$

APPENDIX III.

Comparison between the Summation and Single Frequency Methods of Balancing.

In the simple summation method (A) the joints are so designed as to reduce the algebraic sums of the unbalances due to capacity, inductance and resistance respectively below predetermined limits, which are chosen so that the resulting interference with speech is within a certain value; similarly in the single-frequency method (B) the calculated residual has to be brought down below a definite value. In both cases, the residual R and the interference with speech are related by an equation of the form

$$\Psi_{\text{speech}} = K_1R^2 + K_2 \quad . \quad . \quad . \quad (103)$$

* G. A. Campbell: "Cisoidal Oscillations," *Transactions of the American I.E.E.*, 1911, vol. 30, p. 873. S. Butterworth: *Proceedings of the Physical Society of London*, 1921, vol. 33, p. 314.

and the method is valid only up to the point beyond which the term K_2 becomes excessively great. We shall investigate this relation for a simple case and show that, other things being equal, K_2 depends on the length of the sections in which the balancing is carried out, and it will appear that as the length is increased method (A) breaks down while method (B) can still be successfully applied. It is legitimate to assume that these deductions apply in the general case.

Consider the cross-talk between two similar long circuits of impedance Z_0. Equation (26) gives

$$\Psi = \frac{J^2}{4}Z_0^2 = \frac{F^2}{64}Z_0^2$$

From equation (91),

$$\Psi_{\text{speech}} = \Psi_1 k_1 + \Psi_2 k_2 + \ldots$$
$$= \frac{Z_0^2}{64}(F_1^2 k_1 + F_2^2 k_2 + \ldots) \quad . \quad (104)$$

assuming, as is the case approximately for loaded cables that Z_0 is independent of frequency.

Let there be a capacity unbalance $-B$ at the near end and another A at a short distance l. Then the residual by simple summation is $A - B = R_a$. The actual residual is

$$Ae^{-2\gamma l} - B = A(1 - 2\gamma l) - B \text{ approximately, since } \gamma l \text{ is small}$$
$$= A - B - 2jalA \text{ approximately}$$
$$= A - B - j\lambda\omega, \text{ where } \lambda = 2\sqrt{(LC)}lA.$$
$$\therefore \quad F = j\omega(A - B - j\lambda\omega)$$

and
$$F^2 = \omega^2\{(A - B)^2 + \lambda^2\omega^2\} \text{ in magnitude} \quad (105)$$
$$= \omega^2(R_a^2 + \lambda^2\omega^2) \quad . \quad . \quad . \quad . \quad . \quad (106)$$

$$\therefore \quad \Psi_{\text{speech}} = \frac{Z_0^2}{64}\{R_a^2\Sigma(\omega^2 k) + \lambda^2\Sigma(\omega^4 k)\} \quad . \quad . \quad . \quad (107)$$

In method (B), using a frequency ω_0, the residual is

$$A - B - j\lambda\omega_0 = R_b$$
$$\therefore \quad R_b^2 = (A - B)^2 + \lambda^2\omega_0^2$$

Substituting in (105), we have

$$F^2 = \omega^2\{R_b^2 - \lambda^2(\omega_0^2 - \omega^2)\}$$

$$\therefore \quad \Psi_{\text{speech}} = \frac{Z_0^2}{64}\{R_b^2\Sigma(\omega^2 k) + \lambda^2\Sigma(\omega^4 k) - \lambda^2\omega_0^2\Sigma(\omega^2 k)\} \quad (108)$$

Example.—Let the speech current contain only the three frequencies $\omega = 3\,000$, $5\,000$ and $7\,000$ radians per sec., and assume the corresponding proportions of the total energy to be $k_{3\,000} = \frac{1}{4}$, $k_{5\,000} = \frac{1}{2}$, $k_{7\,000} = \frac{1}{4}$.

Let $A = 1\,000\mu\mu\text{F}$, $b = -800\mu\mu\text{F}$, $Z_0 = 500$ ohms, $a = \omega/20\,000$, $l = 1$ mile.

Then
$$\lambda = 10^{-13}$$
$$\Psi_{3\,000} = 0{\cdot}46 \times 10^{-8}$$
$$\Psi_{5\,000} = 2{\cdot}83 \times 10^{-8}$$
$$\Psi_{7\,000} = 10{\cdot}13 \times 10^{-8}$$

The proportions contributed by the three frequencies to the interference with speech are :—

$$\omega = 3\,000, \ \tfrac{1}{4}(0{\cdot}46 \times 10^{-8}) = 0{\cdot}115 \times 10^{-8}$$
$$\omega = 5\,000, \ \tfrac{1}{2}(2{\cdot}83 \times 10^{-8}) = 1{\cdot}415 \times 10^{-8}$$
$$\omega = 7\,000, \ \tfrac{1}{4}(10{\cdot}13 \times 10^{-8}) = 2{\cdot}532 \times 10^{-8}$$
$$\Psi_{\text{speech}} = \text{total} = 4{\cdot}062 \times 10^{-8}$$

Of this total, the amount independent of the calculated residual in the summation method is $3{\cdot}58 \times 10^{-8}$, and in the single-frequency method is $1{\cdot}49 \times 10^{-8}$. Thus in this case the uncontrolled factor in method (A) is disproportionately great, and therefore the residual is valueless as an indication of the result with speech; whereas in method (B) the uncontrolled factor is still small and the residual is a guide to the actual figure.

It will be observed that there is a greater proportion of the higher frequencies in the induced current than in the original, and a similar effect is obtained with inductance unbalances. It is for this reason that the frequency in method (B) is chosen to be higher than the mean speech frequency.

We may infer that, in general, the limiting factor K_2 in equation (103) will have the same form as the terms independent of the calculated residual in the simple case considered. For any given speech current those involving ω and k are fixed, and the criterion for comparing different cables is, for cross-talk,

$$K_2 \propto Z_0^2 LCl^2\overline{A}^2 \quad . \quad . \quad . \quad . \quad (109)$$

where l is the length of the sections and $\overline{A}$ is the average magnitude of the capacity unbalances.

Let
$$n_c = \frac{\text{unbalanced capacity}}{\text{actual capacity}} = \frac{\overline{A}}{LC}$$

Then
$$K_2 \propto C^2L^2l^4n_c^2 \quad . \quad . \quad . \quad . \quad (110)$$

Similarly for overhearing, which is due principally to self-inductance and capacity unbalances, we obtain

$$K_2 \propto C^2L^2l^4(n_c + n_l)^2 \quad . \quad . \quad . \quad (111)$$

where
$$n_l = \frac{\text{unbalanced inductance}}{\text{actual inductance}}$$

In equations (110) and (111), n_c and n_l represent the quality of the manufacture of the single sections.

DISCUSSION ON

"POWER FACTOR AND TARIFF."*

THE AUTHOR'S REPLY TO THE DISCUSSIONS AT LONDON, MANCHESTER AND BIRMINGHAM.

Mr. E. V. Clark (*in reply*) : I regret that none of those who took part in the discussion on the papers by Mr. Dorey and myself have entered the lists, either in support or in opposition, with regard to my contention that, under a rational tariff, and *ceteris paribus*, of two supply undertakings having equal energy load, the one with the lower power factor should show the better financial returns. This is a point where I seem fundamentally at variance with most of my critics, who appear to imply that power-factor correction by consumers is a natural aim of the undertaking. Mr. Woodhouse, for example, with a two-part tariff speaks quite cheerfully of consumers saving £2 000 and even £6 000 a year by installing apparatus for improving the power factor; whilst Mr. Bennett, with a similar tariff, considers that before long his staff will "convince" all his consumers that correction to about 0·9 power factor is a paying proposition for them. This seems a telling argument against the adequacy of the two-part tariff. Surely his staff are much better employed in convincing non-users of electricity how they may, to their own advantage, augment the gross revenue of the undertaking, than in convincing satisfied users how they may decrease it. While I fully agree with Mr. Kapp that we must have a salesman's tariff and eliminate all accountant's refinements that are found unnecessary, yet I consider it essential that the tariff should accord with the requirements of the accountant to such an extent that each consumer may install whatever apparatus he considers most desirable, without any attempt on the part of the undertaking's engineers to bias for their own ends his judgment as to how his requirements may best be met. If the consumer is to seek advice from the engineers of the supply undertaking, he should know that their only bias will be the inherent one of wanting to sell electricity. Two instances in a contractor's experience will illustrate my point. A client wanted a motor. One of 30 h.p. would have sufficed, but finding that a 50 h.p. motor was not much more expensive, and about as efficient at 30 h.p. load, he installed the larger size in order to have some reserve power. When next the contractor saw him, the client stated that an engineer of the supply undertaking had told him that he had been badly advised, that a 30 h.p. motor would have been a better proposition and that it was wasteful to put in the larger size. Naturally, the contractor was annoyed. In the other case, a small shop was run by a gas engine, fully loaded. A new machine, taking 3 h.p., was bought and electric drive decided on. Prices and efficiencies at 3 h.p. load being obtained for motors of various sizes, a 15 h.p. motor was chosen, in order that on occasions when overtime was required a few machines might be run without using the gas engine. "On applying to the undertaking for a service for a 15 h.p. motor," said the contractor, "I thought it discreet not to mention that the normal load would be only 3 h.p." Now it is quite unnecessary to say that in each case the supply was alternating current. It is unthinkable that a supply engineer should criticize the installation of a 50 h.p. d.c. motor for a 30 h.p. job, particularly in the Australian climate; whilst to persuade a client to install a 15 h.p. d.c. motor for a 3 h.p. load, and thereby take a definite step towards the ultimate supersession of a gas engine, is a thing about which the contractor would boast. In each case, the decision to adopt an electric motor was, as far as the consumer was concerned, entirely independent of the nature of the supply available. The only factors with which he was concerned were the costs of installation and of operation, and the value of convenience, reliability and reserve power. It is solely because the a.c. tariff in force was defective from the accountant's standpoint, that a proceeding quite satisfactory to the undertaking with a d.c. supply should call for criticism on the a.c. mains.

I also regret that no one has ventured to criticize or supplement the figures of my very rough estimate of the running costs of wattless component. I know of no estimate of an authoritative nature of such cost, whether for general use or for a particular case.* It seems highly desirable that the magnitude of such cost should be known with some approximation to accuracy; and I trust that an engineer with access to the records of some undertaking where power factor is a serious matter will collect and publish what information he can on the subject. Various critics have said generally that they consider the importance of lagging current to have been over-rated; but, on the other hand, in the discussion on the late Dr. Kapp's paper on "Improvement of Power Factor" (*Journal I.E.E.*, 1923, vol. 61, p. 111) Mr. Woodhouse said that "A consumer should be prohibited from having a power factor of the order of 0·5 or 0·6"; and though apparently he would arrange the prohibition not by regulation but by tariff, it is evident that he, at least, finds low power factor of serious moment.

Several speakers consider that the two-part tariff meets all reasonable needs; but it fails in that, whilst consumers are encouraged to install correcting devices, they are given no inducement to use them to the best advantage of the undertaking. For example, where condensers and auto-transformer are installed, the wise consumer will, on a two-part tariff, cut them out when his load is less than 75 per cent of his peak, in order to save the transformer losses. Again, synchron-

* Paper by MR. E. V. CLARK (see page 625).

* The late Dr. Kapp (*Journal I.E.E.*, 1923, vol. 61, p. 107 quotes) figures supplied by the Clyde Valley Electric Power Co. estimating that, with an average power factor of 0·72, the increased I^2R losses in generators, transformers, and 11 000-volt mains due to lagging current are 4·85 per cent. Other losses due to lagging current are referred to, but no estimate is given of their magnitude or of the losses in l.t. distributors.

ous and synchronous-induction motors are slightly less efficient with leading power factor than with current in phase, and a shrewd consumer will not overexcite them except at peak load, and then only if he has straight induction motors as well. Only a very small charge and bonus for wattless component are necessary to ensure that the consumer shall gain by phase-advancing as much as the plant he has installed can readily manage. The synchronous motor at 0·95 leading power factor is not more than 1 per cent less efficient than at unity power factor, whilst its wattless component is about 30 per cent of its energy component; and thus a meter bias which rates wattless component at $\frac{1}{20}$th the cost of energy component suffices to make operation at this leading current a paying proposition, whatever the state of the consumer's load.

Turning now to points raised by individual speakers, Mr. Kapp stresses the effect of poor power factor on voltage regulation; but the footnote which he criticizes refers to two consumers who are specified in the text as being neighbours. The voltage regulation of the whole of the system, except beyond the point where the two consumers' mains diverge, is improved by precisely the same amount, no matter which of the two should install the condensers postulated, provided that they are in circuit for the same hours in each case. Diversity factor I take to be $\Sigma P/P_0$, where P is the consumer's peak load, and P_0 is the combined peak load. For simplicity, consider a feeder supplying 10 consumers, each with one motor taking 20 kW at 0·8 power factor at peak load. Then P, the consumer's peak load of energy component, is 20 kW, and Q, the peak load of wattless component, is 15 kVA; ΣP is 200, and ΣQ is 150. If the energy diversity factor is 2, then the peak load P_0 on the feeder is 100 kW. In the unlikely case of its being caused by five motors at full load, the other five being switched off, this peak will have a power factor of 0·8; Q_0, the wattless component on the feeder, will be 75 kVA, and the diversity factor of wattless component will be the same as that of energy. But if, as is probable, peak load on the feeder is due to almost all motors running, with an average of half load on each, then it will have a power factor of about 0·7, and Q_0 will be 100 kVA, so that the diversity factor of wattless component, $\Sigma Q/Q_0$, will be 150/100, or 1·5. In general, it seems that diversity factor of wattless component is bound to be lower than that of energy component in any case where most consumers have their maximum power factors at their peak loads.

Mr. Hart's remedy for poor power factor, namely, to install no motors larger than is necessary, is very hard to enforce; for consumers, like supply undertakings, have to look ahead and install to-day plant suitable for the probable needs of the next few years. Further, where the load a motor is to carry is uncertain, it is far wiser to spend a few pounds more in a motor of ample size, than to risk a possible interruption due to its failure.

Mr. Romero falls into what I believe to be a very general error, in thinking that an annual charge based on kVA of consumer's peak load implies that capital charges on an undertaking are considered to be proportional to kVA and not to kW. This is quite wrong, as kVA's are added vectorially, and not algebraically. Thus, ignoring diversity factor and line losses, if station peak is Q_0 kVA with a phase angle of θ, and a consumer has a peak of Q kVA with a phase angle of ϕ, then this consumer increases the station peak, not by Q kVA, but by $Q \cos (\phi-\theta)$ kVA. Or, to take a specific case, if the station power factor is 0·7, a consumer whose peak is 100 kVA at 0·7 power factor adds 100 kVA and 70 kW to the station peak; while a consumer whose peak is 100 kVA at unity power factor, adds 70 kVA and 100 kW to the station peak. Hence, as far as these two consumers are concerned, it is legitimate to assess annual charges upon consumers' kVA of peak load, if the annual charges on the undertaking depend half on kW and half on kVA. This matter is well worthy of closer study than space allows of here. In this lies the secret of the inconsistency of the kVA charge mentioned in the footnote on page 628. That kVA is not an ideal basis for assessing annual charges is quite certain. It tends to overcharge those whose power factors are appreciably lower than that of the system as a whole, and also those who take a leading current, while it tends to undercharge those whose power factors are somewhat better than that of the system. These conclusions are, however, only arrived at by ignoring diversity factor, and the complexities of the problem are vastly enhanced if one attempts to take this into account, particularly as diversity factor is apt to be much lower for wattless component than for energy component, as I have pointed out above. The concrete case of cost of electricity that Mr. Romero works out seems to me to show the marked superiority of the three-part tariff over the two-part tariff. The former asserts that, on the assumed conditions, two consumers each having a peak load of 100 kW, and each taking 200 000 units per annum, one at 0·5 and the other at 0·9 power factor, are appropriately charged £1 447 and £950 respectively; while the essential argument of the three-part tariff is that of these two, the 0·5 power factor consumer, having the larger bill, is the more profitable to the undertaking and may be freely allowed to continue with his poor power factor as long as he chooses. Under the two-part tariff of £5 plus 0·5d. with which this three-part tariff is strictly comparable, the respective charges upon these two consumers are £1 417 and £972, the difference being £52 less than on the tariff which I advocate. But in view of the remarks of Mr. Woodhouse and Mr. Bennett, it is evident that under a two-part tariff the 0·5 power-factor consumer would be regarded as an unsatisfactory client and a fit subject for persuasion as to the merits of condensers. However, in view of the deficiencies of the kVA charge, I quite agree with Mr. Romero that the above 0·5 power factor consumer would pay an undue annual charge for his supply; though the extent of the overcharge is utterly indeterminate, without some knowledge of the normal power factor of the system. It must, however, be remembered that the case is quite an abnormal one, as it is a peculiar installation which has a power factor as low as 0·5 at peak load. And I should say that an essential requirement of a satisfactory salesman's tariff is that whilst it is reasonably equitable with ordinary consumers, it shall tend to overcharge rather than under-

charge abnormal ones. Mr. Fennell, for example, urges the use of a special tariff for those whose conditions the general tariff does not fit: but this is far more difficult to arrange if the usual tariff charges him too little than if it charges him too much. In the former case the consumer feels he has a genuine grievance. In the latter case he is gratified by a special concession. In general, I think that it is quite safe to say that, despite its defects, the kVA basis for the annual charge departs much less from the accountant's ideal than the kW basis, excepting, first, for consumers taking leading current at peak load, and, secondly, on systems where the power factor is in the neighbourhood of unity.

I regret that the legend attached to the schedule was not explicit. Consumer B, with average power factor of 0·8, nevertheless has the same peak-load power factor, 0·87, as A.

Mr. Howarth expresses the objection many consumers have to any annual charge; and undoubtedly for small consumers, where load factor is low and diversity factor high, a flat rate per unit, requiring but a single meter, has much to recommend it. But it is with consumers such as these that power factor is apt to be excessively poor. For such, the biased meter, set to rate wattless component at about 30 per cent of the cost of energy, i.e. with the two parts set to run 50 per cent fast and slow, should be very suitable, the normal flat rate being reduced 20 or 25 per cent when the change is made to charge per virtual unit. With two consumers, one alongside the station and one 10 miles away, there is of course a difference, both in capital costs and in running costs, in supplying them. Any adjustment of tariff with distance is much more suitably made with a multipart tariff than with a unipart one. In the case in question, the more distant consumer might entail capital charges 50 per cent greater than the nearer, running costs for energy 10 per cent greater, and running costs for wattless component 100 per cent greater. Any adjustment thought desirable can readily be introduced with a three-part tariff. I see no difficulty in answering the question "What does the biased meter measure?" The reply that it measures the total consumption of energy current plus a small percentage of the magnetizing current is probably far more satisfactory to the consumer than any answer that can be devised to the question "What is this power factor that you are bothering me to improve?" And with three-part tariff and biased meter it is only the contractor's salesman who would be troubled with having to answer this latter question.

Mr. Fennell raises the matter of the hour of the consumer's peak load. This introduces the whole question of diversity factor, which is the great stumbling block in any attempt to devise a universal tariff. Except for the difference in diversity factor of energy component and wattless component to which reference was made, the problem is much the same in a.c. and d.c. systems, and consequently was not specifically dealt with in the paper. There is no question but that whatever the form of tariff adopted for general use, those consumers whose load is such as to help to fill up the hollows in the daily or annual load curve are entitled to special concessions. The objection to making such concessions too great or too general is the risk of converting hollows into peaks, and peaks into hollows. The justification of the frequent practice of giving small consumers the choice between a flat rate and a tariff embracing an annual charge rests on the reasonable assumptions that, in general, the small consumer entails negligible cost in transformers and mains restricted to his sole use; and that where load factor is low, diversity factor is high. In advocating a three-part tariff, I certainly do not wish it to be thought that I consider this should be rigidly adhered to by a supply undertaking, to the exclusion of all others. On the contrary, I regard it as suitable for the basic tariff upon which all consumers might elect to be charged if they wished; but a flat tariff—preferably not per B.O.T. unit, but per virtual unit measured by a meter with appropriate bias—based upon a load factor appreciably lower than that of the station, should be offered to small consumers; while, as Mr. Fennell advises, special arrangements should be made, where profitable business may be secured at rates appreciably less than under the normal tariff, with power users whose circumstances are abnormal.

I entirely agree with Mr. Howarth, Mr. Hoseason, and others, that the squirrel-cage induction motor is for the consumer the most reliable and simple piece of electrical apparatus yet invented. My object in advocating a three-part tariff, and in devising a meter which takes wattless current into account to any extent desired, is in order that the supply undertaking may preach the simplicity of the induction motor to those with whom reliability is of prime importance, and the economy of phase correction to those who find cost of power a vital matter, with the full conviction that whatever kind of apparatus is installed, the sale of the electricity it consumes will be a source of adequate profit.

I am much interested to hear from Mr. Hargrove of a case where not only is a sine meter used but, in addition, a direct charge is levied for wattless component at a flat rate per kVA-hour. As he is the only speaker who has given the slightest encouragement to a tariff of this nature, may I invite him to consider my suggestion that the sine meter may be incorporated in the watt-hour meter by giving this a bias in the manner indicated? Not only does this reduce the number of meters required, but it should also simplify the assessment of the penalty in the case of consumers with poor load factor, and overcome any difficulty consumers may find in understanding why units recorded on one meter are priced eight times as much as those recorded on the other. The curves which Mr. Hargrove gives show very clearly the encouragement a tariff of this type gives to improvement of power factor beyond 0·9. If a bonus is allowed for leading wattless component, the curves given for lagging power factor also indicate the charge for leading current, if one reads "Decreased cost per cent" instead of "Increased cost per cent" upon the axis of ordinates. I surmise that the system on which this tariff is used enjoys an average power factor of 0·8 or better; for the tariff as described is much more favourable to consumers with poor power factor than is the more usual two-part tariff. I do not follow the reference to my having taken 0·8 power factor as standard. On the

contrary, my estimate of the cost of wattless component was based on an average power factor of about 0·7, which I took as being reasonable for an undertaking selling alternating current only, and having a lighting load small in comparison with its power load.

I quite agree with Mr. Hall that, as engineers, we should extend our influence towards the improvement of power factor, but would add "where economically justified," since, as pointed out by the late Dr. Kapp, improvement of a system beyond a certain point is not warranted. But just as those who use energy current wastefully must pay for their extravagance in their electricity bills, so should those who use wattless component wastefully; and on ethical grounds there seems to be no reason why supply tariffs should not be such that a demand for wattless current, whether it be used wisely or extravagantly, should be a source of profit to the undertaking. Regarding the matter from a technical standpoint, it is palpably absurd in any one installation to attempt to improve power factor by regarding each motor as an independent culprit, without reference to the others. On the contrary, economy results from overcorrecting such motors as lend themselves to correction, and leaving others alone. Similarly in any large system, the greatest economy will result in general from overcorrecting those installations most suitable for this purpose, and leaving alone those where improvement is not so readily effected. And in view of this fact, which seems to me to be indisputable, it becomes necessary to levy an extra charge on those who do not correct, in order to be able to give to those who overcorrect a rebate greater than would be justified if their installations were considered alone. Naturally, as an aid to a more extensive use of electricity, a progressive undertaking will have a staff of "consumers' engineers," whose main duty is to advise prospective and existing consumers how they may more efficiently make use of electricity. But it must surely hamper such men greatly in seeing matters from the consumer's point of view if they know that elimination of energy waste will react to the benefit of the undertaking only indirectly, whereas elimination of wattless current reacts at once to its pecuniary advantage. In many cases, e.g. replacement of one large motor by several small ones, one may secure a saving in energy at the cost of a poorer power factor, or vice versa. My argument with respect to a consumer's power factor is precisely the same as with the overall efficiency of his installation. Any improvement in either should result in a direct monetary benefit to the consumer, by a reduction in his power bill, and consequently in a slight reduction in the profits of the undertaking. It no more follows from this that an undertaking should deliberately encourage wattless current, than that it should encourage waste of energy. However, I am quite ready to meet Mr. Hall to this extent, regarding the matter from an ethical point of view. A power user may be presumed to know something about mechanical losses; and if he is satisfied to use an inefficient arrangement of plant, the undertaking may not unreasonably consider that he has duly weighed its cost against the capital charges involved in a more efficient lay-out. But the ordinary power user knows little about wattless current, and hence when he uses this extravagantly there is perhaps some onus on the undertaking to point out to him how economy is possible. As regards complication of metering and computing accounts, there is no reason why the biased meter should exceed the ordinary meter in cost by more than a few shillings; and by its use, whether in conjunction with a maximum demand instrument or alone, we may secure, I think, the benefits of an improved form of tariff, with no increase in number, and negligible increase in cost, of the requisite measuring instruments.

DISCUSSION ON

"THE ENGINEER: HIS DUE AND HIS DUTY IN LIFE."*

DUNDEE SUB-CENTRE, AT DUNDEE, 11 FEBRUARY, 1926.

Mr. J. Conway : In the title of the paper the "due" is placed before the "duty," but the author confines his subject mainly to the latter and practically ignores the former. In regard to the finding of engineers, I was very much struck by the statement of the schoolmaster, Dr. Johnston, who had observed that the fact that a boy can repair a bicycle pump, etc., does not necessarily mean that he has engineering ability. I should never have thought that anyone who was not an engineer would have put that on record, and it shows very keen observation. A desire to seek continual employment for the hands in many cases indicates a low level of intelligence, and the boy who likes to "potter" is a doubtful quantity. It appears to me that the right type of boy would find himself, if the profession were given the status which it deserves. A properly trained engineer is of as good a mental calibre as, say, a doctor. He therefore deserves the same status, and one of the reasons why he does not get the same recognition is because he is poorly paid. The engineer will never attain to that status until the qualifications required to practise in the profession are as rigid as those for medicine. At present the return is far too poor for the training and ability demanded. This raises the question of giving advice to others with regard to entering the engineering profession. When a youth is choosing his future career I consider that the question of greater importance is not "What will he like," but "What will he be able to earn a reasonable living at." At first sight this looks far from idealistic, but there is reason in it. For if a boy chooses merely by what he thinks he will like, he may later on be disappointed to find himself in an ill-paid profession in which there is very keen competition even for the minor posts. Certainly he may start out with a liking for his work, and with high ideals, but these will surely fade as a result of poor salaries and lack of opportunity. It is common practice in the electrical world, particularly among the large manufacturing firms, to point to "the interest of the work" or "the experience to be gained" as a sort of makeweight to the lightness of the salary. But it is not everyone who can afford such luxuries, and certainly one cannot live on them. An employer of labour told me some weeks ago that he had now great difficulty in obtaining apprentice mechanical engineers, and that the quality of such as he did obtain was the poorest he had ever known. We all know that nowadays the fitter compares very unfavourably with the municipal dustman, and still more unfavourably with the policeman, both unskilled occupations. I think, therefore, that there is a moral to be drawn from that employer's statement. Make the profession worth while, and we can pick and choose the raw material which may be allowed to enter it. As things stand at present, while our case is not so bad as that of the mechanical engineering industry, yet it appears to me that we must just accept the best material that offers.

Mr. W. Frain : In this exceptionally thoughtful and illuminating statement as to a managing engineer's ideal conduct there seems to be one omission—that of training himself to do always "the first things first," the main feature in which is roughly the allocation of work to others before taking up one's individual task, so that there shall be no time lost in waiting for instructions. I am afraid that the idea of preventing merely unsuitable youths from proceeding with engineering training is impracticable, if only because no one would take the responsibility of deciding upon a compulsory retirement from a selected career. In Dundee, however, there are very successful arrangements for elimination and for guidance of boys of 14, and again of about 16 years of age. A Sub-Committee of the Juvenile Advisory Committee of the Ministry of Labour, with a membership of about 70, visits every school and there endeavours to gauge the boys' qualifications and desires and, if needful, to place them in employment. Another Sub-Committee, along with representatives of employers and of trades unions, visits regularly the continuation schools and advises the boys. Lads observed there to be making good are selected for being brought up to staff jobs. There are, in addition, After-care Sub-Committees, industrial and moral. I agree that engineers have not taken much part hitherto in public life. I am confident that a welcome awaits them. During the past few years in the Dundee City Council, out of, say, 50 men, 5 have been associated with engineering, and their opinions on cognate matters have been much valued, and their help has been greatly used.

[The author's reply to this discussion will be found on page 884.]

WESTERN CENTRE, AT CARDIFF, 1 MARCH, 1926.

Mr. C. T. Allan : The quality of the paper itself and the amount of discussion it has elicited will, I hope, make it the forerunner of others upon the same subject. The engineer's training necessitates longer hours and more exacting work and his average salary is less than in the other professions, and by discussing this subject as the author has done we are increasing the status of the engineer. Perhaps if we chose our assistants purely by Dr. Johnston's method we might not always

* Paper by Mr. T. Carter (see page 193).

obtain the right article. A very necessary requirement for the pupil is common sense. A man may have a mathematical brain, but this does not signify that he can handle men or a large business. The young man who has done comparatively poorly at college usually realizes his shortcomings, takes his work seriously, plods on and frequently in the end passes the more brilliant theorist. In other words "doggedness does it." Of all the methods of training the potential engineer, the college, sandwiched with the works, is in my opinion the quickest and best system. Of the older systems, it is difficult to decide whether it is better to send a young fellow straight from school to college and afterwards to a works, or to a works first and college afterwards. The former method makes it easier for a youth to pass the examination, unless in the latter case he keeps himself informed by evening classes. At all events the oldest method of all, by which an apprentice worked at his craft all day and at his books and evening classes most of the night, was far harder training than the other two methods, it separated out the triers and stayers and certainly produced industrious men, very many of whom, at this moment, hold leading positions; but in all three cases the man with the trained brain has the advantage over the ordinary craftsman. This, coupled with common sense and the art of getting on with his colleagues, learnt at the works, will help a young engineer eventually to reach the top, where we are sometimes told there are many vacancies but few to fill them. The training of marine engineers is a good example of head-and-hand training. A great number of them are now engaged in electrical work, especially in power stations. Their training and work call for quick decisions and self-reliance in times of trouble. They do not wait to ask what to do and how to do it, but do it. Engineers, as the author says, have not taken enough part hitherto in public life, and when one considers that the great engineering projects discussed and legislated for in Parliament, and discussed and voted upon in municipal life by men who are not engineers, one comes to the conclusion that if the engineer will put aside his dread of publicity, train himself for debate and take part in public life, the recognition of his status will be assured.

Prof. F. Bacon: The author pleads especially for consideration of the problem of the finding of real engineers to be trained. I do not dispute his contention that the finding of engineers to train is far more important than the finding of methods of training them, but I remain sceptical as to whether it is possible, or even desirable, to formulate rigid systems of selection at an early age. Reference has been made to tests of intelligence and vocational tests. The only people competent to express an opinion on their value are those who have had opportunities to impose such tests on a number of boys whose subsequent development could be watched. I therefore feel inclined to attach much significance to Mr. A. P. M. Fleming's statement on page 222 to the effect that he did not think there would be much help forthcoming from intelligence tests and the work generally of the psychologists, although one appreciates the attempt made to solve the problem on scientific lines. I also doubt very much whether it is either fair or wise to expect headmasters to determine who should be pushed into, or held back from, the engineering profession. Progressive weeding out from a broad basis of entry is the secret of the Admiralty system of training dockyard apprentices which had achieved such notable results during the last three-quarters of a century. I went to Belgium and Luxembourg last autumn and was interested to observe that those countries select their engineers by methods which involve drastic weeding out, not previous to, but during the process of specialized training. I was informed that about 450 students enter the University of Liége every year to study engineering and mining. The examinations at the end of the first year cut down the number to, say, 120. Further reductions follow at the end of the second and third years, until eventually only about 50 succeed in graduating at the end of 4 or 5 years. Greater strictness in limiting the number of young men who start training to be engineers is only to be desired in so far as it will deflect unsuitable candidates to other callings. It would be a positive misfortune to deter able young men from following such courses simply because the engineering profession might not be able to absorb them. I am strongly of opinion that an engineer's training ought to be regarded as a fine educational equipment for a variety of industrial occupations. The subjects taken at college are vastly superior to many of the miscellaneous combinations of courses taken by those graduating at provincial universities, and a year or two of workshop training ought to prove a valuable asset in almost any walk of life. An overflow from the engineering profession into other callings is something to cultivate rather than avoid, as its consequences should be beneficial both to the community and to the profession. In regard to economics, the need for the study of which has been pointed out, at the Swansea University College a public accountant is voluntarily giving a course on what he calls "the theory of accounts and factory costing," which is being followed with keen interest by the students and staff. The accountant's point of view naturally has great influence with boards of directors, and for this and other reasons it is most desirable that the engineering student should come in contact with it at an early stage in his career.

Mr. H. D. Madden: I should like to associate myself with the general trend of Mr. Allan's remarks. I am in accord with the point made in the paper as to the personal bearing and characteristics of the budding engineer. Administrative engineering training is highly important, and in this connection I favour the public schoolboy, who has learned discipline, knows his place, and has the faculty of earning the friendliness of the workmen, thus securing their co-operation. When he has had some workshop experience he should be sent to college, as by this time he will be more fitted to understand the lectures. Normally a boy does not develop until he is 22 or 23. I am a strong supporter of the Cardiff Technical College, but that institution was not meant to be a machine for turning out engineers by the hundred every year, whether suitable or not. In my opinion, some boys go there who are too young for technical training; they should rather be learning

English and the classics, etc. The time for technological teaching is after the age of 16, when the mind can absorb it intelligibly and intelligently. I have had something to do with the training of engineers for my own branch of the profession. It has taken three years to evolve a scheme of examinations for the different sections, and my remarks are based upon that experience. Some young fellows have a natural aptitude and instinct for research and investigation; these are born engineers.

Mr. H. S. Thomas: The wise man is never too old to learn, and the paper will bear reading again and again. With regard to what Mr. Madden has said as to taking youths into the workshop who want to be engineers, what is more fascinating than watching a blacksmith at his forge? I fully agree with Mr. Madden in respect of putting youths into the works at the outset, in preference to sending them to college first. The handling of men, the study of human nature, is perhaps as important an item as any other in the education of an engineer. I feel that much time has been devoted to stating how an engineer should be educated, but the reference to the necessity of first catching the hare before one can have hare-soup is surely closely analogous to first taking care of having the necessary ingredients for making a young engineer; and when one sees the diminishing birth rate and takes cognizance of the utter disregard paid to the selection of one's life partner, one is struck with the idea that perhaps we begin at the wrong end, and that selection on eugenic principles might be a proper subject for due consideration by the committees who have in hand the matter of the training of engineers. Perhaps, however, this aspect of the subject has already received consideration in the proper quarters.

Mr. P. J. Plevin: I feel that the professional engineer (as distinct from the operative engineer) suffers from the fact that there exists no controlling authority whose license would establish his status. The legal and medical professions form "close" corporations, no members being allowed to practise without licence from their respective associations, which licence is not granted unless the applicant has the necessary professional qualifications. The technicalities of these professions are little known to the layman, who usually takes no interest in them unless he happens to be ill or needs legal advice. Moreover, even though a layman may possess a knowledge of medicine, he would risk a charge of manslaughter were the exercise of his knowledge to lead to results unfortunate for the patient. Similarly, many of the lawyer's functions are such that their performance by a layman is illegal. The profession of engineering, on the contrary, suffers by comparison in that a considerable knowledge of its principles and practice is frequently acquired, and can be exercised without legal risk, by persons who are not engineers by training or profession. When such persons are users of engineering apparatus it is difficult to find any reasonable objection to this condition, since a good workman must be familiar with his tools, and must be able to judge of their suitability for his purposes. None the less, the condition entails on the profession a disability which is not incidental to those of law and medicine, and which constitutes a grave disadvantage to its members. It is, of course, not to be expected that inherent disabilities such as this could be overcome as a direct result of the introduction of a licensing system, but there is no doubt that a system of the kind would benefit the public, in that the employment of a licensed engineer would ensure competent service, and would also help the qualified engineer by improving his status. The science or engineering diploma of a university is recognized by the engineering institutions as exempting candidates for membership from examination, and such a diploma might well form one of the qualifications for licence. Sound practical experience and good character would form other qualifications. Practical experience is, perhaps, a factor even more important than technical qualification, but it takes many years to acquire, and the engineer may reach a mature age before he can expect to obtain his licence and reap financial benefit from the money expended on his training. There is thus all the more reason, if he has ability and is industrious, that he should then have reasonable prospect of a competency. At the present time, on the contrary, there is no profession in which the return on money invested in training is more slow and precarious than that of engineering, and some action to improve its status, especially in respect of remuneration, is urgently needed. When a user of machinery buys a new tool he is guided in his selection by his past experience of the performance of different designs and makes, and selects that which has proved most suitable. If the tool is required for a new purpose of which he has no experience, he will, if he is wise, select one which bears the "hall-mark" of a first-class maker, even though it may be more costly. When he selects an engineer he has little but his faculty of discrimination to guide him, since he cannot assess merit by the criterion of personal experience, and the properly qualified engineer, as things are now, has no generally recognized hall-mark by which he can be identified. If the engineer possessed a hall-mark such as a licence, the task of selection would be simplified, since choice would be confined to licensees. Such a limitation would enhance the status of the properly qualified man, and, as a consequence, his remuneration.

Mr. J. R. Morgan: I have already served an apprenticeship before entering on a college course and I think the arrangement very advantageous in that the student can the more easily correlate theory and practice. First and foremost, the engineer should be a practical man and the possessor of sound common sense. The value of a college course lies not so much in the theoretical knowledge obtained, as in the confidence which it instills in the student, and the ability to apply this knowledge successfully to problems which present themselves in the course of a day's work.

Mr. W. Nairn: There is one duty of the engineer which does not receive the attention which it deserves, and that is the duty of looking after his health. Many engineers work too long hours and smoke too much, with the result that their constitutions are gradually undermined and they thus become unfitted for the calm consideration of labour problems and engineering emergencies. The author refers to the duty of culti-

vating courtesy and humour; both these qualities come naturally to the healthy man.

Mr. S. B. Haslam: I am altogether in agreement with Mr. Madden as to the value of a public school training. It is an old saying that no man can command unless he can be commanded, and the discipline a boy receives at a public school, not only from those in authority, but also from the other boys, will serve him well throughout the whole of his life; it can be summed up in the expression "playing the game." I am very interested in the remarks that have been made as to the specialized efforts being carried out by certain headmasters with the object of discovering the trend of a boy's mentality while at school, but I would go even farther and suggest that it is quite possible to find out very much earlier in life whether boys have engineering brains. Motor-cars, motor-cycles, and even Meccano sets could be used with this object. The question of the rotation of the practical and theoretical training is always a controversial one. I quite agree with Mr. Madden that it is desirable for the practical side to come first, and that the "sandwich" system is the ideal one. It makes the theoretical side much easier if the student knows, from his practical experience, what the theorizing is about. The late Mr. T. Hurry Riches, one of the leading experts in technical education of his day, was very emphatic upon this point. Although I sympathize with the diploma-of-admission idea, I do not think it is possible in our profession. There is no profession in the world which offers such an opportunity to what I might term, for want of a better expression, the "rankers." Ordinary technical education that is available both in evening classes and in the "sandwich" course, opens up the highest posts in the profession in a way that cannot be equalled in any other profession, and it must not be forgotten that some of the leading engineers of the world would never have got into the profession at all if they had had to sit for an entrance diploma.

Mr. W. Cleaver: Although I have as much admiration as anyone for the real born practical engineer of the old school, there is very little excuse for these to-day. With the existing facilities for gaining technical knowledge at colleges and universities, every young engineer should be well equipped with the kind of theoretical training which, in combination with the still unavoidable (and one may almost say the "primary requisite") practical training, makes the successful engineer of to-day. Trouble is, however, in my opinion usually experienced through too much cramming on the one hand, and on the other hand the unattractive way in which theoretical knowledge is usually taught in most colleges. The high-sounding terms and phrases, used generally without any clear or analogous explanation, more often than not frighten the average student at the commencement, just when it is most necessary to interest him; and in that sense I think it would be well if many of the engineering professors, lecturers, etc., would read and digest the preface to the first edition of Trautwine's "Civil Engineer's Pocket Book." In my opinion the principle inculcated somewhat concisely in that preface still holds good, and is deserving of wider application and repetition. I quite agree with the author in his remarks in regard to the necessity of impressing on all students the necessity of acquiring self-confidence, and in fact the advisability of sometimes taking risks, so long as any more or less indeterminate work undertaken is always based on the consciousness of sound knowledge of principles.

Mr. V. Harrison: I consider the "sandwich" system of training to be the ideal one, but before youths are permitted to enter the profession they should be called upon to submit to an examination, the nature of which should be decided upon by the engineering profession. This would serve to eliminate at the outset many who have no aptitude for the profession. A safe guide to a boy's bent is enthusiasm; if he is enthusiastic about his work it will carry him far.

Mr. J. W. Burr: One reason why engineers are not taken at their true value is that they are too prone to depreciate themselves. If engineers have need for a religion it is set down on page 193: "This, then, is a proper life: a constant giving and receiving, a perpetual interchange of services, ideas, and commodities, with an unfailing consideration of our neighbour's good as well as of our own, and a constant recollection that those who forget their common obligations, and merely demand their own due without caring what happens to others, are the slayers of the nation's soul."

Prof. G. Knox: I am entirely in agreement with the author when he emphasizes the fundamental principles that go to the formation of character, so essential to success, in the widest sense of that term. It is true that knowledge and the ability to apply it may, without character, be a danger instead of a blessing. It is in this respect that teachers can be helpful in shaping the future of embryonic engineers in their preparatory, vocational and technical training. It cannot, however, be too often stated that the teaching of science can be adapted to the formation of character as well as in the case of classical training. Mr. Gregory's admirable work "Discovery" may be quoted in this respect. He says: "Do you wish education to cultivate supreme regard for truth? Then let it include the study of Nature, for in dealing with her every false coin is inexorably nailed to the counter. Do you wish to create a sense of moral responsibility? Then learn from Nature that every act has a consequence and every sin a penalty. Is a habit of mind required which will not be deceived by the noisy huckster of sensational statements? Then give attention to training in scientific method, by which a critical faculty is developed that enables fact to be distinguished from fable and is cautious in arriving at conclusions. Do you believe in the dignity of work and the duty of self-sacrifice? Then turn to science which demands devoted labour for the benefit of others. Are satisfaction with the superficial and a desire for continuous excitement to be the characteristics of the new generations? If not, see that interest is aroused in the nobler views of life opened by scientific knowledge. Regard for veracity, patience, logical thought, responsibility, discipline and original work are all taught by the study of science, and those attributes are as desirable in every one of us as in the investigator whose life is an exemplar of them." The modern idea of all education is based on the fact that human (or social) progress is mental progress, and consists in the preparation of the in-

dividual for an understanding of and willing co-operation in the world's affairs. But, according to Earl (A. J.) Balfour, "science is the great instrument of social change—all the greater because its object is not change —and its silent appropriation of this dominating function amid the din of political and religious strife is the most vital of all the revolutions which have marked the development of modern civilization," and "the scientist has his hand on the throttle valve of this instrument of social change." In the selection of the potential engineer much may be done by intelligence and vocational tests to overcome the haphazard choice, whether from "birth" or "accident," but in most cases wider experiments are necessary to enable the student to make his final choice. It is no uncommon thing for students (from public and other schools) entering technical colleges to be trained as engineers to be without the slighest understanding regarding the phase of engineering for which they are best adapted. As an example of what frequently happens, three applicants for entry in the chemical engineering course at the South Wales School of Mines gave as the reason for their choice that chemistry was the only practical subject taught in their respective schools. On being offered and accepting a few weeks' experience in engineering works they all decided that they would prefer to be mechanical or electrical engineers. They were then given an opportunity of spending a few weeks underground at a colliery and two of them decided to be mining engineers; the third hesitated between mining and electrical engineering, but chose the latter owing to objections which his parents had to his taking up mining engineering as a profession. All three have done well in their educational training and show signs of becoming successful engineers. They are also very grateful for the advice tendered and the opportunities granted them to choose careers which interested them more than the one originally chosen. Having determined that the youth is going to be an engineer, his course of training becomes the next consideration, and here again care must be taken to distinguish between the two types of apprenticeship, because the career of an apprentice differs fundamentally from that of a "pupil," in that skilled handicraft rather than proficiency of brain power forms its basis. This must not, however, be taken to imply that the embryonic skilled craftsman must necessarily be of lower mental calibre than the pupil—although many of them may be —but it makes it essential that provision be made for the transfer of the apprentice to the pupil class where the former shows the necessary ability to profit by it. There is a large measure of agreement to-day among both industrialists and technologists in accepting the sandwich system as the most suitable method of training youths to fill official posts in industry, where practical experience combined with technical training is required. When compared with the college as post-works training, or the works as post-college training, the sandwich system has many advantages: the pupil has no break in his educational career and therefore does not forget how to learn or what he has already learned. His general knowledge of workshop appliances makes it easier to instruct the pupil in technical processes, and the work becomes more interesting. The pupil obtains all the practical and humanistic value attached to mixing with his fellow workmen. This establishes human values in his mind and enables him to determine accurately the value and quality of work done. In the later years of pupilage in passing through the official departments he learns the value of order and discipline, and in alternating school periods is taking an active part in the management of his own students' association. The pupil is also advised how by tact and patience he can obtain the knowledge gained from experience of those with whom he associated when employed at the works. He thus acquires a knowledge of character and human understanding which assists in developing that executive ability so necessary and yet so often lacking in engineers. He is also encouraged to question the solution propounded to every problem, and not to take anything for granted without inquiry. He is thus taught that self-reliance is essential before he can accomplish self-direction, and that both are essential in the cultivation of initiative, without which he could never be trusted with large responsibilities. I quite agree with the author that to memorize results is useless as training. A college is a place in which to learn fundamental principles and accuracy in thinking, working, observing and classifying, and not to acquire merely purely technical details. It is the duty of the college to provide the student with an intellectual equipment which, with the aid of experience, as he advances in his profession, will become more and more useful to him, rather than provide him with the details of present-day practice which very soon get out of date. To obtain the best results from any scheme of educational training, contact with the industry and the closest possible co-operation between the college and the industry of the district are absolutely essential.

Mr. C. G. Bevan: With regard to the finding of engineers, the profession of a youth is generally settled by economic causes in connection with his family, and if he has common sense and a trained character he will be a success in any profession irrespective of his bent. Otherwise how would recruits be obtained for professions such as "dental surgery," which cannot of its nature be attractive? Personally I consider that engineering loses fewer of its born members than any other profession; the entrance to the engineering profession is so wide that more undesirable recruits are gained than good men rejected. Who is to be made responsible for their rejection? With a full-time student who has come from a secondary or public school, it is possible that, even if admitted, his performance during the first year's course may be sufficient indication to himself or his parents as to whether or not he has chosen wisely. A technical college, however, usually has to deal with young men who have already chosen their vocation and are definitely apprenticed. It is obvious that those responsible for their training could often give excellent advice on the interchange of particular youths in their selected spheres, but I cannot regard the possibility as being in any way practicable. We can hardly do more than advise a student as to which branch of the profession he should aim for—provided he has such a choice. Referring now to section (6) of the paper, since the world we live in is so highly dependent on the engineer and his products, it certainly is strange that he takes so little

part in public affairs, especially when one notes the similarity of capital and labour, and heat and energy, or taxation for wasteful relief or excessive interest with a wattless current. I can imagine no one whose opinion on everyday problems would be of more weight than that of a charge engineer of strong and sympathetic character. His knowledge of costs and output, handling of men, plant and material, and accurate and quick decision in times of emergency should be of the utmost use to a nation.

Mr. T. Stretton: In his opening remarks the author has, with admirable outspokenness, recorded opinions and ideas which many people hold but have not the courage to voice. If it were only possible to put into actual operation a law whereby the fittest to live were allowed to survive, what a much more efficient race of people we should be. However, as it is useless to strive after impossibilities we must make the best of the world as it is. Under section (3) the author stresses the necessity of selecting children for the engineering profession at an early age, and with this I agree, but he goes on to suggest that this selection should be part of the duty of a teacher. With this I entirely disagree. My own experience teaches me that the natural propensities of a child towards any particular sphere of activity are much more apparent to the parents than to the teacher, and, therefore, the parents are in the best position to decide on the proper sphere for their children. Mistakes must be made, but I believe they are made less frequently by parents than by teachers, and naturally so. Under section (4) I should have expected the author to lay stress on the vital necessity of learning to speak in public as part and parcel of the training of an engineer. That it is a vital necessity no one will dispute, but sufficient encouragement and opportunities are still not given to the young engineer. Matters are certainly improving in this direction, but that the engineer is not found to any great extent in public life is, in my opinion, due to his inability to voice his ideas in public. Has an engineer been Prime Minister of this country? I think not, and the only possible reason is the one I have stated—there can be no question of his ability to fill that high office with credit to himself and to his profession. A question we must ask ourselves in connection with the training of an engineer is: Are we becoming too specialized? It is agreed that, as regards early education, the ideal is a system arranged to suit the special requirements of each individual, but I believe that the specialized pupil is apt to be turned out too highly insulated for the current of everyday life. Take our engineering institutions and associations—their name is legion, and they are multiplying daily without being fruitful. To those young engineers who may wish to extend their knowledge by belonging to more than one specialized institution, the gates are closed owing to the expense entailed. Why should there not be one great engineering institution with sections devoted to the various branches of engineering? A moderate subscription and an enormous membership would enable such an institution to raise the status of an engineer to at least that of other professions, which have far less justification for existence than that of the engineer to whom the progress of the world is mainly due. There would result a far greater interchange of ideas amongst the members of the various sections, and I believe this would be of inestimable benefit to the young engineer as well as to the old.

Mr. W. Roberts: One aspect of the paper which is of very great importance, but is in these days insufficiently stressed, is the fact that there is no right without a corresponding responsibility. The whole trend of legislation for the past 25 years has been to do things for the individual without exacting anything in return, and an engineer who is by nature fitted to see the essential fallacy of perpetual motion should be the type of man to appreciate that, just as it is impossible to obtain output without input, so it is impossible to expect a well-balanced individual when all is taken and nothing given. The community demands an equal proportion of impression and expression, and looked at from this point of view the engineer should be more fitted to take a greater part in public work than he has done up to the present.

The Author's Reply to the Discussions at Dundee and Cardiff.

Mr. T. Carter (*in reply*): These last two discussions follow largely the same lines as the earlier five already replied to; and I would say here, as before, that if I do not specifically mention the name of every contributor, or deal individually with all the points that were raised, I hope it will at least be found that I have so caught the essential spirit of the discussions that my reply is adequate. Some parts of the paper were again more commented on than others, but there is scarcely any part that was not referred to in some way. Thus further evidence is afforded of the real place that the whole subject has in the common thought of engineers, perhaps mostly unexpressed in words; and once more I suggest that the Engineering Joint Council, or, failing that body, the several engineering Institutions, might well examine very closely the question of how to use our human resources adequately. Mr. Stretton suggested the possibility of one great engineering Institution with a section for each branch of engineering; I am heartily with him there. The Engineering Joint Council is a possible nucleus of the Council of the Institution of British Engineers, which is the body that Mr. Stretton wishes to see established. At present, according to Article 4 of its Constitution, the Engineering Joint Council may not initiate proposals, and is only an advisory body without executive powers; but, just as not very long ago the existence of even this link between the constituent Institutions might have been thought impossible, so it may not be very long before some closer union is achieved. The present Institutions would be the sections, each having its own Council with executive powers limited only by the constitution of the general body; and the general body would take care of the interests of the whole profession of engineering. One of the important questions with which it would doubtless deal is that of status, to which so many

speakers referred in the discussions. The status of a profession in the eyes of the community must always depend on the general effect of the profession's activities. It is obvious, for example, that members of the Institution of British Burglars, were there such a body, would not be greatly cherished by the community, except so far as the occasional provision of food (plain but wholesome), clothes (adequate for covering but not made to measure), and shelter (in a place that is weatherproof but terribly dreary), might be described as cherishing them. Height of regard is commensurate with extent of proved service; and on no other foundation can it in the end be built up. Even so, it seems to be necessary to exert organized effort to secure a proper return for services rendered; there are not many people who eagerly rush to pay an account before it is sent in. So, surely, the Institution of British Engineers could well do for engineers what the General Medical Council does for doctors. In order "to enable persons requiring medical aid to distinguish qualified from unqualified medical practitioners," the General Medical Council of Medical Education and Registration was set up under the Medical Act of 1858, and thus both the scientific and—shall I say?—the industrial interests of the profession are within its province. Similarly, in the legal profession there are the General Council of the Bar and the Council of Legal Education for barristers, the one having executive powers to deal with all matters affecting the profession, and the other superintending the education and examination of students; the Law Society for solicitors, controlling the education and examination of articled clerks and the admission of solicitors in England and Wales; and other corresponding bodies in Scotland and in Ireland. So a General Engineering Council might weld all British engineers into one Institution, and might confirm the status they had built up for themselves and secure the rights they had acquired because of their services to their fellows. Education is already seen to by the individual Institutions; but co-ordination of education by the General Engineering Council would doubtless be valuable. Registration of engineers, corresponding to the other part of the duties of the General Medical Council, has not been widely undertaken, though some sections, such as the electrical contractors, have already established it for themselves. I take it that the General Engineering Council would be bound to see to that; and here I must mention a notable attempt to put the proposal for the registration of engineers into words, namely, the Bill drafted, if my information is correct, by the Society of Technical Engineers, and introduced into Parliament on the 29th April, "to provide for the registration of and to regulate the qualifications of engineers." Whether or no registration comes in such a way as the Bill suggests, it would seem to be one of the next great steps in engineering politics; and the advantage of the Bill is, if no more, that it gives us something concrete to discuss. It will be seen by those who refer to it that it contemplates the setting up of a "General Council of Engineering" having the duties indicated in its title. I would hope that the General Engineering Council, which I have suggested as the unifying body for all the engineering Institutions, would be allowed to go further, and would be endowed with power to deal with and take action on all matters affecting engineers. Whatever its ultimate fate, the Bill now before Parliament may become a lasting landmark in the history of the profession.

It is largely because of what may be called the unestablished position of the profession that engineers have been too feeble a force in shaping the course of public life; their possibilities of individual and corporate usefulness do not come naturally to the public mind. As I write, I have at my side a copy of *Engineering* for the 9th July, the leading article in which, dealing with industrial statistics, points out that the Committee formed some months ago to collect and publish information about manufacturing operations "included employers of labour, trade union leaders, and experts on economics, accountancy, and law," and then makes the following useful comment: "Curiously enough, or perhaps we should say characteristically, no provision appears to have been made for the representation of the technical personnel, which by position and experience is particularly well qualified to deal with the questions involved. The opinion, long prevalent in the country, that the conclusions of the scientific and technical expert should be given to the public solely at second-hand, through men having what Mr. Webb has called characteristics suited to government, dies hard." Characteristics suited to government are far more acquired than inborn; and men will not have them until they are allowed to train themselves into the proper habit by practice. For a body so vital to civilization as the whole body of engineers to have so little a part in the counsels of the nation is an anomaly that must be corrected; and an established position, however attained, is certainly one of the first requisites, if not the very first. I am glad that Mr. Stretton specifically mentioned the value of learning to speak in public, which was implied to some extent, but not definitely enough expressed, in what I said in the paper about the necessity for the accurate use of words; it has an important bearing on the whole question of public influence, and it would help to counteract the tendency to self-depreciation deplored by Mr. Burr. My last word here on this great subject of the establishment of the profession will be that the very variety of personalities included under the general term "engineer" will perhaps make it immensely difficult to define the boundaries of engineering; but, particularly in the view of engineers, difficulties exist only to be overcome.

Recalling, in passing, Mr. Thomas's interesting but, I fear, very controversial eugenic suggestion, I must now turn to other matters. Difference of opinion on the age at which it is possible to ascertain the bent of a human being, and on the agency or agent through which or whom it is to be ascertained, leaves untouched what seems to me to be general agreement on the advisability of somehow ascertaining it. There seems to be much distrust of the head master or the teacher as the agent; and here I can only express again my view that while many teachers at present have no inkling of how to make the discovery, many parents have just as little, and both will need to realize the problem as they do not now before they can co-operate with each other. That is what I intended to suggest in the paper;

not that one or the other should decide alone, but that all the results of observation, from the very different points of view of parent and teacher, should be used for the good of the persons observed, be they infants, youths, or older men. Prof. Bacon shares Mr. Fleming's fear that we shall not get very much help from the schoolmasters; but I regard his objection quite frankly as one that will be found to be invalid when we have gained more experience. In sorting coloured wools, we begin with a general division of the bulk into a few large classes, and it is not until we become quite expert that we can distinguish the finest gradations of shades. The analogy is far from perfect, but it has some bearing; let us begin to classify broadly, and see whether finer distinctions will not soon be evident. To question whether a thing can be done is the way to prevent its being done; but that is not a scientific attitude. Philosophic doubt may lead to so nice a balance of possible choices that the doubter is paralysed; scientific doubt is a stimulus to discovery and achievement. Look, for example, at the work of the Dundee Sub-Committee described by Mr. Frain; look at the work being done by Dr. Johnston at Highgate; and do not imagine that there is anything in the atmosphere of Dundee or of Highgate that makes miracles possible in either place. Could any miracle happen in unromantic Dundee? The difference is (and perhaps, after all, this is a miracle) that people are found there who not only have seen a need and made a resolution about how to deal with it, but have carried out their resolution and begun to meet the need.

Here is a fable of "The Hill," told by Laura E. Richards: "I cannot walk up this hill," said the little boy. "I cannot possibly do it. What will become of me? I must stay here all my life, at the foot of the hill: it is too terrible!" "That is a pity!" said his sister. "But look, little boy! I have found such a pleasant thing to play. Take a step, and see how clear a footprint you can make in the dust. Look at mine! Every single line in my foot is printed clear. Now, do you try, and see if you can do as well!" The little boy took a step. "Mine is just as clear!" he said. "Do you think so?" said his sister. "See mine, again here! I tread harder than you, because I am heavier, and so the print is deeper. Try again." "*Now* mine is just as deep!" cried the little boy. "See here, and here, and here, they are just as deep as they can be." "Yes, that is all very well," said his sister; "but now it is my turn; let me try again, and we shall see." They kept on, step by step, matching their footprints, and laughing to see the grey dust puff up between their bare toes. By and by the little boy looked up. "Why!" he said, "we are at the top of the hill!" "Dear me!" said his sister. "So we are!"

Prof. Bacon, Prof. Knox, Mr. Bevan, and others referred to the weeding-out of unsuitable persons. To Mr. Bevan's question, Who is to be made responsible for the rejection? the answer of the future will be, I am sure, the General Engineering Council; meantime let us try to create such a body. Prof. Knox gives exceedingly interesting examples of skilled guidance of students from preparation for a less suitable to preparation for a more suitable career, again showing what can be done when the right man does it; and Prof. Bacon instances the procedure at the University of Liége as showing how weeding-out may proceed. But what I wish he had stated is what becomes of the 70 students weeded out in the second and third years. It is quite true, as he says, that an engineering training is a fine thing for anyone; but not everyone can afford it, and if out of 450 students who begin only 50 finish the course, some at least of the 400 who drop out must be handicapped for other means of livelihood by their delay in getting to the right thing. It all goes to show how essential it is to discover the dominant tendency at the earliest possible age, using all likely ways of doing it. If we say "earliest possible," and leave it at that, we may avoid controversy on what the age is to be, and, as in Dundee and at Highgate, we may even begin to discover the tendency for ourselves. I am still of the opinion that it would be well to reduce the number of those who become engineers; but that, as Prof. Bacon will agree without hesitation, has nothing at all to do with restricting the number of those who take an engineering training because it is a fine equipment for some other industrial occupation.

On the whole, the discussion seems to show a preference for the sandwich system of training engineers, as more likely than others to preserve the capacity for intellectual edification while not neglecting the contact with people and their habits in works that is so essential for a right understanding of the administrative side of an engineer's duty. Prof. Knox emphasized a vital point when he stressed the need for close co-operation between the college and the industry of the district; and what I know of the South Wales Electric Power Distribution Company's training schemes makes me think that they meet the need in an eminently useful way.

Noting, in passing, Mr. Nairn's valuable hint as to health, Mr. Cleaver's reminder of the absolute necessity of understanding at least the probable underlying principles before any new kind of work is attempted, and Mr. Stretton's regret, which everyone shares, that it is almost impossible nowadays for any of us to keep our knowledge as wide as we should like it to be, I must next pause to draw special attention to Prof. Knox's reference to education as a preparation of the individual for an understanding of the world's affairs and a willing co-operation in them, and to quote beside it something said by Dr. Jacks in his book "Realities and Shams." "The educated man is, before all else, the man who understands everything about his own work, and enough about other people's to enable him to co-operate with them intelligently in the social complex. *Per contra*, he who understands everything about somebody else's work . . . and next to nothing about his own, may well stand as the type of the uneducated man. . . . The only happy man is the man who enjoys daily work, and the only good man is he who does it to the best of his ability." Marcus Vitruvius Pollio, a Roman architect and engineer who wrote a book called "De Architectura" about 2 000 years ago, demands from the engineer a variety of qualifications that shows, if it is legitimately demanded, how difficult it is for him to understand everything about his own work. "The

engineer" (I quote from *The Arc* for July, 1925, published by Messrs. J. Halden & Co., Ltd.) "should be a good writer, a skilful draughtsman, versed in geometry and optics, expert at figures, acquainted with history, informed in the principles of natural and moral philosophy, something of a musician, not ignorant of the sciences, both of law and of physics, nor of the motions, laws, and relations to each other of the heavenly bodies. Moral philosophy will teach him to be above meanness in his dealings and to avoid arrogance. It will make him just, compliant, and faithful to his employer, and, what is of the highest importance, it will prevent avarice from gaining an ascendancy over him; for he should not be occupied with thoughts of filling his coffers, nor with the desire of grasping everything in the shape of gain, but by the gravity of his manners and a good character should be careful to preserve his dignity." Here is something for us to live up to!

In connection with the matter of the accurate use of words, I must refer to some books that I have found of the greatest possible value. These are: "The King's English," by H. W. Fowler and F. G. Fowler; "The Concise Oxford Dictionary," by the same authors; "A Dictionary of Modern English Usage," by H. W. Fowler; "The Sounds of Standard English," by T. Nicklin, M.A.; and "Speaking," by William Mair, D.D. All are published by the Clarendon Press except the last, which is published by William Blackwood and Sons; the first three are particularly useful as guides in composition, while the last two are intended as aids to correct utterance.

I hope that the information given by Prof. Bacon about the valuable work of the public accountant at Swansea University College will be noted, and that similar service will be rendered in other places to those who may have no other opportunity of getting a sound knowledge of economics. It is so obvious as scarcely to need mentioning, that if only all those who guide the many parties associated in engineering could be told the full story of the dependence of everything upon everything else, there would be fewer party slogans to mislead, and more frequent common efforts to strengthen every member of the engineering body, whose health depends on the co-ordinated activity of all its parts. A famous schoolmaster hoped at the end of his days that he might not have harmed the boys who had been in his care; what might not our gain be if we all, small and great, went through life in the same fearful spirit?

In an address delivered over telephone wires from New York to the Pacific Coast Convention of the American Institute of Electrical Engineers at Seattle on the 17th September, 1925, Dr. M. I. Pupin, then President of the Institute, pointed out how, shortly after the American Colonies separated from Great Britain, George Washington's engineering instinct caused him to suggest that a meeting of commissioners from all the States, at that time by no means united, should be held to consider a national question, namely, the navigation of territorial waterways. The discussion of this engineering problem in a way suggested by an engineer was thus begun, and was adjourned to another meeting to be held at Philadelphia in 1787. This eventually became the Federal Convention in Philadelphia, at which, under Washington's presidency, the Constitution of the United States was framed. Political chaos and thoughts of individual sovereignty gave place to political order and a recognition of the need for united effort; and thus, as Dr. Pupin said, "the resourcefulness of the engineer . . . helped to save the situation at the most critical moment in the early history of the United States." There we have one side of the engineer's influence on public life, given a great opportunity and a great man to use it; the other side, the haphazard and dreary result of visionless throwing together of bits and pieces, is typified in a sentence written, I think, by Michael Arlen: "Now and then an omnibus rolled by, rolled on, and on, and on, the red-and-wite monster born of man's divine gift for making his life intolerable."

Although the paper is little more than a series of pegs to hang discussion on, it has at least brought together a company of kindred souls to think for a moment or two of fundamental things; and who knows what far-off ends may not have their beginning here? The ebb and flow of night and day monotonously following night and day will wear us down to a dull flatness if we do not escape now and again from immersion in details to some vision of wider spaces. Only so shall we preserve a lively hopefulness and save ourselves from passive acquiescence; only so can we be moulded to a finer shape. What we pass through counts for nothing unless we come out of it cleansed and strengthened; that is everything. The most that we can discover is but a little here and there in the great universe; and yet some of our seeking is not in vain. Let us hold fast what we find, and be glad that amongst much dross there are at least a few specks of gold. Treasuring these, we shall never cease to search for more; and thus our life shall find noble expenditure until, as night falls, we lay down our work and go to rest.

DISCUSSION ON
"AN ALL-ELECTRIC HOUSE." *
SUPPLEMENT TO THE AUTHOR'S REPLY.

Dr. S. Parker Smith (*in reply*): Tables J and K below show a comparison of the results obtained in the first and second years for the all-electric house (10 rooms) with six persons in the house, excluding guests.

First year (52 weeks): 12th July, 1924, to 11th July, 1925.
Second year (52 weeks): 11th July, 1925, to 10th July, 1926.

TABLE J.

Total Consumption in Units Recorded on Main Two-Rate Meter, and Cost.

	First year				Second year			
	Units	Cost			Units	Cost		
		£	s.	d.		£	s.	d.
Fixed charge ..	—	12	10	0	—	12	10	0
Day load at ½d. per unit ..	10 299	21	9	2	9 713	20	4	8
Night load at ⅜d. per unit	6 043	9	8	10	5 827	9	2	1
Total for year	16 342	43	8	0	15 540	41	16	9

Cooking.—The only noteworthy change is in the reduction of the consumption for cooking. With the original cooker with open-type boiling-plates, the average weekly consumption over 35 weeks was 60·3 units. With the new cooker with utensils with self-contained elements, the average weekly consumption over 17 weeks was 25·4 units, with a maximum of 30 units. Thus cooking with self-contained utensils not only gives the required celerity and safety, but reduces the daily consumption per person to 0·6 unit.

Reliability.—It is satisfactory to report that, from the time of our entering the house, the supply has not once failed.

Troubles.—Beyond the initial inconvenience of sorting out good from bad appliances, and the development of a satisfactory cooker, the only trouble worthy of mention is that arising from the use of flexible cables. These have now been abolished with the cooker. A periodic inspection of all flexible cords and cables is desirable. The flat-iron is the chief offender, and on one occasion a bad burn resulted from a broken wire. Though the iron can scarcely be called characteristic of an all-electric house, it emphasizes the need for a satisfactory solution of this problem of flexible cords and cables.

TABLE K.

Analysis of Consumption in Units.

Separate meters	First year	Second year	Remarks
Heating ..	5 954	6 636	Increase due to severe winter
Hot water, day	1 242	1 245	—
Hot water, night	6 043	5 827	—
Cooking ..	2 777	1 858	Decrease due to self-contained utensils
Lighting ..	568	687	Increase due to larger lamps
Total	16 584	16 253	
House closed ..	19 days	10 days	

* Paper by Dr. S. P. Smith (see pages 289 and 777).

PROCEEDINGS OF THE INSTITUTION.

739TH ORDINARY MEETING, 18 FEBRUARY, 1926.

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 4th February, 1926, were taken as read and were confirmed and signed.

Messrs. H. W. Hartridge and E. Ambrose were appointed scrutineers of the ballot for the election and transfer of members and, at the close of the meeting, the result of the ballot was declared as follows :—

ELECTIONS.

Member.

Robinson, James, D.Sc., Ph.D.

Associate Members.

Amos, William Josiah.
Busbridge, Horace Claude.
Scherman, Elie.

Graduates.

Avis, William John.
Blythe, George Edward K., B.Sc.
Brown, Harry.
Calver, Frank Norman.
Clayton, John Richard.
Dass, Amendranath.
Evans, William John.
Fisher, John Philip.
Garrett, Percival Theodore.
Haines, Harold.
Humphreys, Harold Victor.
Hutton, William Alfred, B.A.
Orchard, Patrick Connelly.
Pradhan, Gopinath Krishna, B.Sc.
Simms, Thomas Lowndes, B.Sc.(Eng.).
Weir, William.
Wood, Charles Frederick.

Students.

Aldis, Ronald Edward.
Allworth, Spencer Leigh.
Anslow, Frank.
Aziz, Abdul.
Ballard, William Edwin.
Barry, Henry.
Beaney, Cyril Ernest.
Best, William Bernard.
Billson, Frederick William.
Bond, Foster William.
Bond, John Harold.
Bradley, William Edward.
Brown, Philip.
Buckingham, Leonard Joseph.
Burchfield, John Ernest.
Burrows, Herbert Felix.
Callingham, Walter Sidney.
Carter, John.
Catt, Roland Charles.
Charles, Geoffrey Russell S.
Clouston, Charles Edward.
Cundell, Humphrey Heywood.
Dastidar, Nagendra Nath G.
de Fernandeze, Josie Augustine A.
de Thalis, Vincent Tudor.
Duncan, Maurice John.
Dutt, Sukumar.
Eayrs, Percival George W.
Edwards, Cecil Herbert L.
Elsom, Leonard Ernest.
Elworthy, Bernard Charles T.
Ezekiel, Maurice.
Fairbotham, Lionel Victor.
Faux, Frank.
Ferris, Sidney Herbert.
Field, Douglas Conan, B.A.
Fisher, William Garrow.
Fletcher, Fred.
Forster, Ernest William.
Francis, Cyril John.
Gardner, Victor Albert.
Gethin, Ernest Lewis.
Gourlay, Colin Alfred G., B.Sc.
Grundy, Eric.
Haigh, Leslie Baines, B.A.
Harwood, James Stanley.

Students—continued.

Hoare, Edmund.
Hollander, John Michael.
Hunter, John Garner.
Jarvis, Raymond Frederick J.
Jenkins, Cyril James H.
Jones, Geoffrey Charles.
Joyce, Richard Charles W.
Justice, Charles Reginald.
Kashyap, Harivansh Lal.
Kennedy, Reginald Patrick.
King, Stanley George.
Leigh-Sarney, Harvey Frederick.
Leitch, John Muir.
Lewis, William Emlyn.
Long, Frederick Charles.
Lovatt, Gordon Harold V.
Lusk, David.
McCabe, Ernest.
McCulloch, Robert Percival.
McLaughlin, Cecil Francis.
Mandahr, Narain Hans R.
Meyer, Leslie William.
Middleton, Leslie H.
Mills, Christopher Stanley.
Morse, Clifford.
Nixey, Dennis Edward.
Nottage, Wallace George.
Park, Robert Thomas.
Parker, Harry.
Parrish, Harry John.
Patel, Jashbhai Gouindbhai.
Patel, Kantilal Chaturbhai.
Payne, George.
Peck, Cuthbert Fielding.
Pegg, John Edwin.
Percival, Raymond Edward.
Richards, Percy.
Risso, Arthur Eladio.
Roberton, James Samuel P., B.Sc.
Rose, Lewis Campbell.
Rusby, Hermann.
Scott, Robert.
Sears, Herbert William.
Shoults, Norman George.
Simmonds, Nevil Reginald J.
Skillman, Thomas Samuel.
Smith, Eric.
Sproul, Charles James.
Stentiford, Wilfrid John.
Stockwell, Reginald William.
Sturman, Edward Albert.
Thomas, David Frank.
Thompson, John Leslie.
Thorn, William Alfred J.
Thornton, Cyril.
Thorpe, James Rothschild.
Todd, Donald Walter.
Tompsett, Francis John.
Thornley, Ernest Joseph.
Vatcha, Shiavux Bejonji.
Vincent, Horace John.
Vyas, Baldevbhai Motiram.
Walker, James Roy.
Ward, Charles Geoffrey.
Watts, John Lea.
Way, John Christopher.
West, Francis Richard J.
Whittaker, Douglas, B.Sc.
Whyte, Cyril Leonard A. le B.
Wilkins, Arnold Frederic.
Williams, Alan Cyril O.
Winstanley, William.
Winter, Francis Edward.
Wray, Walter Dean.

Associate.

Hoyle, Harry.

TRANSFERS.

Associate Member to Member.

Bairsto, George Edward, D.Sc., D.Eng.
Brown, George John L.
Cleaver, Richard Lovell, B.Sc.(Eng.).
Dania, George.
Jenkins, Daniel, M.Sc.Tech.
Lazarus, Edmund George.

Graduate to Associate Member.

Amerasinghe, Richard Peter.
Hortop, Cecil Lawrence.
Kaempf, Emil.
Macarthur, Neil Brown, B.Sc.
Pennington, John Hawley.
Wakefield, Paul Stuart, B.Sc.
Wilkins, Cecil.

Student to Associate Member.

Bainbridge, Stanley Rendle.
Baker, John Henry, B.Sc.(Eng.)
Barraclough, Alfred.
Gallizia, Enrico.
Garwood, Godfrey Thomas, B.Sc.
Tustin, Arnold, M.Sc.
Wilck, Charles Augustus.
Wilmshurst, Arthur Percival.

Student to Graduate.

Addison, Joseph.
Allen, John William.
Bader, Ernest, Lieut. R.E.
Barnes, Wilfred Charles.
Bearcroft, Hubert Percival.
Booker, William Mason.
Busby, Arthur Henry W., B.Sc.
Butterley, Archibald Donald.
Church, Leonard Phillips.
Crompton, Oswald James, B.Eng.
Crosbie, Sydney.
de Kretser, Horace Egerton S.
Ferguson, John Donald.
Grech, Vincent Owen.
Gregson, William Herbert, M.Eng.
Grundy, Geoffrey Earnshaw.
Hardaker, Ernest Victor, B.Sc.
Hardy, Alexander Edward.
Harrison, Arthur Casswell.
Healy, John Quarry.
Hegazy, Hamed Mahmoud.
Holder, John Eric D., B.A.
Hook, Herbert James.

Student to Graduate—continued.

Howse, Henry Arthur G.
Hunter, Charles Moore.
Kellie, John Gordon, M.Eng.
Lackie, Donald Walker.
McAinsh, Neville James.
McCarter, Alan Lailey.
Meneze, John Arthur.
Metcalfe, Percival Ignatius H., B.Sc.
Morton, James.
Perkins, James William.
Pewtress, Noel Cecil.
Pistorius, Leo Henry.
Price, Arthur Conrad, B.Sc.(Eng.).
Redclift, Ronald David.
Rodrigues, John Rosario.
Roulson, William Percy.
Ryle, Peter Johnston, B.Sc.(Eng.).
Shishini, Mahmoud El, B.Sc.Tech.
Smith, Cyril Blake.
Srinivasan, Mandayam, Thondanore, B.E.
Stevens, Sidney George, B.Sc.(Eng.).
Taylor, Horace.
Thavenot, Joseph Raymund.
Thomson, Alexander Stuart, B.Sc.
Tingle, Howard Grantley.
Turner, Wilfred.
Walker, Allan Matthias.
Wheeler, Edmund Frank.
White, Sidney Robert.
Wiliams-King, Evan Baker.
Williamson, Peter Blanche, B.Sc.

A paper by Mr. H. Parodi, entitled "Electrification of a Section of the Orléans Railway," was read, on behalf of the author, by Mr. Roger T. Smith, and was discussed.

On the motion of the President votes of thanks to the author, and to Mr. Roger Smith for reading the paper, were carried with acclamation, and the meeting terminated at 8.10 p.m.

52ND MEETING OF THE WIRELESS SECTION, 3 MARCH, 1926.

Major B. Binyon, O.B.E., M.A., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 3rd February, 1926, were taken as read and were confirmed and signed.

A paper by Mr. R. A. Watson Watt, B.Sc.(Eng.), Associate Member, entitled "The Directional Recording of Atmospherics" (see page 596), and a paper by Messrs. R. A. Watson Watt, B.Sc.(Eng.), and J. F. Herd, Associate Members, entitled "An Instantaneous Direct-Reading Radiogoniometer" (see page 611), were read and discussed.

On the motion of the Chairman a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 8 p.m.

740TH ORDINARY MEETING, 4 MARCH, 1926.

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 18th February, 1926, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see page 401) was taken as read and the thanks of the meeting were accorded to the donors.

A paper by Mr. R. Borlase Matthews, Member, entitled "Electro-Farming, or the Application of Electricity to Agriculture" (see page 801), was read and discussed.

On the motion of the President a vote of thanks to the author was carried with acclamation, and the discussion was adjourned at 8.15 p.m. until Thursday, 11th March, 1926.

741ST ORDINARY MEETING, 11 MARCH, 1926.

Lieut.-Col. K. Edgcumbe, R.E. (T.A.), Vice-President, took the chair at 6 p.m., in the absence of Mr. R. A. Chattock, President.

The minutes of the Ordinary Meeting held on the 4th March, 1926, were taken as read and were confirmed and signed.

The discussion on Mr. Borlase Matthews's paper, entitled "Electro-Farming, or the Application of Electricity to Agriculture" (see page 801), was continued.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.50 p.m.

742ND ORDINARY MEETING, 18 MARCH, 1926.

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 11th March, 1926, were taken as read and were confirmed and signed.

Messrs. A. H. Allen and E. W. Dickinson were appointed scrutineers of the ballot for the election and transfer of members and, at the close of the meeting, the result of the ballot was declared as follows :

ELECTIONS.

Associate Members.

Boothby, Thomas Edward.
Lawton, Frederick William.
Maxim, James Leonard, M.Sc.
Reid, Meredith William.
Thompson, Mark, M.A.
Turner, Reginald Alfred.
Wheeler, William.

Graduates.

Aldridge, Percy Spencer.
Aspin, John.
Bryden, James Emmanuel Z., B.Sc.(Eng.).
Burns, John.
Cheney, Cuthbert Samuel G.
Espitalier, Theodore.
Flemons, Sidney.
Goodyear, Sydney.
Haddock, Ralph Burdon.
Harris, Charles Hardie.
Johnston, Eric Montague.
Leeds, Robert James.
Lloyd, Harold.
Lloyd, Norman.
Minowa, Nobuyoshi.
Nakashima, Tomomasa.
Pratt, Joseph Hewitt.
Randhawa, Tara Singh.
Roddis, Charles Henry.
Sutton, Charles Frank, B.A.
Swettenham, Norman Alexander M., B.A.
Tayler, Frederick William.
Wood, William Robert B.

Students.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A paper by Mr. L. C. Grant, Associate Member, entitled "Developments in High-Power Fusible Cut-Outs," was read and discussed.

On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.45 p.m.

INSTITUTION NOTES.

Council for the Year 1926-27.

The scrutineers (Messrs. P. M. Baker, A. Murray Coombs and A. F. Harmer) appointed at the Ordinary Meeting held on the 22nd April, 1926, in connection with the ballot to fill the vacancies which will occur in the Council on the 30th September next, have reported to the President that 1 420 ballot papers were returned, of which 20 were spoiled, and that the result of the ballot is as follows :—

President : Dr. W. H. Eccles, F.R.S.

Vice-President : Colonel T. F. Purves, O.B.E.

Hon. Treasurer : Lieut.-Col. F. A. Cortez Leigh, T.D., R.E.

Ordinary Members of Council : (Members) Mr. A. C. Cramb, Dr. A. H. Railing, Dr. S. Parker Smith, and Mr. A. J. Stubbs ; (Associate Member) Mr. F. W. Crawter.

The Council for the year 1926–27 will therefore be constituted as follows :—

President.

W. H. Eccles, D.Sc., F.R.S.

The Past-Presidents.

A. Siemens.
Col. R. E. Crompton, C.B.
J. Swinburne, F.R.S.
Sir R. T. Glazebrook, K.C.B., D.Sc., F.R.S.
W. M. Mordey.
S. Z. de Ferranti, D.Sc.
Sir John Snell, G.B.E.
C. P. Sparks, C.B.E.
R. T. Smith.
Ll. B. Atkinson.
J. S. Highfield.
F. Gill, O.B.E.
A. Russell, M.A., D.Sc., LL.D., F.R.S.
W. B. Woodhouse.
R. A. Chattock.

Vice-Presidents.

Lieut.-Col. K. Edgcumbe, R.E. (T.A.).
A. Page.
Col. T. F. Purves, O.B.E.
Prof. W. M. Thornton, O.B.E., D.Sc.

Honorary Treasurer.

Lieut.-Col. F. A. Cortez Leigh, T.D., R.E.

Ordinary Members of Council.

A. C. Cramb.
F. W. Crawter.
The Viscount Falmouth.
Prof. C. L. Fortescue, O.B.E., M.A.
R. Grierson.
Major E. O. Henrici, R.E. (Ret.).
W. E. Highfield.
H. Jones.
E. Leete.
Sir B. Longbottom.
R. W. Paul.
A. H. Railing, D.Eng.
C. Rodgers, O.B.E., B.Sc., B.Eng.
E. H. Shaughnessy, O.B.E.
S. Parker Smith, D.Sc.
A. J. Stubbs.
J. W. T. Walsh, M.A., M.Sc.
S. J. Watson.

And

the Chairman and Immediate Past-Chairman of each Local Centre.

Associate Membership Examination.

The Council have revised and extended the list of qualifications which exempt from the Associate Membership Examination. Full particulars relating to such exemptions can be obtained from the Secretary.

National Certificates and Diplomas in Electrical Engineering.

The following have been approved under the scheme drawn up by the Board of Education and the Institution :—

Approved for Ordinary Grade Certificates (Senior Part-time Course) :—

Barnsley Technical School.

Approved for Higher Grade Certificates (Advanced Part-time Course) :—

Stafford County Technical School.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 June–25 July, 1926.

ELECTRIFICATION OF A SECTION OF THE ORLÉANS RAILWAY.

By H. Parodi.

(*Paper received 4th January, 1926; read at a Joint Meeting of* The Institution *and the British Section of the French Society of Civil Engineers 18th February, also before the* South Midland Centre *17th February, and before the* North Midland Centre *23rd February, 1926.*)

Summary.

The author first discusses the conditions which have led the French Government to consider an extensive electrification scheme, of which the railways will form only a part, and he then explains the general method adopted in drawing up the scheme and utilizing in the most economical manner the sources of power available.

Particulars are given of the power supply to the Orléans Railway and the rolling stock already in use and on order.

Finally, the design of electric locomotives is discussed, and a comparison is made between electric and steam locomotives.

Introduction.

This paper is not intended to describe in detail the important electrification scheme now being carried out by the Orléans Railway Company, but merely to outline those features which will show how it fits into the general electrification programme of France.

At the present time, when Great Britain would appear to be on the eve of extensive electrification work, which will doubtless be carried to a successful conclusion in view of the exceptional skill of British engineers and the determination of the Government, the author thinks that it may be of interest to describe the schemes proposed for France and the methods which are being employed. In this connection British engineers will probably be more interested in the reasons for the selection of particular methods than in the actual methods themselves, because valuable information obtained by experience in any large undertaking cannot be profitably made use of unless the real aims of those responsible for the work, together with any conditions which may have been laid down or which may have arisen during the progress of the work, are thoroughly understood.

It will be obvious that so vast a programme of electrification as that projected in France cannot be carried out immediately, especially when it is remembered that many big undertakings have required the efforts of several generations before being brought to a successful conclusion. If, however, the general plan is outlined and the principles underlying its organization and the methods adopted for carrying it out are clearly explained, it will be realized that the work—the completion of which has been retarded by the present financial stringency—will be taken up again with a new zeal as soon as circumstances permit, because its realization constitutes, for a country like France, one of the most efficient means of re-establishing stable conditions.

It is for this reason that, in the first part of the paper, the author has outlined the main factors which have dominated the whole of the investigation regarding the scheme of electrification in France and the development and economical use of water power. The second part of the paper is devoted to a brief description of the electrical equipment installed, or being installed, by the Orléans Company.

The author would have liked to explain the technical considerations which influenced the choice of those sections of railway to be electrified first, and also to describe the principles and methods which have been applied in the design and construction of the high-tension transmission lines, substations, transformer stations, and distribution lines. It is, however, impossible for him to go into all these questions now, and he therefore proposes merely to include in an Appendix a few remarks on the layout of the electric locomotive rolling-stock. Those who are interested in these questions will, however, find a detailed description of the electrification of the Orléans Railway system in a paper which the author has written for publication by the *Revue Générale des Chemins de Fer.*

Part 1.

Scheme of Electric Power Supply and Railway Electrification in France.

The electrification of the Orléans Railway is of particular interest, not only on account of the importance of the scheme, but also owing to the magnitude of the problems arising in carrying out the work. It was a question not merely of substituting electric traction for steam traction on a line having a dense traffic, but also of providing a large distribution system of which the power plants and transmission lines could be utilized for a supply of electric power in all the districts through which the railway passes.

The policy adopted in France in connection with the electrification of the railways is substantially different from that followed in other countries. The substitution of electric power for steam on the railways is considered in France to be one stage of a more comprehensive scheme, whereas in Germany, Switzerland, Austria, Sweden, Norway and other countries, the electrification of the railways is considered independently of the problem of a general supply of electric power. The railways in all the countries mentioned belong to the State, and special power stations and transmission lines have been installed for the generation and utilization of single-phase current at a low frequency. Two entirely separate and independent systems are thus being developed side by side, the power supply to the industrial system being by three-phase current at 50 periods, and the State power-supply system for electric traction being single-phase current at a frequency of $16\frac{2}{3}$ periods. The only indication of a desire to

establish at a later date an electrical connection between the traction and industrial systems, with a view to an exchange of power between them, is that the ratio between the frequencies of the two systems is a whole number, namely $50 \div 16\frac{2}{3}$, i.e. 3.

In Great Britain, France, Belgium, Holland, Spain, Africa (Morocco, Algeria and Natal), as well as in South America (Chili, Argentine, etc.) electric power for traction will be generated and transmitted as three-phase current at 50 periods (60 periods in South America).

All the countries which have followed the policy of interconnecting the traction and industrial power systems have adopted high-tension direct current at 1 500 to 4 000 volts as their standard for traction. Such current can, of course, be obtained whatever the frequency of the current generated. It should, however, be pointed out that in certain countries, such as Italy and Hungary, very interesting tests are at present being made with a view to using for single-phase or three-phase traction three-phase current of a frequency such as is employed for the industrial supply. In Italy three-phase locomotives having gears and connecting-rods and using current at the industrial frequency have been tested on the Mont Cenis lines; and single-phase and three-phase 50-period locomotives fitted with synchronous converters on De Kando's system are under test in Hungary on a suburban line near Budapest.

This development, which is taking place in countries where low-frequency alternating-current traction has been in operation for a long time, proves more conclusively than any theoretical considerations the practical advantages to be obtained by standardizing the various systems adopted for the generation and transmission of electric power.

As the main flow of traffic always follows in every country the same direction whatever the form of transport, it would seem that the general direction of the main power-transmission lines should practically coincide with that of the railway lines which have a very dense traffic, and such railway lines are, as a matter of fact, those where the question of electrification is of most interest. For instance, the railway from Paris to Toulouse through Orléans, Limoges and Brive, is the route of the power-transmission line which would allow of an exchange of power between the large steam-driven power stations of the Paris district and the hydro-electric stations of the Central Plateau and the Pyrenees.

Considered from this aspect, the electrification of the railways no longer appears merely as an " end " but also as a "means." It will therefore be understood why eth French Government had, even before the war, brought pressure to bear upon the large railway companies supplying districts rich in water power to electrify their systems so as to prepare the way for a still more extensive electrification.

The total coal consumption in France now reaches about 70 million tonnes* per year, 75 per cent of which is obtained from the country's mines and 25 per cent from English, Belgian and German mines. The whole of the French railways do not consume more than 9 million tonnes, i.e. about 13 per cent of the total. From this it can be seen that the electrification of the railways, even if extended to include every line, would result in only a small reduction in the import of fuel into France.

In order to obtain an appreciable reduction in the amount of coal purchased abroad, which forms a serious item in the trade balance, it is necessary to transmit electrical energy obtained from water power to large cities like Paris, Lyons, Bordeaux and Toulouse, where the coal bill in connection with the generation of the electrical energy required for industry, namely motive power and lighting, is far bigger than that for traction purposes.

Fig. 1 clearly shows this condition. On each railway line where the electrification is complete or nearly complete, a rectangle has been drawn having its area proportional to the annual consumption of coal for traction on railways. In this connection it should be remembered that the traffic figures for 1913 are now exceeded on all the railways.

A circle has been drawn round Paris and its area represents to the same scale the fuel consumption in the steam-driven power plants of the Paris district which supply the industrial requirements for electric power and lighting. The amount of coal thus consumed in Paris (1 200 000 tonnes in 1924) is more than three times greater than the coal consumption for steam haulage of all the trains of the Orléans Company between Paris and Brive.

By the end of 1935 the consumption of electrical energy in Paris will reach 2 000 million kWh, whereas the requirements for electric traction on the Orléans system (the lines from Paris to Brive, from Saint Sulpice to Gannat, and from Brive to Clermont) will very probably not be higher than 400 million kWh. The maximum demand in Paris will be about 1 million kW, whereas the traction demand will not exceed 80 000 kW.

The whole problem of the electrification of the Orléans Railway has been dominated by the desire to transmit electrical power from the Central Plateau to Paris without burdening the railway electrification with capital charges which are out of proportion to the present traction requirements. The solution of this problem has been found in the systematic use of transmission lines at as high a voltage as possible.

Power Transmission System.

The use of very high voltages presents considerable advantages from an electrical point of view, particularly in connection with the great strength of such lines and their almost complete immunity from atmospheric phenomena. Economically the advantages are not less important, and they become more evident when, bearing in mind that the amount of power which can be transmitted to a given distance varies as the square of the voltage, it is found that the first cost increases practically only as the voltage.

Owing to the increase in the transmission voltage, a saving is certain to result if we transmit over the same line a long-hour load such as traction (say 4 000 to 5 000 hours per annum) and a shorter-hour industrial load (2 000 to 2 500 hours per annum).

From experience on distribution systems in France, it is found that the cost of a transmission line can be

* Wherever "tonne" is mentioned in this paper, "metric ton" (1000 kg) is meant.

FIG. 1.—Map showing for the year 1913 the coal consumption per kilometre per annum on the electrified lines.

represented approximately by an expression of the form

$$a + bE$$

where E is the transmission voltage.

The minimum return which must be obtained each year in order to cover the capital charges and the working expenses should also be of the form

$$a + bE$$

If N be the number of hours during which an amount of power kE^2 is transmitted or can be transmitted along the line, the amount of energy transmitted yearly will be kE^2N.

If p be the average receipts per unit transmitted, in order that the revenue and expenditure may balance we must therefore have

$$kE^2Np = a + bE \quad . \quad . \quad . \quad . \quad . \quad (1)$$

If, now, in order to allow loads of various types to be superimposed, we increase the voltage without altering the tariff p, we get by differentiating equation (1)

$$kp(E^2dN + 2ENdE) = bdE$$

Therefore

$$\frac{dN}{dE} = \frac{b - 2kpEN}{kpE^2} = -\frac{pkEN + a/E}{kpE^2} \quad . \quad . \quad (2)$$

Whatever the values of the constants, the quantity dN/dE is thus negative, which means that any increase in the voltage will enable a reduction in the minimum time of utilization necessary in order to be able to transmit power at a given price.

With the voltage of 150 kV now used, it is possible to transmit economically 40 000 to 50 000 kW from the Central Plateau to Paris, a distance of about 450 km (280 miles). By increasing the voltage to 220 kV, however, it would be possible to double (i.e. $220^2/150^2$) the amount of power transmitted, and to superimpose on a traction load of 30 000 to 40 000 kW a power load of 60 000 or 70 000 kW, which could be used for industrial power and lighting.

The high-tension system of the Orléans Company now includes a 150-kV line which can later be converted for use at 220 kV by the addition of a few units and a shield to the present chain insulators. The sizes of the aluminium conductors with their steel cores (293 mm^2 total section), and also the dimensions of the towers, have been based on the ultimate adoption of a voltage of 220 kV. In fact, the normal distance between conductors (about 7·80 m, or 25 ft. 6 in.), and that between conductors and the main support (about 3 m, or 10 ft.) are larger than those actually employed on the 220-kV lines in operation in California.

Correct Method of Generation and Utilization of the Power Obtained from Waterfalls.

In countries like Great Britain where electric power can be obtained only by burning coal, and in countries possessing waterfalls fed from water sources all of the same type, as in Switzerland, the problem of the generation of electricity is almost exclusively a technical one, particularly when, as is the case in both the countries mentioned, the coal resources in one and the water-power resources in the other are very much larger than the national requirements.

The problem becomes, however, much more complicated in countries like France where important coal resources and considerable water power are both available at the same time, although the amount of water power varies throughout the year. The coal resources of France are estimated at 22 000 million tonnes, taking into consideration only those deposits which can be worked with the appliances at present available. With the present output of 40 to 60 million tonnes per annum, coal will thus be available in France for between 400 and 500 years. The water-power resources, which are renewed every year by solar heat, are estimated to represent normally about 5 million kW, of which about 3·3 million kW is in the form of waterfalls fed by glaciers, and 1·7 million kW is in waterfalls depending for their water supply on rain. Of this total, only 0·67 million kW was being utilized on the 1st January, 1925, whilst 0·28 million kW was in course of development at the same date.

The present consumption of electric power in France is about 7 500 million kWh, of which about 4 500 million kWh is generated by steam plants, the output of which represents 2 000 hours' use per annum, and 3 000 million kWh is obtained from water power, representing 4 300 hours' use. The combined load of the interconnected electric distributing systems represents about 2 500 hours' use per annum, i.e. a load factor of about 28 per cent.

The Government is considering at the present time in France, in close co-operation with manufacturers, a programme of gradual equipment and of progressive linking-up of the various distribution systems, rather than Government control of electricity generation. The problem is too important, from the point of view of the country as a whole, for the Government not to try to outline the method of generation to be followed; and it is also too complicated, owing to the various opposing interests, to admit of the laying down of a hard-and-fast technical solution.

From the point of view of the rapid utilization of the waterfalls, decentralized efforts are perhaps desirable; but as regards the operation of the plant and its efficiency, unity of control is essential. Let us therefore try first to state the conditions of the problem from the purely technical point of view, and then to discuss how the action of the railway companies would seem to facilitate the carrying out of a comprehensive electric power scheme on correct lines.

The power $F(t)$ available at each instant in a complex system consists of four terms, each a function of the time. Thus

$$F(t) = \Sigma H(t) + \Sigma R(t) + \Sigma S(t) + \Sigma T(t)$$

where $\Sigma H(t)$ represents the total power available from stations using streams and rivers where there are no reservoirs or where the reservoirs are full;

$\Sigma R(t)$ represents the total power available from power stations having daily or weekly reservoirs;

$\Sigma S(t)$ represents the total power available from power stations with seasonal reservoirs;

and $\Sigma T(t)$ represents the total power available from steam-driven stations.

In the case of a complex power system the problem to be solved, first as regards the layout and then as regards the operation of the system, consists in proportioning those items which are more or less completely disposed of at the commencement of the scheme; that is to say, of so equipping the power stations referred to as H, R, S, and T above, and determining the capacity of the reservoirs in connection with stations R and S, as to allow of dealing with the fluctuations of load $\phi(t)$ with the smallest expenditure of fuel.

Power stations without reservoirs (H above) are essentially those the output of which must not be controlled. Power stations R are the peak plants or "system regulators"; and power stations S and T are the additional ones substituted for H and R during periods of drought.

The available power $S(t)$ of a system should include any power $H'(t)$ taken from a neighbouring system if the plant H' is driven by a water supply of a type different from that used by the plant H of the first system.

If the load $\phi(t)$ is solely traction, it will be found that the monthly or, even, weekly power demand is practically the same throughout the year. Whereas if the load $\phi(t)$ is an industrial one for power and lighting, in addition to large daily variations there will also be seasonal variations, the maximum power demand occurring during the winter and the minimum during the summer.

Whatever the nature of the consuming system, the load curve for $\phi(t)$ is characterized by two "factors" corresponding to the normal periods of variation of the load. The load curve can therefore be considered to be practically a double function of the time. To each period of 24 hours corresponds a portion of curve of almost constant shape, which is repeated daily with but slight variation.

Supposing now that from the load curve $\phi(t)$ we obtain a second curve representing the variation in the total amount of electrical energy generated during each period of 24 hours throughout the year, and let us represent by e the amount of energy generated during the day having the greatest output. If we call E the total amount of electrical energy generated during the year and P the maximum demand, we shall be able to define three load factors:—

The normal load factor

$$f = \frac{E}{365 \times 24P}100$$

The daily utilization factor of the maximum demand P

$$\lambda = \frac{e}{24P}100$$

And the yearly utilization factor of the maximum daily output

$$\mu = \frac{E}{365e}100$$

The normal load factor is equal to the product of the two others divided by 100.

That is

$$100f = \lambda\mu$$

If, instead of defining the factors λ and μ in distinguishing in the load curve of a system the customary periods, the day and the year, we define similar factors λ' and μ'—the first corresponding to the equivalent hours of use of the maximum demand during the month of heaviest load, and the second to the utilization during the 12 months of the year of the maximum monthly demand—we shall have facilitated somewhat a solution, as it will then be comparatively easy to compare the curve $F(t)$, defining the available power, with the curve $\phi(t)$ representing the demand.

The equipment of water-power stations possessing

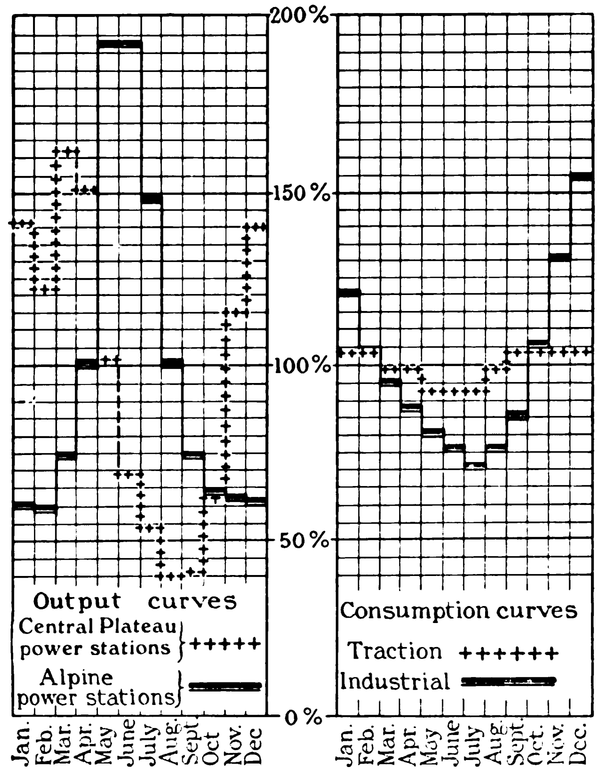

FIG. 2.—Curves showing output of the Central Plateau and Alpine power stations, and the energy consumption for traction and industrial purposes.

daily or weekly reservoirs $R(t)$ should be such that they can develop, with the help of plants $H(t)$, an output as nearly as possible that defined by the utilization coefficient λ'.

Water-power stations possessing seasonal reservoirs $S(t)$ should be equipped in such a manner as to be in a position to give, at times when plants $H(t)$ and $R(t)$ will only be able to operate at reduced load, an output as nearly as possible that defined by the utilization coefficient μ'.

The extra seasonal power will be supplied by the steam-power stations or by water-power stations $H'(t)$ obtaining their water from a source different from that of the plants $H(t)$.

In the case of a traction supply, μ' differs only slightly from 100 per cent, and λ' is about 50 to 60 per cent according to the length of the electrified line. For

industrial purposes μ' is about 75 per cent and λ' about 33 per cent.

Fig. 2 shows the relative variation in the number of units generated and consumed per month, compared with the number generated and consumed per year. The left-hand side of the figure shows the percentage variation in the number of units generated by the flow of water in the case of a plant depending on rain for its supply (Central Plateau stations), and also of a plant where the water comes from glaciers (Alpine stations). The right-hand side gives the monthly variations in load of an electric railway system and of an industrial system supplying power and lighting.

to the working in parallel of the Eguzon plant (50 000 kW installed) and the large steam-power stations of the Paris district, it will be possible to utilize to the fullest extent the power available from the River Creuse.

In the first stage of the electrification of the Orléans system, the Eguzon plant will represent in the system of power stations of the Société l'Union d'Électricité the equivalent of a 50 000-kW set located at a distance of 300 km (186 miles). This set will be started when water power is available from the Creuse, and it will be stopped when there is no water; but the existence of the weekly reservoir will allow, on the other hand, this power to be used any time during the 24 hours when this reserve

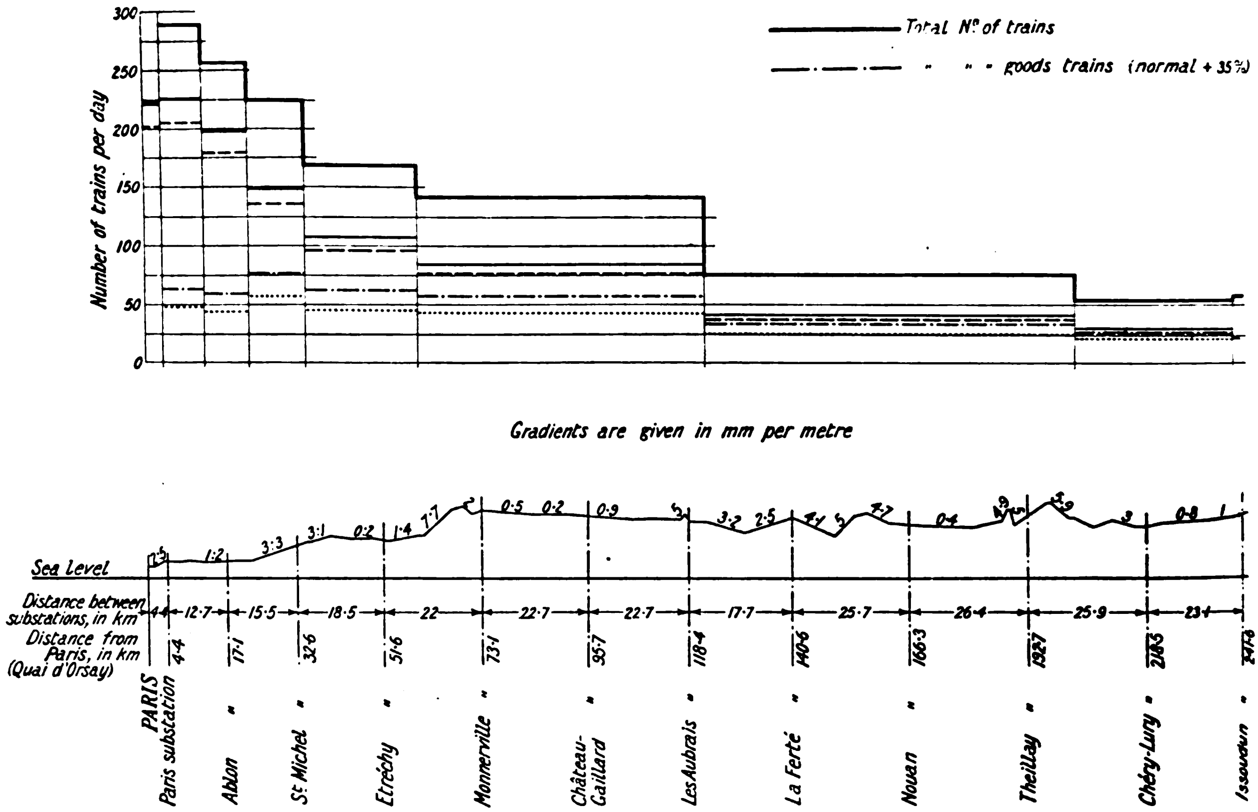

FIG. 3.—Traffic and longitudinal section of the line from Paris to Brive.

As the output curves of water-power plants depending on the rainfall are approximately of the same shape as the consumption curves of industrial systems, we can see at once the advantage which there would be in supplying electric power to Paris from the water power of the Central Plateau, it being particularly easy in this case so to adapt the power available that it will meet the demand.

This was realized by the Government when it authorized the Orléans Company to form, with the help of the Société l'Union d'Électricité, the Société l'Union Hydro-Électrique, in order to install the Eguzon water-power plant on the River Creuse.

The fact that this plant has a dam allows the storage of a sufficient quantity of water to form a weekly reserve, without the possibility of seasonal regulation. Owing

will be most advantageous from the point of view of either economy or reliability.

In the second stage of the electrification of the Orléans system, use will be made of power generated by the hydro-electric plants of the Haute Dordogne. The equipment of the waterfalls will include for the most important power plants the construction up-stream of a reservoir, in order that the adaptation of the available power to the demand may be secured by the use of this reservoir and by the exchange of power with a neighbouring system having water-power plant of a type complementary to the Central Plateau plants.

Owing to this combination and the policy of mutual assistance, the electric traction service of the Orléans Company will be operated under exceptionally reliable

conditions, without the average demand for additional steam power being more than 10 per cent of the total power. Should, in the future, large amounts of hydro-electric power be transmitted from the Central Plateau to Paris, the lines of the Orléans Company could be easily adapted for this transmission.

In superimposing the industrial load on the traction load of the various 90-kV and 220-kV lines, it would be possible to transmit economically 100 000 kW a distance of 450 km (280 miles). The author thought it advisable to emphasize this question of electric power electrify first are the lines having the greatest density of traffic and, consequently, the biggest consumption of coal.

It can easily be shown that the greater the coal consumption per mile of line, the more favourable will be the financial results of electrification. For this reason and others, to which reference will be made later, the Company, after having investigated with the Government the question of commencing the electrification by converting to electric traction the lines in the neighbourhood of the waterfalls of the Central

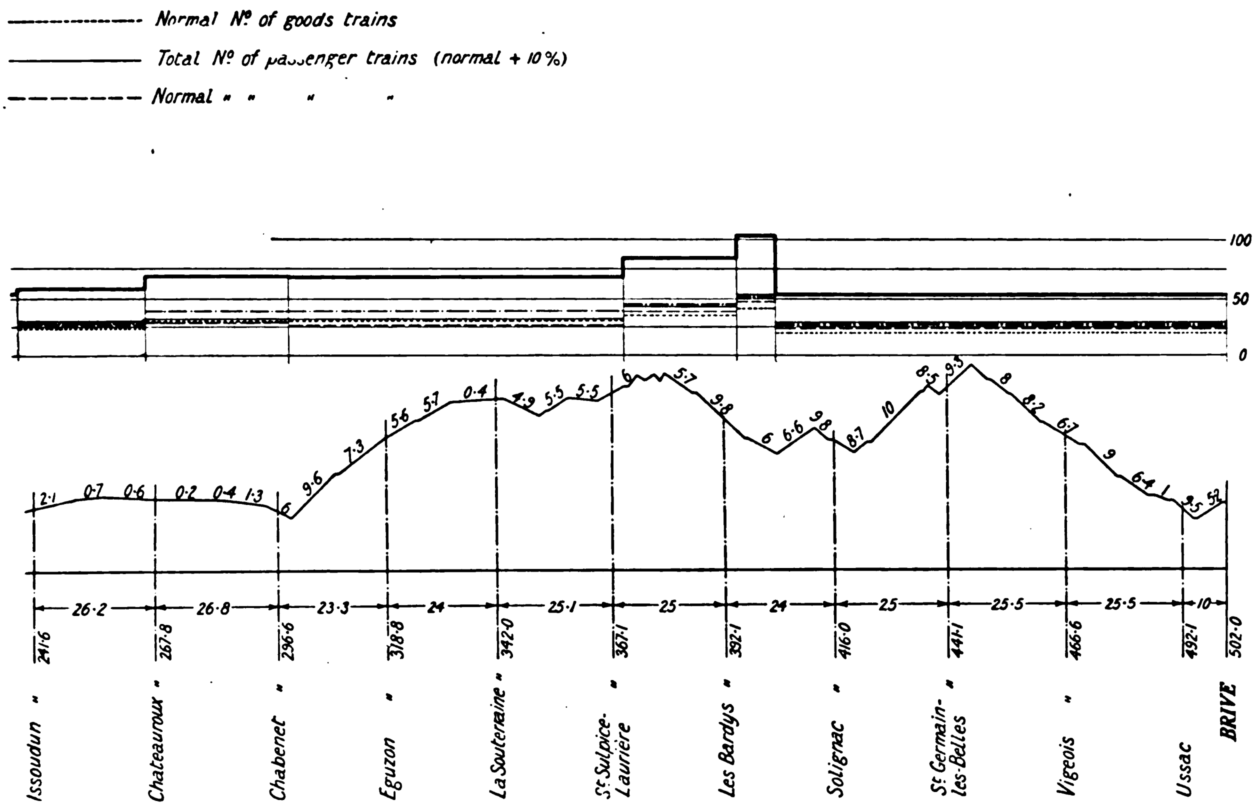

FIG. 3.—*Continued.*

production in a complex system, because on its more or less favourable solution depends the success of the electrification, not only of the railway, but also of the whole country it supplies.

If in a country possessing an abundant supply of coal, such as Great Britain, considerable attention is given to the most economical methods for the generation and distribution of power, it can readily be understood how in France this problem is becoming very important and, we might say, even urgent.

Part 2.

Electric Traction Installation of the Orléans Railway Company.

Of the railway lines from the Central Plateau to Paris, those which the Orléans Company propose to Plateau, eventually decided to carry out the electrification in the following order (see Fig. 1):

Paris to Brive : a length of 502 km (about 312 miles), of which 65 km ($40\frac{1}{2}$ miles) comprises four tracks, and 477 km (297 miles) is double track.

Brétigny to Dourdan : 27 km (about 17 miles) of double track.

Saint-Sulpice to Gannat : 190 km (about 118 miles) of single track.

Brive to Clermont : 198 km (about 123 miles) of single track.

These make a total of 1 576 km (about 980 miles) of main-line track, excluding switching tracks, sidings, and sorting and shunting stations. On these lines

electric traction will replace steam traction for the whole of the passenger, goods, and shunting services.

Figs. 3, 4, 5 and 6 give, for each of the four sections under consideration, a longitudinal section of the line, the distances between the substations, and the number of trains per day.

The scheme has been drawn up with a view to making provision for the following traffic per year :—

40 million tonne-km on the Paris–Orléans section,
20 million tonne-km on the Orléans–Vierzon section,
12 million tonne-km on the Brétigny–Dourdan section,

although, as a matter of fact, the traffic in 1923 only reached 22, 12 and 3½ million tonne-km per kilometre respectively on these sections.

Fig. 7, showing the average yearly traffic on the Paris–Orléans section from 1897 to 1923, clearly indicates the necessity of providing, as has been done, for increased requirements in the future, so as to avoid changing the plant materially during the next 15 years at least.

The orders for the Paris–Vierzon and Brétigny–Dourdan electrification, involving the equipment of over 600 km (370 miles) of main-line track, have all been placed since 1923. Already a number of electric trains are running from Paris (Quai d'Orsay) to Etampes and from Brétigny to Dourdan, a total length of 96 km (59½ miles) of route, and the electric service will be

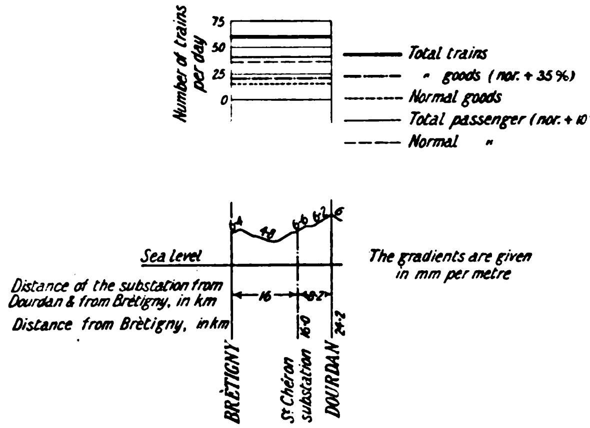

FIG. 4.—Traffic and longitudinal section of the line from Brétigny to Dourdan.

extended as far as Orléans and Vierzon before the end of 1926.

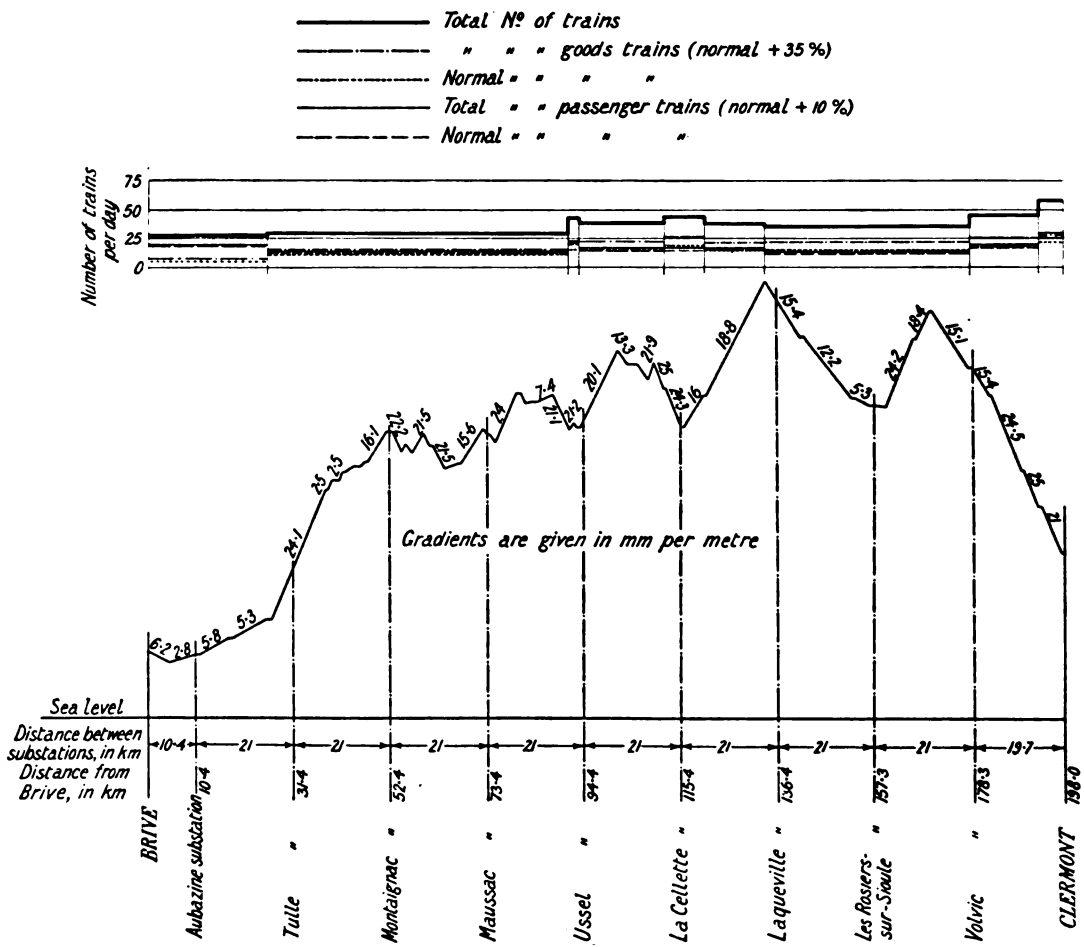

FIG. 5.—Traffic and longitudinal section of the line from Brive to Clermont.

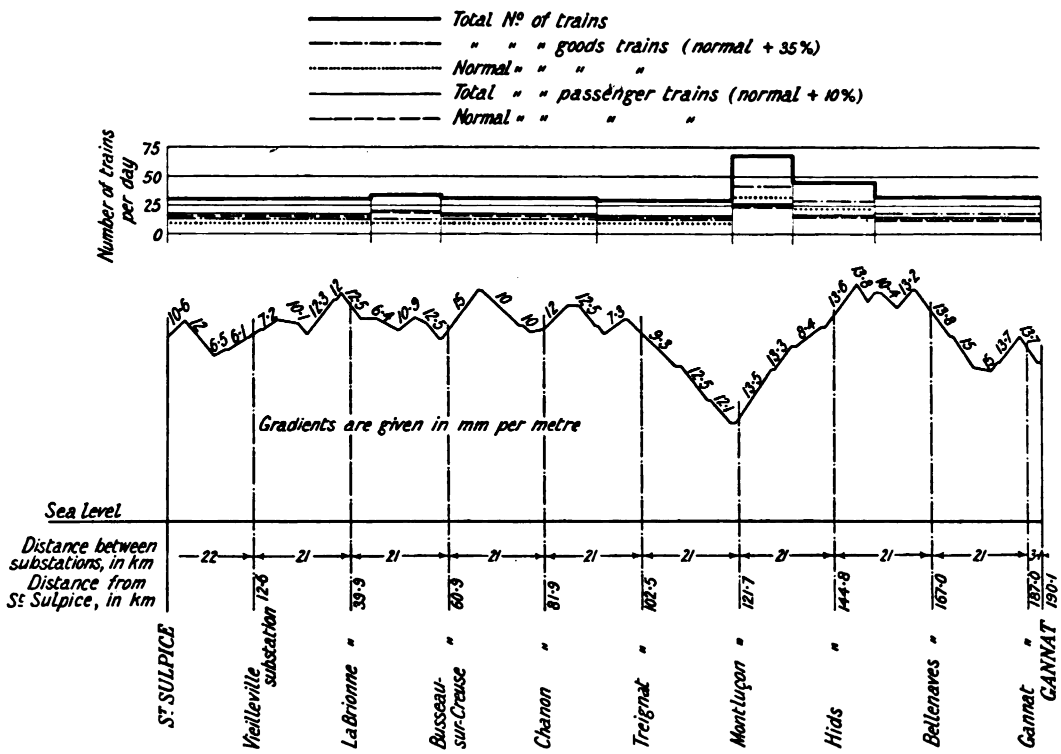

FIG. 6.—Traffic and longitudinal section of the line from St. Sulpice to Gannat.

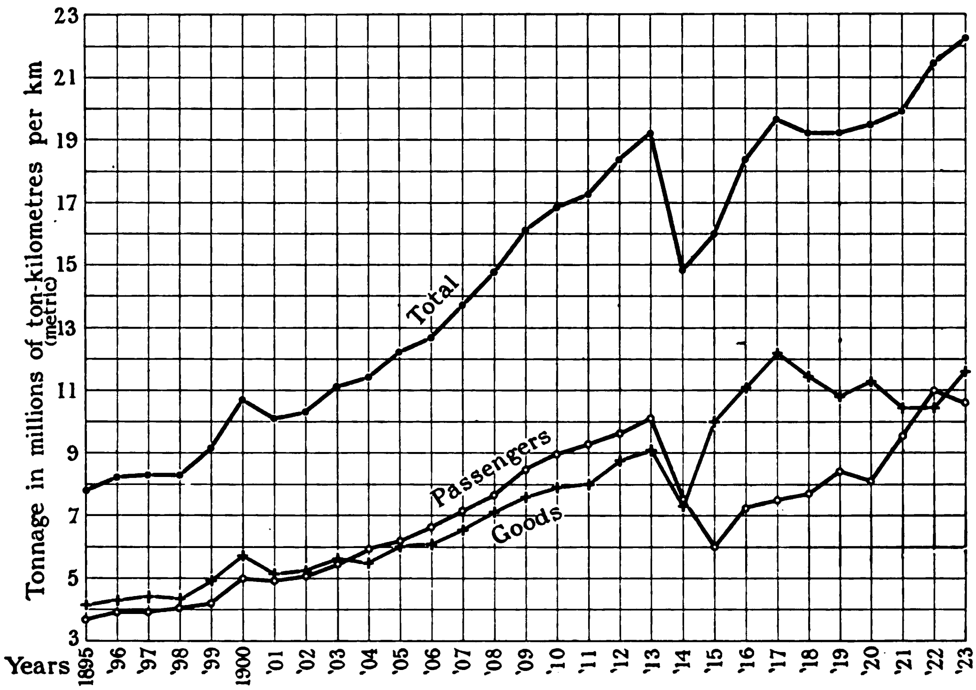

FIG. 7.—Growth of traffic on line from Paris to Orléans.

Electrification of the Paris–Vierzon Section.

Generation of electrical energy.—The electrical energy is generated as three-phase alternating current in a system of power stations comprising at present:—

(1) The steam-power stations of the Paris district, namely the Gennevilliers power station (250 000 kW) * and the Vitry power station (80 000 kW) of the Société l'Union d'Électricité.

(2) The water-power plant of Eguzon on the River Creuse, which has a capacity of 50 000 kW and belongs to the Société l'Union Hydro-Electrique, in which the Orléans Company holds an interest.

(3) A group of water-power stations forming part of the concession granted by the State to the Orléans Company. These stations can supply throughout the year an average demand of 100 000–150 000 kW depending on their equipment. Two plants, those at Coindre (20 000 kW) and Chavanon (25 000 kW) are in course of erection. A third, that at Marèges of 100 000 kW capacity, is under consideration.

The unavoidable fluctuations in the output of the water-power stations will be completely compensated, in the case of the plants on the River Creuse, by the exchange of power between the Eguzon water-power plant and the Gennevilliers steam plant; and in the case of the Haute-Dordogne plant by means of the Chavanon reservoir and by the exchange of power with the Alpine hydro-electric stations. This method, which is rather complicated, is of special interest and reference will be made to it later.

Figs. 8 and 9 (lantern slides), from photographs taken during the course of erection, show the arrangement of the Eguzon and the Coindre plants.

Transmission of power.—The power generated in the various hydro-electric and steam-power stations will be transmitted as follows:—

At 13·5 kV by three three-phase cables, of 150 mm² section per phase, from the busbars of the Vitry steam plants to the Paris and Ablon substations of the Orléans Company.

At 60 kV by three groups of three single-phase cables, of 150 mm² section per phase, the pressure between each phase and earth being 35 kV, from the busbars of the Vitry power station (2 groups of cables) and from Gennevilliers (1 group of cables) to the busbars of the Chevilly substation of the Paris–Orléans Company.

At 90 kV by two three-phase overhead lines, of 238 mm² section (aluminium cable with steel core) and about 300 km (186 miles) in length, from the busbars of the Eguzon power station to those of the Chevilly substation, passing through the 15 traction substations situated along the line from Paris to Eguzon. These lines will be extended to Souillac to feed the seven substations which distribute current for traction between Eguzon and Brive.

* The power indicated in brackets is the capacity of the plant installed.

At 150/220 kV through an overhead line connecting the four transformer substations of Chevilly, Chaingy, Eguzon and Vernéjoux.

At 120 kV through a line connecting the power stations of the Central Plateau to the Alpine stations and following approximately the proposed line under consideration from Commentry to Saint-Germain les Fossés (new section of the Bordeaux–Lyons line).

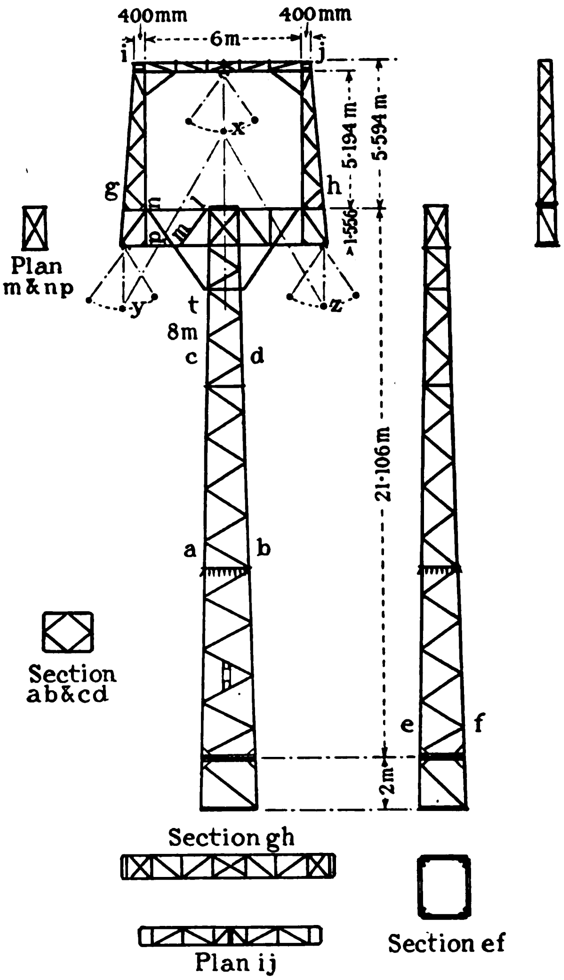

Fig. 10.—Straight-line and 2° angle-type tower for 150–220 kV transmission line.

Span = 250 m.
3 aluminium-steel cables (293 mm).
2 galvanized steel earth wires (60 mm).

Fig. 10 shows the general arrangement of the 90 kV and 150 kV towers, namely, the straight-line towers for 150 kV, the standard towers for 90 kV, and also special towers for the crossing of the River Loire at 90 kV. A view of the lines is given in Fig. 11 (lantern slide).

Transformer substations.—The transmission lines at 60 kV, 90 kV, 120 kV and 150 kV, will be interconnected through five transformer substations situated respectively at Chevilly, Chaingy, Eguzon, Vernéjoux and Commentry. The Chevilly substation connects the 60-kV

system of the Société l'Union d'Électricité to the 90-kV and 150–220-kV systems of the Orléans Company, by means of three banks of static transformers having a total capacity of 75 000 kW, namely: Two banks of 25 000 kW, transforming the current from 60 kV to 90 kV, or vice versa; and one bank of 25 000 kW transforming the current from 60 kV to 150 kV, or vice versa.

This substation is intended to receive later three further lines at 150–220 kV, and eventually two extra lines at 90 kV.

The Chaingy substation is a sectionalizing, transforming and regulating substation. It contains two banks of static transformers, each bank having a capacity of 20 000 kVA. These transformers, of which the two high-tension windings at 150 and 90 kV are star-connected, carry a third winding delta-connected at 6 kV. These 6-kV windings feed the synchronous condensers, each of which is able to supply a maximum reactive power of 10 000 kVA, the current leading or lagging according to the excitation. This substation is intended to receive, in the future, two 90-kV lines which are to be erected in the direction of Tours, and seven extra outgoing feeders at 150–220 kV.

The Eguzon substation connects the Orléans Company's 90-kV and 150-kV systems through the intermediary of the 10 000-volt busbars of the Eguzon power station. The substation contains three banks of transformers totalling 25 000 kVA, namely: Two for transforming from 90 kV to 10 kV; and one for 150 kV to 10 kV.

The plant for the Marèges and Commentry substations has not yet been ordered.

Fig. 12 (lantern slide) shows the general arrangement of the Chevilly substation which has been in operation since October 1924. Fig. 13 (lantern slide) is a view of the 60-kV switches in the Chevilly substation and the incoming underground cables from Gennevilliers.

Rotary transformer substations.—Three-phase current at 50 periods is transformed to direct current at 1 500 volts at 11 substations, representing a total capacity of 54 000 kW for the sections Paris to Vierzon alone (200 km, or 124 miles) and Brétigny to Dourdan (27 km, or about 17 miles). The plant consists of twenty-seven 2 000-kW sets of exactly similar type. Each set comprises two 1 000-kW 750-volt rotary converters connected in series.

Table 1 gives particulars for each substation of the capacity of plant installed and available at peak load.

Fig. 14 (lantern slide) is a view of the static transformers in the Aubrais substation. These comprise three 90 000/555-volt transformers feeding the rotary converters for the traction supply, each of which is rated at 2 000 kW and has a maximum ouput of 6 000 kW, and three 90 000/30 000-volt transformers for supplying the power and lighting requirements of the district.

Fig. 15 (lantern slide) shows a general view of the Etréchy substation in which transformers having a total capacity of 6 000 kW are installed for the traction supply.

Contact conductor.—Direct current at 1 500 volts is distributed along the track by means of compound catenary lines having a double contact wire. The poles are placed on alternate sides of the track and are spaced 64 metres (210 ft.) apart.

The main supporting cable is of phosphor bronze of 116 mm² section. The other cables are of electrolytic copper of the following cross-sections: auxiliary carrier 104 mm²; contact wires 107 mm².

Fig. 16 (lantern slide) is a view of the lines in the 4-track section from Paris to Etampes; whilst Fig. 17 (lantern slide) shows the lines at the entrance to Juvisy station.

On the suburban section from Orsay to Brétigny a third rail,* used also as a feeder, is provided in addition to the overhead line. The shape and method of support of the third rail are shown in Fig. 18. Beyond Brétigny the carrying capacity of the catenary line is increased by means of a copper feeder of 240 mm² section.

ROLLING-STOCK.

The suburban trains consist of motor coaches and trailers, whilst the main-line trains, both passenger and goods, are made up of the ordinary rolling stock hauled by electric locomotives.

Motor coaches.—Each motor-coach multiple-unit train consists of one, two or three power units, each unit comprising an electric motor coach weighing 65 tonnes and two bogie-type trailers each weighing 34 tonnes, the total weight of the train therefore being 133 tonnes. Each motor coach is fitted with two independent bogies, and each bogie carries two 250-h.p. 750-volt motors which are permanently connected in series.

An order has been placed for 80 motor coaches, from which 25 multiple-unit trains of three units each will be formed for the suburban service. At present eight motor coaches are in service, some at 1 500 volts and others temporarily at 600 volts on the old electric traction system.

Locomotives.—Goods and passenger trains rated for

* Experience has shown that this third rail allows current to be collected with certainty even in the winter. Owing to two neighbouring tracks being provided with third rails having the ordinary type of surface contact, it has been possible to make definite comparisons, with the above-mentioned result.

speeds lower than 75 km per hour are hauled by double locomotives comprising two units. Each unit, or half-locomotive, is supported on two bogies, and each bogie carries two 1 500-volt motors with forced ventilation. Each motor has, depending on the type, a one-hour rating of from 375 to 430 h.p. and a continuous rating of from 300 to 375 h.p. The unit is designated by the symbol " BB + BB."

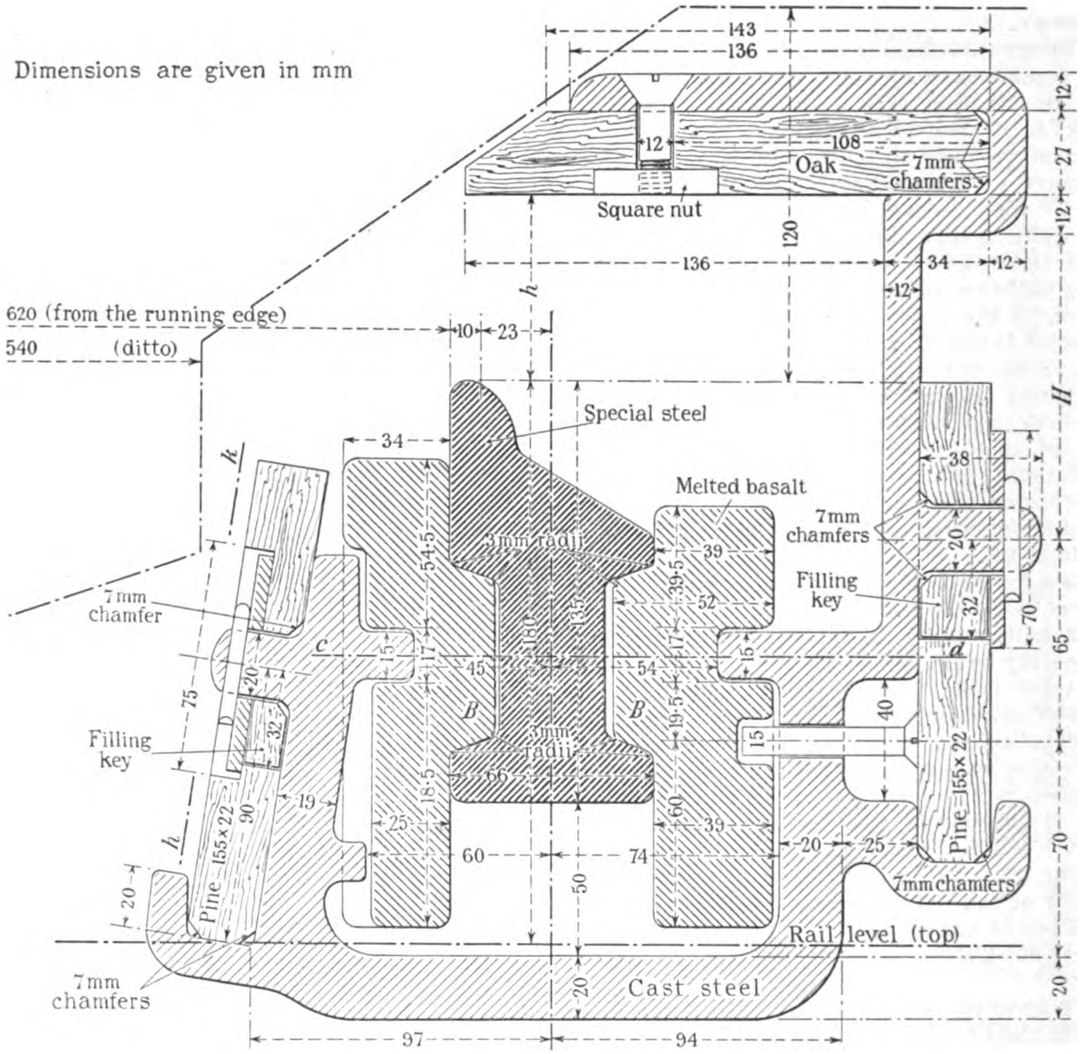

FIG. 18.—Contact rail.

200 half-locomotives have been ordered, and more than 50 of these have been delivered and are under test or in operation on the electrified lines.

Express trains, that is trains having a nominal speed higher than 65 or 70 km per hour, are hauled by special locomotives of slightly greater power than the double goods locomotives, but of lighter construction and specially designed for attaining high speeds.

Five experimental locomotives have been ordered, three of which have been delivered and are under test and adjustment. One is a gearless locomotive of the type " 2C + C2," having a one-hour rating of 2 700 h.p. and capable of developing 2 100 h.p. continuously. Two of the locomotives are of the type " 2D2 " with connecting-rod drive, and have a one-hour rating of 4 000 h.p. and a continuous rating of 3 500 h.p. One of these is fitted with " hyperstatic " connecting-rods and motors of the usual type, whilst the other has " isostatic " connecting-rods, flexible couplings and fully compensated motors. The other two locomotives are of the type " 2D2 " with outside gear-drive and small connecting-rods, and have a one-hour rating of 3 600 h.p. and a continuous rating of 3 000 h.p. One of these locomotives is provided with standard running gear and motors, and the other with adjustable articulated running gear and fully compensated motors arranged for regeneration.

Figs. 19, 20 and 21 (lantern slides) show a gearless locomotive, a locomotive with connecting-rods, and a locomotive with external gears respectively.

APPENDIX.

The Composition of Electric Locomotive Rolling-Stock.

There is one question of general importance to which the author would like to draw the attention not only of electrical engineers but more particularly of railway engineers, namely, the composition of the electric locomotive rolling-stock necessary to operate a given service. In using the term "a given service" the author intentionally makes a mistake, against which he would like to warn all those who may have to study the question but who have had experiénce of steam or electric traction only on tramway or underground systems. If the service to be maintained were definitely settled, it would be sufficient to replace each steam locomotive by a corresponding electric machine, which would be capable of hauling, on a line having a given longitudinal section, the same weight of train at the same speed as the corresponding steam unit.

Assuming that the problem is put in this form, it is easy to show that the weight of the electric locomotive is always less than the weight of the corresponding steam engine (excluding the tender). The difference in weight depends much more on the type of locomotive than on the nature of the current used; and when we take, for comparison, machines of the tramway type with two motor bogies, so that we have a large number of motors of small power, we are considering the most unfavourable case for electric traction.

Anything we may say regarding the specific power of machines of the type B + B or C + C is thus equally applicable to machines having a small number of powerful motors, taking into consideration the large reduction in weight owing to the better utilization of material in powerful motors having a large number of poles.

Even for types BB and CC it is possible to build machines at 1 500 volts weighing less than 50 kg per horse-power of continuous rating. This is, for instance, the case with machines BB 101–180 of the Orléans Company weighing about 75 tonnes and capable of giving a continuous output of 1 500 h.p. (one-hour rating, 1 720 h.p.) With high-power locomotives like those of the connecting-rod type 2D2 of the Orléans Company a continuous output of 3 500 h.p. is obtained for a total weight of 130 tonnes, or about 37 kg per horse-power (continuous).

In steam engines of European manufacture, although the continuous output is much less well-defined than in an electric locomotive, we might say that it is difficult to go below 55 kg per horse-power, excluding the tender. Therefore, if we admit that for equal sustained power the weights of electric and steam locomotives are the same, we make an error which is altogether to the advantage of steam traction.

This first point being established, it is easy to show that in comparing their normal running characteristics the machines under consideration are suitable for the same service.

Fig. 22 shows the curve of maximum sustained output for a steam locomotive of the Mikado type having $4 \cdot 31$ m^2 of grate area and weighing, without its tender, 82 tonnes unloaded and $91 \cdot 6$ tonnes loaded. It is known that this curve is the envelope of a series of curves representing the tractive effort as a function of the speed, and is hyperbolic in shape.

The electric locomotives of the series BB 101–180 have been so constructed that when connected in parallel, corresponding to running with full field and with 40 per cent of full field respectively, the combined characteristic is similar to the output curve of the Mikado locomotive.

Examination of Fig. 22 shows, in addition, that curve C, representing the tractive effort which can be sustained indefinitely without undue heating of the motors, passes very close to the point of intersection of the characteristic for the BB locomotive at full field and that of the Mikado locomotive.

For speeds ranging from 50 to 70 km per hour the electric locomotive will thus be able to develop indefinitely a drawbar pull greater than that which can be obtained for a considerable period from a steam engine. By decreasing the gear ratio it would be possible to increase the power available at high speeds from the electric locomotive and to show a still greater superiority over the steam locomotive.

At starting, the electric locomotive, which is of the total-adhesion type, will be able to develop a tractive effort higher than, or at least equal to, that of the steam locomotive, which has generally some non-coupled axles; in fact, in the case in question the weight on the driving wheels is slightly lower for the Mikado locomotive than for the BB locomotives.

We have, therefore, grounds for saying that for equal weights a direct-current locomotive can, even if considered from the most unfavourable aspect, replace a steam locomotive, its adhesive weight being in general higher and its power always considerably greater.

Assuming, to facilitate comparisons, equal weights, the first costs of the rolling stock will be:

$$\Sigma NPp \text{ for steam traction, and}$$
$$\Sigma N'Pp' \text{ for electric traction,}$$

where

N = number of steam engines,
N' = number of electric locomotives,
p = cost per kg of steam engines,
p' = cost per kg of electric locomotives, and
P = weight of locomotives, whether steam or electric.

In general, the cost of the tender is one-quarter of the cost of the locomotive, its weight being about $0 \cdot 5\, P$ and the price per kg about $0 \cdot 5\, p$.

The total cost of the steam engines in working order will therefore be $1 \cdot 25\, Pp$.

For high-tension direct-current machines the cost p' per kg of the electric locomotives is about 70 per cent higher than p. Notwithstanding alterations in economic conditions, this ratio, $1 \cdot 7$ to 1, seems to have remained constant, being the same before and after the war.

In order that the cost of construction of electric rolling stock shall be less than that of steam rolling-stock, it is necessary to have

$$\Sigma N'(1 \cdot 70 Pp) \leq \Sigma N(1 \cdot 25 Pp)$$

or

$$\Sigma 1 \cdot 36 N'Pp \leq \Sigma NPp$$

This condition will be satisfied in every case if the average mileage of the electric locomotives exceeds by 36 per cent the corresponding mileage of the steam locomotives.

Electric locomotives being always available, except in the case of repairs, their average mileage is considerably higher than that of steam locomotives, the tubes of which must be periodically scraped and the clinker removed from the fire grates. It appears, therefore, that the first cost of electric locomotives will always be less than that of steam locomotives if we assume that the two types of rolling stock have equal " useful service capacities."

In investigating as a whole the electrification of the system, the problem takes, however, an entirely different form. It is not a question of ensuring a clearly defined service, or of knowing what certain steam locomotives can do, in order to try to do as well or better electrically: it is really a question of ascertaining what is the general tendency as regards methods of operation on European railways, in order that provision may be made for the probable service conditions in future, taking into account the effect which electric traction may have on the operating methods themselves.

One might discuss at length the speed and extent of such developments, but the author thinks that he is not going too far in assuming that still heavier and still faster trains will be used in the future. Indeed, he considers that great developments in that direction would already have been made if the horse-power of a steam engine had not been limited by the boiler, the dimensions of which would seem to have practically reached their limits.

All the European railway systems are now taking steps to strengthen their carriage and wagon couplings, and within a short time some systems will consist only of vehicles fitted with 70-tonne standard couplings. Such apparatus would appear to allow a sustained tractive effort of about 20 000 kg. Already in Sweden and Norway, with special material, locomotives able to develop a sustained drawbar pull of 27 000 kg are used.

The application to goods trains of automatic brakes—at present under consideration in all European countries, and in use in a few—will allow the practical use of longer and heavier trains than those foreseen at the present time.

In accordance with a more or less settled programme, work is in progress everywhere in connection with the reinforcement of the track, with a view to allowing an increase in axle loads and in average speeds, without there being any necessity for exceeding the maximum speeds of 120 to 130 km per hour now obtainable with steam locomotives. Already in Switzerland, as in France (Paris–Brive line), it has been possible to increase to 20 tonnes the maximum load per driving axle of the electric locomotives, thus enabling us to obtain :—

Exceptional and momentary tractive efforts of 20 tonnes × 25 per cent, i.e. 5 000 kg per driving axle, using sand if necessary at starting ;

Sustained efforts (one-hour rating) reaching 12 to 16 per cent of the adhesive weight, according to the gear ratio, i.e. 2 400 to 3 200 kg per axle ;

Continuous efforts (continuous running) of 9 to 12 per cent of the adhesive weight, i.e. 1 800 to 2 400 kg per axle.

The feasibility of the above developments naturally points to the use of locomotives similar to those designed by the Orléans Company, leaving out of consideration the special suburban service, for which multiple-unit motor-coach trains will provide not only an increase in speed and comfort, but more particularly a valuable increase in the capacity of the Quai d'Orsay terminus.

Goods locomotives.—For goods trains, the nominal speed of which is never anywhere higher than 55 km per hour and frequently falls, as in the United States, to 25 km per hour, there is no reason why total-adhesion locomotives should not be used systematically.

Experience having proved that it is possible, by adopting forced ventilation, to construct motors having a continuous output of 300 to 400 h.p. (1 800 to 2 400 kg at 45 km per hour), there is really no reason why, on account of the facilities it affords for maintenance and repairs, the tramway type with 4-wheel or 6-wheel bogies should not be adopted, notwithstanding its higher price and weight.

For these reasons, on the chief railway systems in France, namely the Ouest-Etat, the Midi and the Orléans Railways, type BB total-adhesion locomotives have been adopted, with free bogies in the case of the Ouest-Etat and most of the Orléans locomotives, and coupled bogies for the Midi Railway and some locomotives of the Orléans Company.

On the Orléans Railway the normal goods-train locomotive comprises two type BB machines coupled together, and such a double locomotive will be able to develop a continuous effort of about 20 000 kg at 45 km per hour.

On the line from Paris to Orléans most of the goods trains, the average weight of which is over 700 tonnes, can be hauled by one BB machine, the use of the two-unit normal locomotive being reserved for the heaviest trains, in which case one crew drives the two half-locomotives from a single control position.*

Although these locomotives have no bogies or bissel-trucks, they have run on the three systems at speeds as high as 100 km per hour without undue effect on the track or material. This is not surprising, as the old 50-ton BB machines of the Orléans Company, built in 1899, attained about 20 years ago speeds higher than 100 km per hour on the line from Paris to Juvisy.

On certain American tramways, as well as on some French suburban lines, speeds of over 100 km per hour are attained daily with type BB electric motor coaches of 12 to 20 metres length, and it is of interest to recall the well-known Zossen experiments made in 1901–1902, when speeds of 200 km per hour were reached with electric motor coaches of the total-adhesion tramway type with two motor bogies of the 4- and 6-wheel type.

The stability of high-speed type BB machines is such that there is a possibility of extending their use

* The Orléans Company has also had under consideration the question of using double trains formed by coupling together two half-trains of 500 to 700 tonnes each, and of having two locomotives, one in front and the other in the middle of the train. Tests have also been made, with very encouraging results, with a view to the installation of a control system in which distant control can be effected by means of high-frequency currents (3 000 to 10 000 periods per second) superimposed on the traction current.

to the hauling not only of slow trains, but also of a certain number of express trains running at nominal speeds of 70 to 75 km per hour (maximum speed, 100 km per hour).

High-speed locomotives.—It is just as difficult to determine the type of high-speed locomotives as it is easy to settle the type for goods and ordinary traffic. At the present time, nowhere in the world is there a high-speed electric service for passenger traffic, and the tests made on certain systems, although very interesting, only supply incomplete information as to what may be expected from electric tractors.

an electrified line as possible. For the present, as there was available only about 60 km of 4-track line for our tests, we have been able to obtain information merely in regard to the general operating conditions of the locomotives, running stability, smoothness of the transmission system, and output of the locomotives in practice; and it will be necessary to wait several months before we are in a position to make a final choice between the various types of machines tested.

The author proposes here merely to indicate how these locomotives have been designed, as regards their power and their electrical characteristics, and he con-

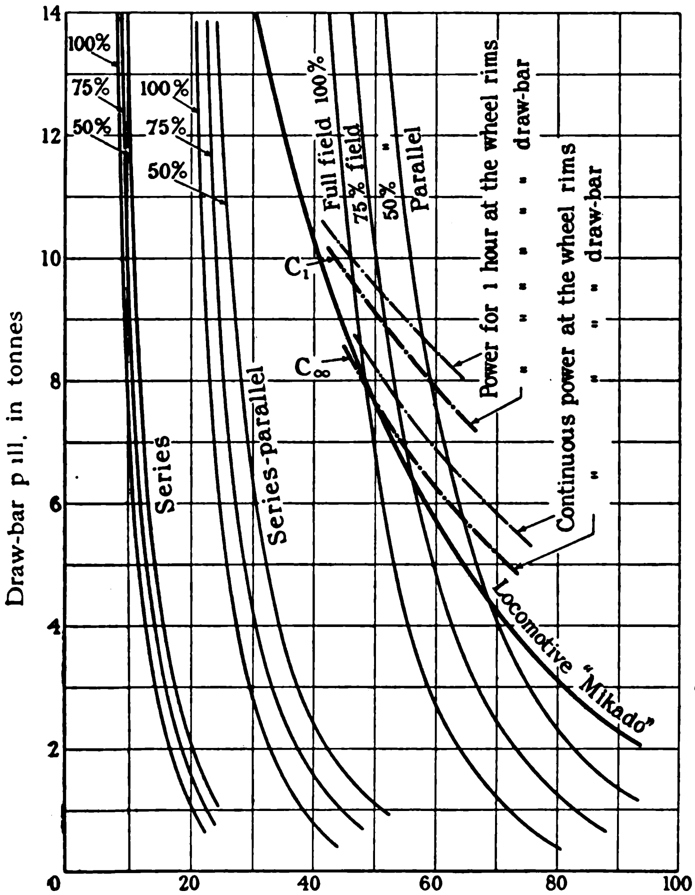

Fig. 22.—Curves showing drawbar pull and motor characteristics at 1 350 volts for locomotives of type EBB 101–180.
Gear ratio = 3·47. Diam. of wheels = 1 350 mm (53 in.).

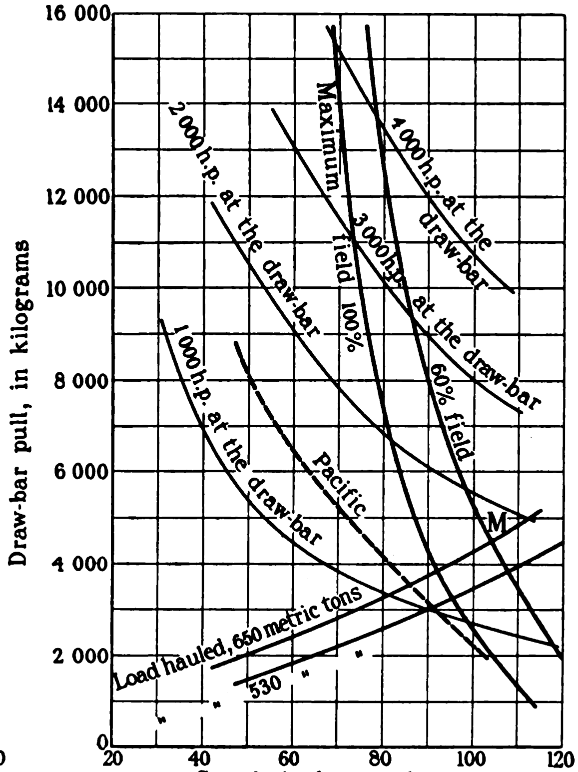

Fig. 23.—Curves showing drawbar pull of high-speed steam and electric locomotives.

At the present time, to speak only of French railways, express steam trains are running on the Nord, Est, P.L.M. and Orléans systems at average speeds of 95 to 100 km per hour, and the steam locomotives run distances of from 300 to 400 km without any stop being necessary.

The high-speed electric locomotive, as we conceive it, must, however, be able to maintain for the same maximum speed a higher average speed than the steam engine and over much greater distances, such as 600 to 1 000 km per day.

The problem thus defined can be solved only by arranging for time tests on regular services for as long

siders it preferable not to go further into their mechanical characteristics, the arrangement of the tracks, and the transmission system (which differs for different machines). He would refer interested engineers to his paper, mentioned on page 893, which is to be published in the *Revue Générale des Chemins de Fer*.

The tractive effort and the speed characteristics which have been decided on are about the same for the four locomotives of the type 2D2. Their construction has been governed by the conditions which allow a train of 650 tonnes to be hauled on the level and in a straight line at a speed higher than 100 km per hour. As the

maximum weight now accepted on the Orléans system for express trains is about 530 tonnes, we believe that sufficient provision has been made for any future requirements.

Fig. 23, in which curves have been drawn representing the tractive efforts necessary to haul trains of 530 and 650 tonnes at various speeds, also shows the running characteristics of locomotives of the type 2D2 of 3 500 h.p. continuous output with maximum field (100 per cent) and reduced field (60 per cent). The latter curve goes through the point M of the resistance-output curve of the 650-tonne train, corresponding to 104 km per hour.*

In the same figure has been drawn, for comparison, the curve representing approximately the maximum tractive effort at the drawbar hook of the tender of a Pacific engine of the Orléans Company weighing (including its tender) approximately the same as the connecting-rod electric locomotives of the type 2D2.

The comparison of these characteristic curves shows that for all speeds from 90 to 110 km per hour the useful power obtainable continuously at the drawbar hook of the electric locomotive is about 2·5 times greater than that obtainable at the drawbar hook of the tender of the steam engine.

For lower speeds the difference would be still greater, as the motors of the connecting-rod locomotive can supply continuously about 3 500 h.p. at speeds from 70 to 85 km per hour.

A very important margin of power has been provided, which enables tractive efforts of about 10 000 kg at 80 km per hour to be obtained at the hook, in order to be able to maintain that speed on the 1 per cent up-grades which are encountered rather frequently south of Limoges on the Paris–Brive line. Already, with a locomotive fitted with outside-gear drive and weighing 116 tonnes, we have been able to haul between Paris and Etampes a 650-tonne train at 120 km per hour, and at this speed the locomotive runs with a smoothness comparable with that obtained with the best bogie coaches.

Fig. 24 shows two records obtained at high speed with the Hallade recording apparatus, one on locomotive 2D2–501, and the other on a 4-wheel bogie coach. It is hardly necessary to draw attention to the fact that it is impossible, on account of the amplitude of the pendulum blades, to take similar diagrams in front of the engine of a Pacific locomotive without damaging the apparatus.

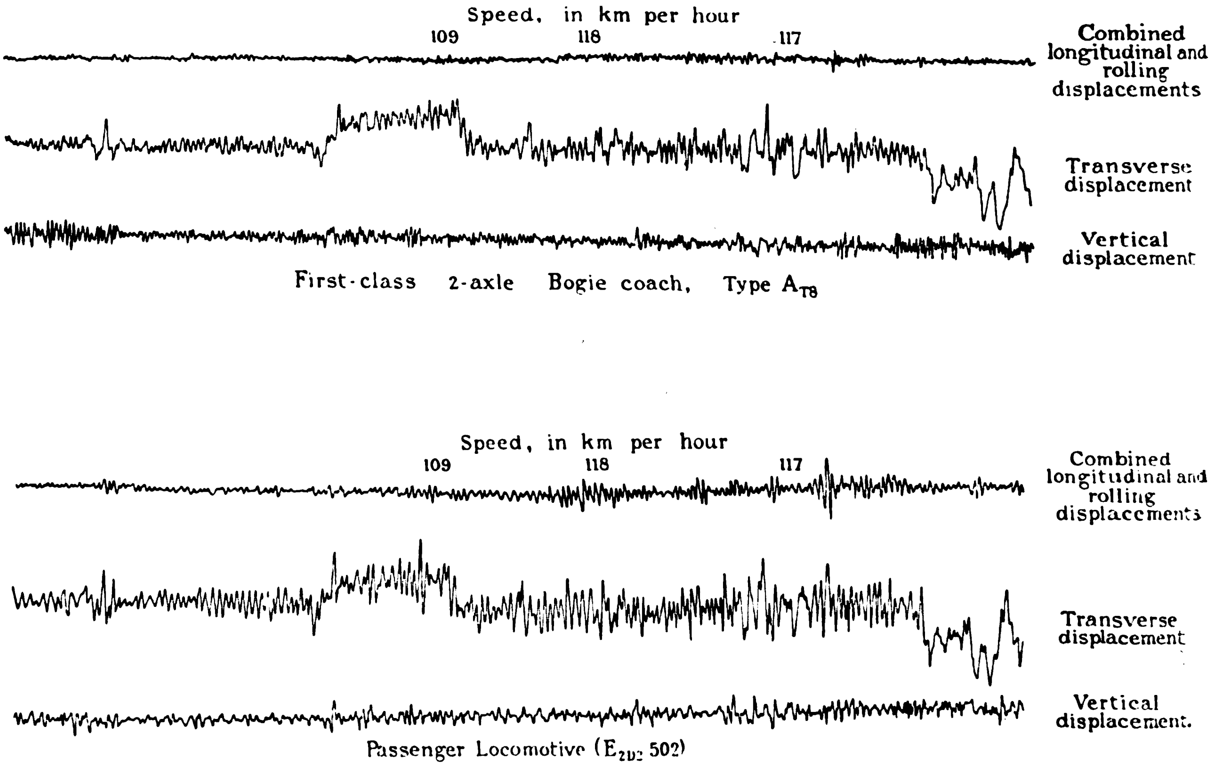

FIG. 24.—Records obtained using the Hallade apparatus.

From tests made with other types of machines, on the Orléans Company's tracks or on the tracks of manufacturers, it may be hoped that all the machines tested will comply with the electrical and mechanical conditions set forth in our specifications, and it is almost certain that all the transmission gears under consideration have proved, or will prove, satisfactory on official tests. Encouraging as they may be, however, these tests will not allow us to make a final choice between the various types under consideration until each locomotive has run a distance of between 100 000 and 120 000 km (62 000 to 75 000 miles), which in our opinion is the average mileage we should obtain per annum from a high-speed electric locomotive.

* Attention must be drawn to the fact that if we know merely the position of the point M, we can almost completely define the characteristics of the motor with reduced field (60 per cent) and maximum field (100 per cent) for small changes, due in direct-current motors to variations of the saturation and of the air-gap.

DISCUSSION AT A JOINT MEETING OF THE INSTITUTION AND THE BRITISH SECTION OF THE FRENCH SOCIETY OF CIVIL ENGINEERS, 18 FEBRUARY, 1926.

Mr. Roger T. Smith: If a diagram time-table be drawn, the ordinates being time and the abscissæ distance, dotted lines representing goods trains and full lines passenger trains, it is clear that where there are two sets of trains, one running at less than half the speed of the other, the greater the parallelism of the sloped lines representing the high and low speeds, the more trains can be put into that time-table. Ideally, to get the greatest use out of a given investment in the permanent way and stations, all the time-table lines should be parallel, but of course this is never possible. The steam locomotive is a constant-output machine, and a characteristic curve of the Orléans Mikado locomotive, of which the English equivalent is the 2–8–2, is given in Fig. 22. That shows, as compared with the BB electric locomotive, which is standardized in France for goods and slow traffic, that an increase in drawbar pull results in a very much greater decrease in speed in the steam locomotive than it does in the electric locomotive. Between 5 tons and 14 tons of drawbar pull, as shown in Fig. 22, there is a comparatively small decrease in speed in the electric locomotive, i.e. from 60 to 45 miles per hour; whilst for the same range of drawbar pull—that is, from 5 to 14 tons—there is in the corresponding steam locomotive a fall of from 40 to 15½ miles per hour. Special design can reduce the electric drop in speed if necessary. As an ideal which might be realized, if all the fast traffic ran at 100 km per hour (62 m.p.h.) and all the slow and goods traffic ran at 70 km per hour (40 m.p.h.) many more trains could occupy the line than is the case with steam haulage, and the boiler of the steam locomotive to do this, if it were possible to make it, would be very uneconomical. Electric traction gives railwaymen the opportunity of considerably increasing the traffic on congested parts of their main lines, and it is this aspect of the advantages of electric traction which is really important—the fact that the speed of the slow traffic can be so increased as to make the occupation of existing lines much greater with electric traction than with steam traction. It is a point which should be emphasized and driven home to the traffic officials and the management of our railways. The author has explained the reason which made France intent on preventing the import of coal as far as possible and designing hydro-electric stations and water storage for a combined supply for railway electrification and for industrial and domestic use. The seasonal variations in output of the hydro-electric stations supplied by rivers in the Central Plateau are largely balanced by the opposed seasonal variations from the stations in the Alps, which take their water from the melting of glaciers and of snow in the summer. This balance is incomplete, however, and the deficiencies are made up by steam stations in Paris which are interconnected with both types of hydro-electric stations already mentioned. This interconnection in France is essential, but is enormously costly, and would never be undertaken, I venture to think, if it could be avoided. The interconnectors feed the railways all along the route, but for industrial supply there is nothing between Brive and Paris except the town of Orléans. Just now in this country, when it is rumoured that a large system of interconnection of steam stations is proposed, and where there is little difference in the shape of the annual and daily load curves, the French problem is, I think, particularly interesting to us. All interconnection has to be paid for, and there is a natural form of interconnection when the transmission lines of two systems spread until they meet. Interconnection is then obvious, and the interconnector supplies load along its length. Some people in this country, however, hold a theory that there is economic merit, as well as technical merit, in what I may call idealistic interconnection as opposed to natural interconnection when two great centres of electric production in different areas are linked up by cables able to transmit large loads. I very much doubt if the economy of this has ever been proved.

Lieut.-Col. H. E. O'Brien: The author refers to the tonne-km per kilometre. It is important to know whether these tonne-km are gross tonne-km, including the weight of the locomotive, or whether they are net tonne-km, merely the weight of the train behind the locomotive. In discussing electrification problems it would be of great assistance if these densities of traffic could always be expressed more definitely as net or gross tonne-km per track mile, it being defined clearly whether or not the track mile includes the mileage of sidings: it is a matter of great interest to know the ratio between the amount of sidings and the amount of main-line track which has to be electrified, for this has a very important bearing on the cost of the electrification. In the Appendix the author shows that the charge for electric locomotive stock is not a capital charge; in fact he shows that for equal services the electric locomotive costs less than the steam locomotive. If the electric locomotives are provided on renewal account in the course of normal renewals—which, of course, would be the sound financial policy to adopt, even though it may temporarily involve a heavy overdraft on the renewal fund—the cost of the renewals ought always to be based on the provision of haulage capacity equal to that of the steam locomotives displaced. If, in making the renewals, the haulage capacity of the locomotives is increased, the capital is actually being increased. Therefore, if for equal haulage capacity the electric locomotive costs less than the steam locomotive which it replaces, it appears to me that there can be no question of there being any capital expenditure in connection with that part of the electrification. If, in addition, current is purchased from an external source and supplied to the railway, the sole capital charge that arises in connection with electrification is the capital charge in connection with the equipment of the track. I should like to ask the author, in

connection with the very high voltages employed for feeders, what precautions have been taken in regard to communication services—telegraphs and telephones. At what distance from the telegraph lines has it been considered necessary to run the high-tension lines, and how far in general are they from the railways? In connection with the locomotives, it would be of the greatest interest to see the result of the author's experiments. He is rendering a very great service to the electric traction industry in making these extensive experiments with such different types of locomotives. It is probable that the type which does not employ connecting rods of the large type will be the most successful, apart from certain other limitations which the outside-gear type has in regard to gear ratio. It has been emphasized a good many times in discussions on electric traction in this country that where there are brasses there are fitters, and fitters mean maintenance. Anybody who has seen the results obtained on locomotives similar to the 2D2 type will be inclined to think that that type will prove to be the best. It would also be of interest if the author would say something about the anticipated cost of current in his reply, because there is a general impression that electricity generated by water power is extraordinarily cheap compared with electricity generated by coal. That is not necessarily the case, at least at the point of delivery to the track, and it would be a pity if it was thought generally that these electrifications in France were merely due to the fact that there was extraordinarily cheap water-power-generated electricity available. It is credible that the third rail fulfils its function admirably, but it seems to be a very complicated and expensive design compared with the recent under-contact third-rail designs, which have a very much simpler type of guarding and are equally effective in protecting the rail against snow and ice, and also in protecting the staff against danger of shock. The author seems to have demonstrated very clearly the immense superiority of the electric locomotive over the steam locomotive. One is almost tempted to say that the electric locomotive is as superior to the steam locomotive as the steam locomotive in its early days was to the stage coach.

Mr. F. Lydall: One of the principal questions referred to by the author is whether an electric railway scheme should draw power from its own power station or whether it should rely on the general power supply of the country or of the area through which the railway runs. The author has mentioned various countries in which the practicability of drawing from the general supply is more or less excluded, and he has mentioned other countries where the conditions make it quite feasible to take power from the general source. In this country, opinion is not quite unanimous on the matter. I may put the position like this. Many railway engineers feel that security of supply is of the first importance and that the actual cost of power comes second. There is no doubt that that is a very important consideration from the railway point of view. They are charged with transport, and it is essential that they should make absolutely sure, so far as is possible, of security of supply. On the other hand, there is no doubt that there are advantages, financial and general, in taking the supply from a general system; but it is essential that the management of that general system should be absolutely sound, the reliability unassailable and the commercial, technical and financial position of the supply undertaking beyond reproach. There are also advantages quite outside the question of the position of the railway in the matter of taking the supply from the general source. Some of these are referred to by the author. There is no doubt that the combination of a railway load with the general load is to the good of the country at large. The author has really set out these two alternatives in his paper, and he has shown us the way in which the Orléans Railway has solved the problem. It has not only its own power station, but is also taking supply from the general source; in fact it has set itself up as part of the general system. This is a very bold and interesting method of attacking the problem. The circumstances, of course, must differ in every country, and the conditions in France which have led up to this solution are perhaps quite peculiar and do not necessarily apply to other countries—certainly to this country. There is another point about this description, namely, the very great extent of the electrification scheme. This has a marked effect upon the point I have just been mentioning, namely, the general question of power supply. There has been in the past a good deal of tendency in this country to regard electrification of railways as something to be nibbled at. "Let us electrify a bit of main line first. We will deal with a section of 30 or 40 miles, and if we get good results out of that we can go on with another 10 or 20 miles," and perhaps in the time of our grandchildren we shall get to 200 miles. The drawback of that method is the probability that the first 30 miles will not show any advantage, and that will be the end of it until someone points out that the problem is being tackled in the wrong manner. The Orléans Railway has started off with a very big scheme, which will enable the advantages to be reaped at once. There are many difficulties in getting the full advantage of electrification schemes on a small scale. In the first place there are traffic disadvantages, and in the second place there are the disadvantages in regard to cost of power and of all the plant which must be used on rather a small scale. Therefore I think that this particular railway-electrification scheme is an example to many as to how electrification matters should be dealt with. It is not always realized that the power demand in electrification schemes is comparatively small. The position is that for any particular scheme the kilowatt demand is very small and not necessarily a very attractive proposition to put before a supply undertaking. In regard to the scheme referred to in the paper, the estimated annual demand is 400 million units, with a maximum demand of 80 000 kW. That 80 000 kW must be a fairly steady demand. It is made up necessarily of the demand of a large number of comparatively small individual units taking power intermittently. This question of the intermittent demand is a very important one in railway-electrification schemes. There is a modern tendency to increase the size of railway trains. A railway train necessarily is less expensive to run from the staff point of view if it is

increased to its maximum capacity. That in itself means that the power demand for a single railway train is as much as can be practically utilized on a single unit, and for any given traffic the number of units is reduced to the minimum. This leads to large and frequent variations in the demand for any scheme. For instance, it is not at all uncommon in schemes to find that at a moment's notice 3 000 or 4 000 kW is thrown on or off. It comes to this—that for a comparatively small scheme the intermittency of the load is, or would be, a serious matter if the demand had to be supplied from a single station erected for the purpose. Where the supply comes from a large organized system of general supply, such fluctuations are of relatively little importance. As an illustration, I may quote some figures which I have recently obtained from a main-line electrification scheme. The average demand over a single week was 9 500 kW. The sustained maximum demand was 17 000 kW, and the 2-minute maximum 25 000 kW. This was a main-line scheme in which the traffic was constantly flowing throughout the day and night; it was not like a suburban scheme in which the traffic was all bunched up in a few hours. A diversity factor of nearly 3 is very undesirable. There are a few points in regard to the traction part of the paper which I should like to mention. In Fig. 5, which shows the number of trains on various parts of the system, and also other figures showing the number of trains on the branch lines, there are certain peaks; that is to say, in certain parts of the line there are more trains than others and, so far as I can see, those peaks seem to occur where the gradients are severe. I am not quite sure whether that indicates that heavy trains are broken up at those points into two parts and taken up separately, or whether it indicates local traffic which does not travel beyond the limits of a suburban system at that point. In the Appendix the author gives details of horse-power and weights of locomotives, but I think it is inadvisable to lay too much stress upon this point. There can be at present no standard value of tons per horse-power. It depends largely upon the duty of the locomotive. The locomotive may have to haul very heavy goods trains at comparatively low speeds, and will have to deal with very heavy drawbar stresses and so on. On the other hand, it may be a comparatively high-speed locomotive with a small draw-gear strength and a comparatively high horse-power. The details have to be taken into account. In some cases it is necessary to increase the weight by means of cast-iron ballast in order to give the necessary adhesion. When the various details of the locomotives to which the author refers in the Appendix are available, they will be a valuable assistance in the direction of arriving at a sort of general standardization system for locomotives—not depending on the weight per horse-power but upon the duty they have to perform in several different ways.

Mr. F. W. Carter: One of the most valuable points about this paper is that it deals with an ordinary railway. Most of the problems with which we have hitherto had to deal in connection with electrification of railways have been in some way special; some exceptional difficulties have induced the electrification. In some countries, such as Sweden and Switzerland, it is a question of shortage of fuel; in others it is a question of dense urban traffic, such as we get around all our big cities. In others again it is a question of heavy gradients—the Norfolk and Western Railroad, the Virginia Railroad, the Chicago, Milwaukee and St. Paul's Railroad may be quoted as examples of this. Sometimes, as in the Detroit River Tunnel and Mt. Cenis Tunnel electrifications, it is a question of long tunnels in which the noxious gases are troublesome. The Orléans line, however, is a plain normal section of line, without any of these exceptional features. It might be a section of the London, Midland and Scottish Railway, and its working is exactly the kind for which the steam locomotive was developed, in which it is seen at its best, and in which, in the opinion of many railway engineers, it is still without a rival. If this electrification proves an economic success, it will have been attained under conditions which apply to a great part of the world's railways. If it can be made a success it should provide a big impetus towards general electrification. What is the chief obstacle to electrification under the conditions of this country? It is the great capital burden of electrification. No one is willing to make a start when there is so much capital involved. The French railway engineers have shown the way of meeting this to a large extent by taking the burden of generation and transmission from the railways and including it in the ordinary industrial electrification of the country. This seems to me a step in the right direction, particularly as the railway load is an advantageous one to mix with the industrial load on account of its good load factor.

Mr. A. M. Taylor: I have already, in the discussion at Birmingham,* emphasized the supreme importance of employing the very highest voltage in long-distance transmission, and French railway engineers are to be congratulated upon their appreciation of this all-important factor. I have also pointed out that unless powers of the highest magnitude, transmitted at the very highest voltages, are employed, the fixed charges on the overhead line will give the impression that long-distance transmission in Great Britain is impracticable, because of the comparatively small differences in the cost of power at the two ends of the line, due to the fact that we have no water power in this country. This point is not generally appreciated, as will be manifest from the fact that Mr. W. E. Highfield, in an informal paper read a year ago before the South Midland Centre of the Institution, gave figures to prove that the transmission of 20 000 kW could not be effectively carried out for a distance greater than about 36 miles, based upon the employment of steam power at both ends of the line, and upon the difference in cost in power, the power being transmitted from a large station to a small station. I showed in my contribution to the Birmingham discussion on the present paper that if we consider the transmission of as great a power as 125 000 kW over 100 miles, and with two big stations one at either end of the line, it will pay to do it, provided that the one station generates power at, say, 10 per cent more than the other station, or, to take a concrete

* See page 914.

case, at 0·5d. and 0·45d. respectively. This example applies with greatly increased force if a group of small stations be taken and the question of transmission of power from a large station 100 miles distant to this group be considered. Why cannot the Government and the railway companies combine in a similar way as has been done in France, the railway companies helping to find the capital outlay for the overhead line, which would follow the route between important centres, for example between London, Birmingham, Manchester, Liverpool, Carlisle and Glasgow? Another point of considerable importance is the question of what is known to transmission specialists as "stability" of the overhead line. When large, sudden increments of current occur on a long-distance overhead line, the phase of the voltage (expressed vectorially) swings round, for example, in an anti-clockwise direction, while the phase of the current swings round in a clockwise direction, and when, for example, synchronous apparatus at the receiving end of the line (the phase position of which cannot change instantaneously) is suddenly confronted by a heavy displacement of the voltage, the apparatus is liable either to hunt or to fall out of step. The action is not dissimilar to that which applies when a synchronous motor has a sudden load thrown upon it, causing a phase displacement of the machine with reference to the impressed voltage, causing a break-away. I note that, although the author has a very long line to deal with (280 miles), the only provision for synchronous condensers appears at present to be at Chaigny, a place comparatively near to Paris, and therefore quite out of accordance with the most recent findings of our transmission experts in America, who maintain that the best position for the synchronous apparatus is midway along the line (or preferably distributed along the whole length). Then, also, the amount of synchronous apparatus provided for is, it would appear, quite inadequate for the expected loads, unless it is proposed to increase these synchronous capacities very materially. What I have to suggest is that, with all respect to French railway engineers, the position of the phase-rectifying station is wrongly chosen, and secondly, that the amounts of synchronous power put down are insufficient to avoid serious power limitations on the line, from the point of view of stability. On this same question, I may say that a careful study of such papers as those by Fortescue and Wagner, Shand, Evans and Bergvall, Baum, etc., makes me feel fairly confident in stating that, on the question of stability, applied here in Great Britain, it would be unnecessary when connecting two steam stations 100 miles apart to provide any synchronous condensers whatever—unless perhaps a small amount for adjustment purposes—and in these circumstances one of the gravest disabilities of high-tension transmission disappears. (I may say that this disability is not so obvious where cheap water power is at issue, but is serious where we are transmitting from a steam station to a steam station.) Even this disability, however, is largely countered by the employment of the very highest voltages.

Mr. E. M. Malek: Anyone who has been associated, as I have to some little extent, with railway electrification, must be struck by the fact that the French railway engineers have not only grasped that the first essential for railway electrification is a general supply of energy available everywhere and anywhere in any quantity, but that they have been able to co-ordinate the various public and private interests in such a way as to produce a workable scheme. The author mentions that his railway is only a part of the scheme. At various times French Cabinet Ministers have declared it as the policy of the Government that electricity is to be widely distributed, and that the electrification of railways and everything else would follow. I think that that is right and that main-line railway electrification will follow and not precede general electrification. The problems involved in electrifying small sections of line under special conditions can be solved in various ways; in some alternating and in others direct current may appear most beneficial. If any railway is taken as a whole, however, it will be found that the capital expenditure on power development and distribution—irrespective of the sort of current used for traction—is so enormous that the companies cannot face it, and unless they can be freed from this great interest-bearing charge it does not appear to me that electrification can ever become general. The author seems to believe that the possibilities of the electric motor will lead to an increase in train weights, but I am not so certain on that point. Existing railway working has been built up around the steam locomotive. When railway officials know more about the advantages and use of electricity, and are faced, as they will be, with greater competition from road transport, it is possible that their views on the advantage of infrequent and heavy trains will be modified. French engineers are always willing to spare time and give the results of their experience to English engineers actively interested in railway problems, and if they took advantage of this to study the subject there, I am certain that they would obtain much valuable information applicable to the problems which they will have to face in this country.

Sir Philip Dawson (*communicated*): We are one of the few industrial countries who have little or nothing to show as regards main-line electrification. Incidentally we learn that the first and most important section from Paris to Orléans will be supplied by the steam-driven stations of Gennevilliers and Vitry, thus confirming the experience gained in the United States and Germany, that main-line railway electrification may profitably be undertaken where, as in this country, the current is generated by steam-driven plant. This is a practical confirmation of the results which I worked out would accrue if the line from London to Brighton had been electrified (published in the paper which I read at the World Power Conference in 1924), and of the figures given by Col. H. E. O'Brien in his paper.* I hope that the author's opinion that "Great Britain would appear to be on the eve of extensive electrification" will prove to be correct. Another very interesting statement of the author's is that although the pressure adopted is 1 500 volts, with the exception of the suburban area the whole contact system is an overhead one. He gives very cogent reasons for this, which apply equally in this country. From these it would seem that even if

* *Journal I.E.E.*, 1924, vol. 62, p. 729.

the pressure is limited to 1 500 volts, overhead conductors will have to be adopted. It would be very interesting to know whether the author, if he were to start now with a free hand, would not adopt a pressure of 3 000 volts, which is what has, I understand, under his guidance been adopted for the main-line electrification now proceeding in French Morocco. The great benefits which main-line electrification will bring about in the cheaper generation and widespread transmission of electricity over areas which, but for electrification, would not justify the cost of transmission lines, are very clearly brought out and confirm the views I have so often expressed of the benefits this country would reap from properly conceived proposals to electrify selected portions of our railway system. There can be little doubt of the practical advantage to be gained in this country from the standardization of generation and transmission. In this country, as in France, the general direction of main transmission lines will usually coincide with that of railway lines having the densest traffic, where the question of electrification is also of most interest. The electrification of properly selected sections of main-line railways in this country should be just as beneficial here as in France, where the author states that the realization of vast electrification proposals constitutes one of the most efficient means of re-establishing stable conditions. The author says that before the end of this year the 124-mile section, Paris to Orléans, will be entirely electrically operated and that electric traction will replace steam for the whole of the passenger, goods and shunting services. Many of us are envious that in this direction we lag so far behind. As regards substation plant, rotary converters, two in series, are to be used. For 3 000-volt lines rotary converters are not practicable, and it is fortunate that we have the mercury rectifier, which possesses simplicity of working, very high overall efficiency at practically all loads, and great overload capacity. It is no longer in the experimental stage, as the results on the Midi Railway and on the Turin-Lanzo line definitely prove. Another fact brought out by the author is the very high load factor of a main line as compared with that of purely suburban electrification. His results fully confirm those arrived at by Col. O'Brien and myself, that a load factor of at least 40 to 50 per cent may be expected in the case of any main line on which electrification can be justified on economic grounds. In view of the Electricity Bill which will come before Parliament this session, the author's statement that the French Government is considering a programme for linking up the various distribution systems, rather than Government generation of electricity, is most interesting and instructive. His remarks on electric locomotives on the whole confirm the view which is now being very generally adopted by those who, like myself, have made a continuous and detailed study of the electric locomotive—that with few exceptions to-day a connecting-rod drive for high-speed locomotives is losing ground in favour of some form of individual drive through spring gears. For lower-speed locomotives for handling local passenger and goods trains the tramway type seems eminently suitable, whilst for high-speed locomotives existing spring motors, either individual or twin, located above the axles are rapidly becoming the standard. In this connection the twin vertical motor driving a hollow shaft connected by springs to the driving wheels through bevel gear is most interesting, and the results this type has achieved on the Midi railway are well worth a careful study. The work done, more especially in Germany, by locomotives used for shunting purposes, and even by motor coaches supplied with current from accumulators, deserves careful attention, and it is quite conceivable that such locomotives might form a most useful adjunct in connection with main-line electrification in this country.

[The author's reply to the discussion will be found on page 918.]

South Midland Centre, at Birmingham, 17 February, 1926.

Mr. F. J. Moffett: As the Prime Minister pointed out in his speech at Birmingham on the 15th January, one most important desideratum for cheap and abundant supply of electric energy is a good load factor, and it is generally recognized by all electrical engineers that the readiest means of improving the load factor of our large generating stations is to provide an electric railway load. The proportion of the 24 hours during which a supply is required is far higher on the railway systems than in any industrial concern. Electrical engineers are, I think, agreed that there are no insoluble technical problems in connection with the electrical equipment of our main railway lines. The chief obstacle appears to be lack of capital. It would appear that it is just as feasible for our Government to provide loan facilities for this purpose as for the interconnecting trunk lines and standardization of frequency provided for under the new State electricity scheme.

The Southern Railway report gives no details of comparative costs for electrical and steam-train working, but it is believed, according to *The Times*, that the difference is considerable. Some of the figures given in the report may be of interest and may assist us in arriving at some sort of estimate of the effect of electrification. It may be remarked, however, that allowance should be made for the fact that much of the expenditure on electrification is so recent that the full effects cannot yet be judged.

Southern Railway.

Trains worked by electric traction.

1924	5 019 000 train-miles.
1925	7 605 000 train-miles.

Cars worked by electric traction.

1924	568
1925	1 162

Amount spent on electrical equipment.

1924	Nil.
1925	£397 000

Amount spent on new steam locomotives.

1924	£255 000
1925	£79 000

Total receipts increase in 1925: £423 325.
Total net income in 1925: £6 415 000.
Increase in 1925: £96 700.

Difference between net income and total of dividends and fixed charges in 1925: deficit of £212 900.

At the same time I came across the Great Western Railway report, and for the purpose of comparison I shall quote a few of the figures given. The Great Western Railway have not adopted electrification to the same extent as the Southern Railway.

GREAT WESTERN RAILWAY.

Total receipts decrease in 1925: £814 500.
Total net income in 1925: £7 107 000.
Decrease in 1925: £345 000.

Difference between net income and total of dividends and fixed charges in 1925: deficit of £1 187 000.

The Southern Railway therefore showed increases in total receipts and net income for 1925 over 1924, whilst the Great Western Railway showed decreases in both cases. The deficit for the Southern Railway is £212 900 as against that for the Great Western Railway of £1 187 000. It naturally occurs to me to wonder whether the partial electrification of the Southern Railway is responsible to a certain extent for the better figures shown.

Mr. A. M. Taylor: The interesting fact that here we have an example of the French Government combining with the railway companies in such a way that equipment is being provided for transmitting an initial traction load of some 40 000 kW from the source of water power at the Central Plateau to Paris, with a view to ultimately transmitting an additional 70 000 kW over a distance of not less than 280 miles, provides food for reflection. If it pays the French Government and the railway companies to consider the transmission of such a large amount of power over a distance as great as 280 miles, what difference in the cost of power, as generated at two different places in, say, Great Britain, will warrant a transmission of power in bulk from one to the other? In the case of the French transmission the fact that the power is to be obtained, and presumably fairly cheaply, from water power at the one centre, whereas at the other centre it is obtained from steam power generated largely by foreign-bought coal, no doubt explains the reason for the decision to transmit over such a great distance. It can be said that all the power in Great Britain is produced from coal, and the only question we have to consider is whether the cost of power at two centres, due to local circumstances or other factors which govern either the cost of coal or the capital costs of the stations, may sufficiently differ, even though coal is used in both cases, to warrant transmission from one to the other. I feel that on this question of long-distance transmission, engineers in this country have lost sight of three important points which have been fully grasped by engineers in other countries, who have had long-distance transmission forced upon them by the possession of water power. These three points are: (1) Unless we transmit *very* large powers over a high-tension line, the interest, sinking fund and repair charges are so high that an impression is at once produced that it only pays to transmit power over comparatively short distances. (2) The enormous benefits of operating at the very highest voltages, e.g. 220 000, have not been appreciated. Below this voltage the charges on account of energy lost in the line are higher than the fixed charges due to interest, sinking fund and repair charges. (3) It is only by the employment of the very highest voltages that the capital outlay on a long line, per kW transmitted, can be so reduced as to bring things into the realm of commercial possibility, on account of fixed charges on the line being otherwise too heavy. I have found that on a 100-mile line the interest, sinking fund and repair charges, when transmitting 125 000 kW on a load factor of 33 per cent, are only of the order of 0·025d. per unit, whilst the loss charges are as low as 0·017d. If we take a round figure of 0·045d. per unit as the total charges debitable to transmission on this scale between two towns, it will be seen that it would, for example, pay to transmit power from Birmingham to London, if the cost of power at Birmingham were 0·45d. per unit and the cost at London were 0·5d. Differences much greater than this frequently exist between the costs of power in our large centres. A group of small towns having individual small outputs might in a similar way be supplied from a large centre where the cost was cheaper, even if such centre were 100 miles away.

Dr. C. C. Garrard: I propose to approach the subject primarily from the point of view of how it affects the future of electric supply in this country. The author states on page 899 that "the greater the coal consumption per mile of line, the more favourable will be the financial results of electrification." Now I take it that the density of traffic, and hence the coal consumption per mile, are as great as or greater on British railways than anywhere else in the world, hence the author's general conclusion applies with increased force to British conditions. It is very interesting to see (on page 893) that the substitution of electric power for steam on railways is regarded by the French Government as one stage in a more comprehensive scheme. It is to be hoped that this view will find favour in the discussions on the Electricity Bill about to be introduced into Parliament. On page 896 the load factor of the French electric supply is given as 28 per cent, which is low in comparison, for example, with American conditions, but Fig. 2 shows clearly how the addition of a railway load would improve the load factor. As I take it that one of the chief hopes for cheaper supply under the British Government's proposals is based upon the securing of an improved load factor, this shows how important it is to include railways in the electrification

scheme. It appears to me, however, that the technical question of railway electrification has been settled; moreover, it has been proved, as far as any proposed commercial project can be proved, that it would pay. The difficulty in the way is, in my view, the conservatism of the railway directors. This difficulty has been undoubtedly increased by the railway amalgamations, which have rendered the railway companies more powerful and less likely to make innovations. The chairman of one of the railway companies stated recently that he did not consider it necessary to think about railway electrification for the next 10 years. If the Institution wishes to help forward railway electrification in this country, it must enlist public opinion on its side. Unfortunately, most of the British public do not realize what a very poor transport service the British railways render. The point I wish to bring out is that it is not possible to secure the greater comfort and convenience of travelling unless electric traction is adopted. Take, for example, the great majority of the terminal stations in London and our large cities. They are, to put it mildly, a disgrace, but it is very difficult indeed to do anything with them with the steam system. Unfortunately, I do not think the railway directors will be moved by reason. Therefore I welcome the competition of motor transport. Manufacturing companies already find it in very many cases very much better and cheaper to utilize motor transport for their goods rather than the inadequate service rendered by the railway companies. The same result is coming about to a larger and larger degree with passenger traffic. It is, however, in the long run economically wrong that the roads should be used for transport work that would be better done on railroads.

Mr. F. W. Carter: The contact rail shown in Fig. 18 appears to be a good mechanical job, but I have not hitherto met with a rail of the section shown. The contact tip being of small area would tend to cut the shoe in grooves, and I presume the reason for its use is that the shoe is able to keep the rail clear of ice. I note that some of the locomotives are equipped for regeneration; from the appearance of the gradient profile I should not have thought the advantage of regeneration worth the complication. The freight locomotives are of the 2-bogie type having all the weight on the driving wheels; this type is tending to become standard for this class of work. High-speed passenger locomotives are, however, less standardized, and I am glad to see that the author is to try out a number of types. I am sure the information he will gain will be valuable, and I hope he will be able to put it at the disposal of engineers generally.

Prof. W. Cramp: The great success with which the generating stations have been arranged to co-operate is a striking tribute to the spirit which animates the French electrical undertakings, and it would be of interest to know something about the Government machinery by which such co-operation has been rendered possible. The author states that the greater the coal consumption per mile of line the more favourable will be the financial results of electrification. It seems to me that the financial results will be influenced by the coal consumption per ton-mile as well as that per mile. With regard to transmission, it is interesting to note that the highest voltage adopted on any cable is 60 kV, and that single-phase cables are used. Does the author mean single-phase concentric or single-core cables? If the latter it would be very interesting to know whether they are sheathed with lead or armour, or both, and whether the cores are hollow. What is the maximum dielectric stress allowed and what is the insulating material? The general principles put down on pages 896 and 897 are of universal importance and are, I believe, stated for the first time here. The benefit accruing from the combination of the railways with the industrial load is mentioned but not proved. It seems as though the industrial load factor in France is higher than in England. For an industrial load without trams, 28 per cent is a high figure, except in a colliery district or in a region where there are large steel-works. With respect to the motor coaches, it seems that the goods locomotives have 1 500-volt motors, but for passenger trains it is considered more advisable to use two 750-volt motors in series. The power, however, of the goods motors is greater than that for the passenger coaches, so that it would seem that the disadvantageous series arrangement is due to difficulties of commutation at high speed. There must have been some good reason to lead to an arrangement which permanently reduces the efficiency of control. I should be glad if the author would state what steel is used for the contact rails. The effect of linking up hydro-electric with coal-fire generating stations will be closely followed in this country. The author gives no indication of the relative costs of generation in the two cases, nor of the manner in which the payments for energy are to be adjusted as between the various sources of supply. It is manifest that a coal-fired station cannot afford to give a stand-by supply at the same price as a continuous supply. In other words, the presence of a hydro-electric station would seem to make the load factor worse for the steam station, and since the former takes the cream of the load the latter should be paid more per unit supplied. Can the author say how these adjustments are to be made, and what proportion of the cost per unit is due to the very long feeder system? Finally, the author showed slides of very fine overhead line construction, but I noticed that the elaborate guarding which would be required in this country was conspicuous by its absence. The expense of this addition must not be forgotten when comparing the capital costs of distribution with those which would obtain in England.

Mr. J. D. Carlmark: The author states that "the greater the coal consumption per mile of line the more favourable will be the financial results of the electrification." This, I take it, would always be the case whether the supply is derived from water or steam power, as after electrification the railway should be worked more cheaply. Would not the density of traffic also reduce the capital and working costs per ton-mile, as with very little increase in the cost of line and transmission equipment much greater earning capacity would result and the station and other staff could deal more economically with the heavier traffic? Is this the reason for the saving in the coal consumption? I noticed that on the Paris–Vierzon section 330 000 kW will be

obtained from steam-power stations and only 200 000 kW is at present available from water-power stations, thus showing, even with steam-power plants, the financial soundness of electrification. It is interesting to note from Figs. 3 to 6 inclusive that the distance between substations varies from 4·4 to 26·8 km, but for the majority is about 21 to 25 km. The distance of 21 km (or approximately 13 miles) is very near to the spacing suggested by Col. H. E. O'Brien, of 12 miles between substations for an English main line. The working arrangement of exchange of power between the various water- and steam-power plants is very interesting and shows that a great deal of thought must have been expended on this matter. Similar circumstances in a smaller degree may occur between various steam plants in this country, and the matter is well worth bearing in mind, because of seasonable loads. Do the power transmission lines follow the railways, or are they run more for the convenience of the industrial load than for traction? If the transmission follows the railway, has there been or is there likely to be any electrical interference with telephone or telegraph circuits due to the 150–220-kV power circuits, or electrolysis from the d.c. distribution, and, if so, has a successful cure been found? The three-phase supply would of course balance much better than a single-phase supply, but the higher pressure may cause trouble. Fig. 7 shows a very interesting increase in the traffic; I take it that the author presumes that this will increase at a much greater rate with electrification. It is noticeable that France has departed from the Continental practice of providing power stations for the railway requirements only. This is, I think, a step in the right direction. A further description of the locomotives and their control gear, etc., would have been welcome, but probably this information will be included in the author's paper in the *Revue Générale des Chemins de Fer*. The results of the tests to be carried out on the high-speed locomotives should prove very valuable.

[The author's reply to this discussion will be found on page 918.]

North Midland Centre, at Leeds, 23 February, 1926.

Mr. R. M. Longman: The paper is of great value in several ways. It shows how the Government of one country has made an attempt to assist its industries generally. It is an attempt to combine and deal with the railway load and the industrial load, and it gives the results and investigations carried out in a country where conditions differ considerably from those in this country, but which would serve as a basis on which similar investigations could be carried out. We could adopt their methods, but nothing of the kind has been attempted in this country. We had a Coal Commission, but the result of their labours is by no means comparable with that of the French Committee. The statistics in Part 1 dealing with the transmission of power and the method of operation with the various sources of power supply are lucid and instructive. One cannot help comparing the attitudes of the Governments and the developments which have taken place in the different countries since the war. Germany, who lost the war in a military sense, but who suffered less material damage, set about and reorganized its industries by means which are in their way a greater catastrophe then the war. By their questionable financial operations they have reconstructed their industrial organizations. Practically all their works have written off their capital costs, and they are now able to go ahead without the burden of capital charges which this and other countries have to carry. The author has shown one of the ways in which the French have attempted to repair the ravages of war and the material damage, in which respect they suffered so heavily. They examined their chief items of import and decided to reduce as far as possible the importation of coal, which stands at approximately 17 million tonnes. They realized the advantages of combining railway and industrial electrification. They did not attempt to tax industries out of existence, whereas we have paid our way and paid our debts simply by taxing industry to the limit and at the same time maintaining a huge army of unemployed, which is a double tax on industry. On page 899 the author touches the kernel of the railway electrification question when he says: "It can easily be shown that the greater the coal consumption per mile of line, the more favourable will be the financial results of electrification." In paragraph 2 of the introduction he says: "At the present time, when Great Britain would appear to be on the eve of extensive electrification work." I assume that he intended to add "of railways," but I very much doubt whether we are on the eve of extensive electrification of railways. The grouping of the railways appears to have generally set back all electrification schemes. All energy seems to have been devoted to effecting small economies in staff and other ways of working, all of which are no doubt very necessary and helpful, but nothing in the nature of a more extensive scheme of electrification has been considered. I take the view that after the war we were in a better position to consider the electrification of some of the main lines and particularly those with the heavier traffic, for the simple reason that our rolling-stock and permanent way had got into such a bad condition—particularly the rolling-stock. Instead of providing a large number of new steam locomotives, electric locomotives might have been chosen, as their percentage time of active service is so much higher. Is the railway companies' conservative attitude similar to that adopted 100 years ago when machinery was being introduced into the mills? The transport of coal is a very big item of revenue to the railway companies. Are they afraid of losing it? To my mind the transport of coal, which at present is the life blood of industry, is an item the cost of which should be cut down to the lowest possible level. Again, we must consider the amount of coal used by the locomotives as compared with the amount of coal which would be used in large modern power stations to do the same work. I think that the ratio is more than four to one. We know that in a modern power station as little as 1·7 lb.

of coal has to be burnt per kWh. The general idea that transmission lines should follow the main railway lines is undoubtedly correct, as the railway lines are built where the traffic and the industrial requirements necessitate them. Turning to the technical items in the paper, I should like some further information as to the electrical plant. I notice that at Chaingy two 20 000-kVA transformer units are used to couple the 90-kV system with the 150-kV system. These huge transformers are star-connected on both windings and are provided with tertiary windings at 6 000 volts, to which are connected large synchronous condensers for providing the wattless component and regulating the voltage of the line. It is a most interesting arrangement and one to which I have given much consideration. I should also like to know what provision has been made for earthing the neutral points of the transmission systems, and whether they are earthed at more than one point. I do not know the methods adopted by the Post Office authorities in France, but I believe they find it is necessary and safer to earth the neutrals at more than one point. The arrangement of two 750-volt machines in series is the same as that adopted on the Shildon–Newport line and was adopted on several schemes by English firms in South America. I am rather surprised that they have not adopted converters giving 1 500 volts in one unit.

Mr. H. M. Taylor: I think it is important that we should realize the difference between the financial situation of the French railways and that of our own. In reading the paper the first impression one gathers is that the French seem to have done far more than we have done in regard to the electrification of the railways. I am told, however, that practically all the technical committees which have sat, and which have been drawn from the railway companies in France, have almost universally stated in their reports that from the financial standpoint there is no case for electrifying the main lines. Practically all the railway companies in France are subsidized by the Government. One of the large railways is actually run by the State. Apart from that, all the larger companies are still subsidized, and therefore there is no reason why they need trouble about paying their way. The steel transmission towers shown in the lantern slides are not painted; they are coated with zinc by a special process known as the "Schoop" process, in which the zinc is squirted on under compressed air. I have calculated that the cost of the zinc-coating is about five times the cost of the painting, and I should imagine that the painting is a considerable item in the annual cost.

Mr. C. J. Chaplin: The recorder used for obtaining the records in Fig. 24 was invented by Mr. Hallade, who was one of the divisional engineers and later chief engineer of the Est Company (France). This apparatus has been adopted on the North-Eastern system and was once tried on the London and North-Western system.

Mr. W. E. French: This paper presents, in my opinion, not so much an argument in favour of railway electrification in France, but rather an excellent exposition why Paris and its industrial area should be connected with the Central Plateau and the glacier reservoirs, electric traction being merely incidental and subsidiary to this main problem. France is rightly striving to reduce her coal imports, and so must make economical use of her great water-power resources. As the author points out, the chief power routes will chiefly follow the railways, which in consequence were drawn in to assist in the creation of a good load factor along this transmission line to Paris. The problem in Great Britain, at the present crisis in the coal industries, is different. There are no great sources of water power upon which we can draw, and both the railways and the electricity supply industries are dependent for power on our coal. I think that I am not understating the case in saying that with the electrification of the railways they would experience a reduction at least of 25 per cent in coal consumption. Considering the precarious state of the coal industries to-day it would seem that such a reduction would not be considered favourably by the authorities concerned, and the electrification of the railways must be a costly affair which, as previous speakers have pointed out, the railway companies simply cannot afford. It appears that the combined effect of these will retard for some considerable time the development of main-line electrification in this country. When main-line electrification in this country does come, it will be incorporated in a national scheme. That Germany, Switzerland and Italy developed two systems—one for traction and one for power supply—was simply due to the facts that they were pioneers and that public opinion on the question of electric power had not sufficiently developed to force a national demand, and further, at that period technical opinion was favouring single-phase traction and single-phase commutator motors. The latter of course demanded, from the point of view of commutation and power factor, a low frequency and the development of a low-frequency supply. Assuming national supply for power and traction, frequencies will be either 40, 50 or 60 periods; the battles of frequencies in this country will yet have to be fought, although official opinion has already pronounced in favour of 50 periods. Whatever the standard frequency may be, these frequencies will eliminate the single-phase commutator itself. In this respect the Kando system, now undergoing trials on the Hungarian State Railways, deserves consideration, and according to reports is giving very satisfactory results. Since this system is probably not generally known, a brief description would no doubt be of interest. The supply to the locomotive is high-tension single phase at 50 periods and the drive is by three-phase motors. In order to accomplish this the locomotive carries a phase converter of peculiar construction. It is a single-phase synchronous motor and three-phase generator in one; both machines have a common stator and a common field. The exciter is on the same shaft. The stator carries a single-phase winding covering about two-thirds of the circumference, and a separate three-phase winding covering the whole of the stator circumference. Single-phase energy is taken from the overhead trolley wire, driving the phase converter as a single-phase synchronous motor. The rotating d.c. field system excites also the three-phase generator, which in turn supplies the energy for the three-phase motors. The small exciter is not a constant-

voltage machine, but is arranged for automatic voltage regulation, so that the voltage from the three-phase generator varies approximately as the square root of the motor load, thus ensuring that the motors are working at terminal voltages conducive to maximum efficiency. Simultaneously the alteration of the field values effects a correction of the power factor of the motors, and the overhead trolley system becomes independent of the power factors of the three-phase motors of the locomotives. The single-phase winding can be easily wound for reduced voltages, which will give such currents that the control gear to the motors does not become unwieldy. This presents for single-phase systems a solution much superior to the American split-phase system and, in view of the possibility of using high tension, a serious rival to the d.c. system. Of course, it must be admitted that the d.c. series motor is the traction motor *par excellence*, but it has its drawbacks. There are commutator troubles which can never be separated from d.c. work; the costly conversion in costly rotary substations; and the heavy overhead system owing to the comparatively low transmission voltages. Regarding three-phase traction, the objection appears to be the complexity of the trolley system and the difficulty of speed regulation; in addition, if the national standard of 50 periods is adopted for main-line traction, three-phase motors must have a large diameter and a large number of poles. This objection is overcome by gearing. The objection regarding speed regulation is not so serious as it might appear. Some years ago I was interested in tests with a frequency-changer. This consisted of an ordinary d.c. armature tapped three-phase and supplied with slip-rings. The brushes on the commutator were spaced 120° apart, and the armature worked in an unwound stator. By running the frequency-converter from zero to a maximum speed any desired frequency could be obtained, and by allowing these frequencies to act on the stator of an induction motor any desired speed and an excellent starting torque were obtained. Since then such frequency-converters have been much improved and, by connecting them to the rotor and also allowing correct changes in the voltages, they act simultaneously as phase compensators. The speed regulation discussed was rejected at the time on the argument of complexity of overhead systems with three-phase currents. Yet in Switzerland and Northern Italy three-phase traction has been developed and the authorities concerned appear to have no inclination to depart from their adopted policy. I should like to have the author's views on this point.

Mr. R. A. Thwaites: It is to be regretted that the paper does not give any costs, as costs are all-important in such a scheme as this. The value of the paper would be much increased if the author, in his written reply, would give at least an approximate figure of the cost of energy per unit delivered either to the substations or to the contact wire, together with some indication of the cost per km of track equipment. One of the main objects of this scheme appears to be the reduction in the amount of coal imported, and we in Yorkshire are likely to be seriously affected by any such reduction. The author states on page 894: "From this it can be seen that the electrification of the railways, even if extended to include every line, would result in only a small reduction in the import of fuel into France." But is this quite correct? The amount of coal used by the railways is given as 9 million tonnes, so that if they were all electrified and 90 per cent of the energy were obtained from water power, then France would save something like 8 million tonnes a year. From the figures given in the paper this would appear to be a saving of half the imports of coal into France—a very considerable reduction. Due to the circumstances prevailing, the main transmission lines must follow an almost direct route. It would be interesting to know whether any serious difficulties have been encountered in obtaining wayleaves for these lines, also whether complications are involved every time the line crosses a road, or a telegraph or telephone line.

Mr. H. Parodi (*in reply*): All the sections of the Orléans Company's electrification have been put into service as and when completed. Electric trains have been running for several months between Paris and Étampes and Dourdan, that is to say, over about 60 km of 4-track and 20 km of 2-track route, and the mileage run by the electric trains in this section now exceeds 7 000 km (4 350 miles) per day. For more than a year the city of Orléans has been supplied by means of the 90-kV overhead lines of the Orléans Railway Company from the power stations in the neighbourhood of Paris; and next winter the Eguzon station which was opened in June, 1926, will supply Issoudun, Châteauroux, Orléans and Paris, in addition to the traction substations. Interconnection of the hydro-electric and steam-power stations will thus have been effected, and, in addition, the surplus energy available will be distributed along the above length of railway. Considerable advantages will result from this interconnection of the power stations, for it can easily be proved that it is more economical to transmit between two given points two amounts of energy Q_1 and Q_2 over a single line at a suitable pressure, than over two separate lines at a lower pressure. Considerable advantages from interconnection also will be obtained by the steam stations which will receive energy from the hydro-electric stations in winter when the load on their network is the heaviest, and which will supply with their steam plant electrical energy for the railways in the summer when their load is least. The hydro-electric stations possess ample water storage and will provide a supply of power during those hours of the day which will be most convenient for the steam stations. For example, the Eguzon water-power station can be considered, from the point of view of the Gennevilliers steam station, as an auxiliary supply of 50 000 kW transmitted a distance of 300 km (186 miles). This auxiliary supply will be chiefly used in winter when the demand on the station is greatest, this coinciding with the maximum supply of water.

As regards the relative costs of the steam and hydro-electric supplies, I will merely say that the Union d'Électricité was not neglecting its own interests when it co-operated with the Orléans Railway Company in constructing the Eguzon station.

The installation was designed in the first place by the

Railway Company and subsequently by the General Electric Co. of Schenectady, U.S.A., who supplied the synchronous condensers and the high-tension equipment and gave, through the French Thomson-Houston Co., a full guarantee in regard to the satisfactory working of the complete system. The position and output of the synchronous condensers have been especially approved by some of the distinguished engineers referred to by Mr. A. M. Taylor in the discussion.

The Schoop process has not been employed to coat the Orléans Company's towers, and I do not know why Mr. H. M. Taylor, basing his remarks on incorrect information which is not given in the paper, criticizes a method which has not been employed.

The high-tension lines do not cause any interference with the telephone or the telegraph lines, this immunity being due to the distance apart of the two transmission lines. In carrying out the installation we have complied with the requirement of the Post and Telegraph Administration and the regulations of the Californian Railroad Commission, and in every case it will be found that the new regulations suggested by the Union Internationale des Chemins de Fer have been practically complied with.

It is impossible for me to deal here with comparisons between electric traction and steam traction, such as the energy consumption per kilometre and per tonne-kilometre. These are set out in detail in the articles in the *Revue Générale des Chemins de Fer* mentioned in the paper, and it will be seen that the consumption of electrical energy calculated at the substation busbars corresponds for the same service conditions to a fuel consumption of between 2 and 3 kg (4½ - 6½ lb.) of coal per kilowatt-hour. If, however, a comparison be made—as has very often been done—between actual railway services before and after electrification, but with very different average running speeds, much lower figures will be obtained. As electric traction enables us to obtain a much higher average speed for the same maximum speed as that employed in the steam service, we can run a much more frequent electric service of express trains and goods trains, representing an increase in the carrying capacity of the line. This question is, however, linked up with that of brakes on goods trains, and one may say that it will only be possible to obtain all the advantages of electric traction when we have adopted for such low-speed traffic automatic continuous braking.

As regards the design of the locomotives, the tests which are in progress on the Orléans system will probably show the advantages and disadvantages of the various types suggested, whether individual control of the axles (gearless locomotives with Buchli drive) or group control (locomotives with connecting rods of the "hyperstatic" type introduced by Mr. Kando and of the author's "isostatic" type).

On the question of voltage, it is becoming more and more evident to me that, for the conditions prevailing in Europe, it is desirable to adopt a lower voltage as the density of the traffic increases, whilst for very low traffic density it is essential to employ very high voltages. In the case of metropolitan railways or suburban services there does not appear to be any tendency to give up the use of pressures of 600 or 1 500 volts. Finally, as to the current used, I shall merely state in reply to Mr. French that Italian engineers, after having employed three-phase low-frequency current for the lines of the Northern Railways of Italy, are going to adopt for the Southern Railway electrification three-phase current of the frequency usual for power supply (45 periods). On the other hand, they are going to experiment with direct current at 3 000 volts on the 100-km line from Benevento to Foggia.

For its motor-coach trains the Orléans Company have employed only two methods of connecting the motors, namely, series and series-parallel, instead of three (series, series-parallel and parallel), the sole object being to simplify the control; and I do not know of any metropolitan or suburban railway where the three methods of connection have been used.

Regenerative braking has been used on the high-speed locomotive having fully compensated motors only with a view to obtaining useful information in connection with future electrification of lines having steep gradients.

The rotary converters were connected two in series, because at the time when the matter was under consideration no European or American manufacturer was prepared to build a machine giving 2 000 kW continuously and 6 000 kW for short periods and having 1 500 volts on one commutator. In these circumstances it was much more desirable to connect two 1 000-kW 750-volt machines in series than to have two 1 000-kW 1 500-volt motors in parallel, owing to the much greater reliability and efficiency obtained over high-tension machinery. The Orléans Company have experimented with a 1 000-kW 1 500-volt converter lent by an American manufacturer, but the test has had to be stopped, not on account of unsatisfactory operation but owing to the insufficient output.

With regard to the third rail designed by the author, more than two years' experience has shown that it gives results which are far superior to those obtained with other forms of third rail used on the Orléans Railway, and it has been at the request of the permanent way department that the original pattern of rail has been replaced by the new pattern on the busiest sections of the track. The new rail is of mild steel containing less than 0·3 per cent of manganese and 0·4 per cent of phosphorus; its resistivity is about 7 times that of copper and its breaking strength 36 kg per mm^2 (23 tons per sq. in.), the elongation being 27 per cent.

HIGH-POWER FUSIBLE CUT-OUTS.

Summary.

The subject of high-power fusible cut-outs is one entitled to the greatest respect, but it has undoubtedly been neglected in the past. The author has endeavoured to tackle the subject from a logical point of view in the present paper, and, in view of its fundamental importance, the problem of rupturing capacity has been selected as that to which attention is primarily confined.

The paper includes a consideration of the factors influencing the rupturing capacity of a cut-out, and a description of an extensive series of tests carried out on various types of cut-outs, including many of those most widely used to-day. A selection is given from the records of tests on fundamental forms of elementary construction, on plain cut-outs and on various commercial forms, and this shows clearly the inadequacy of such cut-outs for high-power work. Certain recently developed forms of cartridge cut-outs which operated satisfactorily are referred to and their sphere of usefulness is indicated. A description is given of an ironclad oil-immersed cut-out, which appears from the tests to satisfy nearly all requirements for high-power work. A new design of cut-out for small-current high-pressure services is also described.

An attempt has been made, by carrying out actual rupturing-capacity tests, to indicate how far the various types of cut-outs can be safely employed, and a chart has been drawn up to show a comparison between the rupturing capacities of these types.

A striking feature made apparent by the tests is that there are remarkably few efficient cut-outs available. This is all the more to be regretted when it is realized that a fusible cut-out can be made into a most accurate and efficient device—consistency of calibration and consistency of rupturing performance being possible to a high degree of excellence.

Introduction.

Small powers.—Until comparatively recently, fusible cut-outs have been employed only in circuits in which they are called upon to deal with relatively small amounts of power. For such work a plain fusible cut-out (i.e. one in which no special provisions are made to reduce or restrict the operation of rupturing) is often satisfactory. Thus in lighting or industrial power circuits an appropriately-arranged plain fusible cut-out, for example a fuse wire supported on a porcelain carrier in air, will usually suffice to clear a short-circuit with comparative ease. For the worst fault in such a position, amounting probably to 50 kVA at most, the operation will be accompanied by a fair explosion but by employing a somewhat more costly small fusible cut-out of the cartridge type, such a fault can be cleared without any commotion. The author, however, is not at present concerned with this branch of the subject, for, although there are numerous instances where poorly designed fusible cut-outs are in use, there are already available properly damped carrier-type cut-outs and inexpensive low-power cartridge cut-outs which would adequately meet such small-power requirements, as they have met the more difficult conditions described in the present paper.

Larger powers.—The problem with which the present paper is primarily concerned is that of fusible cut-outs capable of dealing with relatively large amounts of power, for which the simple forms of cut-out are entirely unsuitable. The subject may be roughly divided into three main groups, namely, cut-outs for medium- or comparatively heavy-current high-pressure work, cut-outs for heavy-current medium- or low-pressure work, and cut-outs for small-current high-pressure work. The dividing line between the first two groups is difficult to define, and cut-outs which are suitable for one group are also often suitable for the second. These two groups have consequently been dealt with together in the paper. The third group, however, involves quite different considerations and is consequently dealt with separately in the last main section of the paper.

As instances of circuits in which cut-outs in one or other of the first two groups may be used, may be mentioned industrial substations, power-station auxiliary supplies, transmission feeders and distribution networks. Thus it is usual nowadays in power stations to employ an auxiliary transformer bank of the order of 2 000 kVA which could feed perhaps 50 000 kVA into a fault. One important point of difference between a circuit breaker and a fusible cut-out may here be mentioned, in that a properly designed cut-out operates so rapidly that the peak current and the effect of asymmetry must be taken into account in estimating the kVA to be ruptured.

Distribution is carried out largely by means of transformers up to 1 000 kVA capacity. Such transformers are usually fed from a high-pressure system which is capable of maintaining the full potential on the primary of the transformer under almost any conditions. The use of circuit breakers in such conditions entails considerable expense, and if good cut-outs can be used in their stead it will be an unquestionable economy to do so. Such cut-outs must necessarily have a rupturing capacity of 20 or more times the transformer normal capacity.

One point in favour of the use of a cut-out instead of a circuit breaker is that the protection afforded is generally more consistent with the requirements. The characteristics of many distributors, installations and apparatus are essentially thermal, and it is, therefore,

desirable that the circuit-breaking device should also have thermal characteristics. The author has not succeeded in finding for this service any suitable device other than a fusible cut-out, which consistently reproduces a thermal time/current curve.

Scope of the Investigations.

Attention was at first directed to finding out how far existing designs of fusible cut-out were capable of satisfying the various requirements, and also, if possible, to devising improvements in such designs. A lengthy series of tests was carried out, and during these tests changes in design were made with a view to eliminating the troubles which arose.

At the time the investigations were commenced, the author could not find any cut-outs capable of rupturing, with reliability, heavy currents at medium or high pressures, or any reliable cut-outs suitable for small-current high-pressure use. The latter requirement has been satisfactorily met by one of the new designs developed during the investigations, whilst two other new designs appear likely to satisfy the former requirement. A third design gave promising results on heavy-current low- and medium-voltage tests, although further tests have still to be made on this cut-out.

The tests showed that many of the claims made for existing designs of fusible cut-outs could not be substantiated, and the general impression obtained from the tests was that most manufacturers were not correctly visualizing the problem. In the present paper the author has endeavoured to approach the subject from a logical standpoint. Many important problems are involved, but in the limited compass of a single paper it is impossible to deal with all of them. In view of its fundamental importance, however, the problem of rupturing capacity has been selected as the main subject of the paper.

After giving a brief account of the shortcomings of the heavy-pattern plain fusible cut-out, the author has reviewed the various factors affecting rupturing capacity. This is followed by a selection from the records of the tests and a description of the new designs of cut-out evolved, and an attempt has been made to define the limits within which the various types of cut-out may be usefully employed.

Shortcomings of the Heavy-Pattern Plain Fusible Cut-Out.

To obtain a reasonable degree of protection, ordinary copper fuse-wires must be run at a fairly high temperature, which causes deterioration and premature rupturing of the fuse. Hence, between the time a new fuse element is fitted and the time it may operate, the setting is gradually altering. The time/current curve is therefore difficult to control and almost impossible to maintain with consistency. Deterioration also takes place through mechanical vibration, through innumerable changes in temperature due to load variations, air draughts and other causes, and through electrically induced vibration. These factors are fairly well understood and have been dealt with by other investigators.

Factors Affecting Rupturing Capacity of Fusible Cut-Outs.

General.—The term "rupturing capacity" has hitherto been loosely employed, but the author has attempted

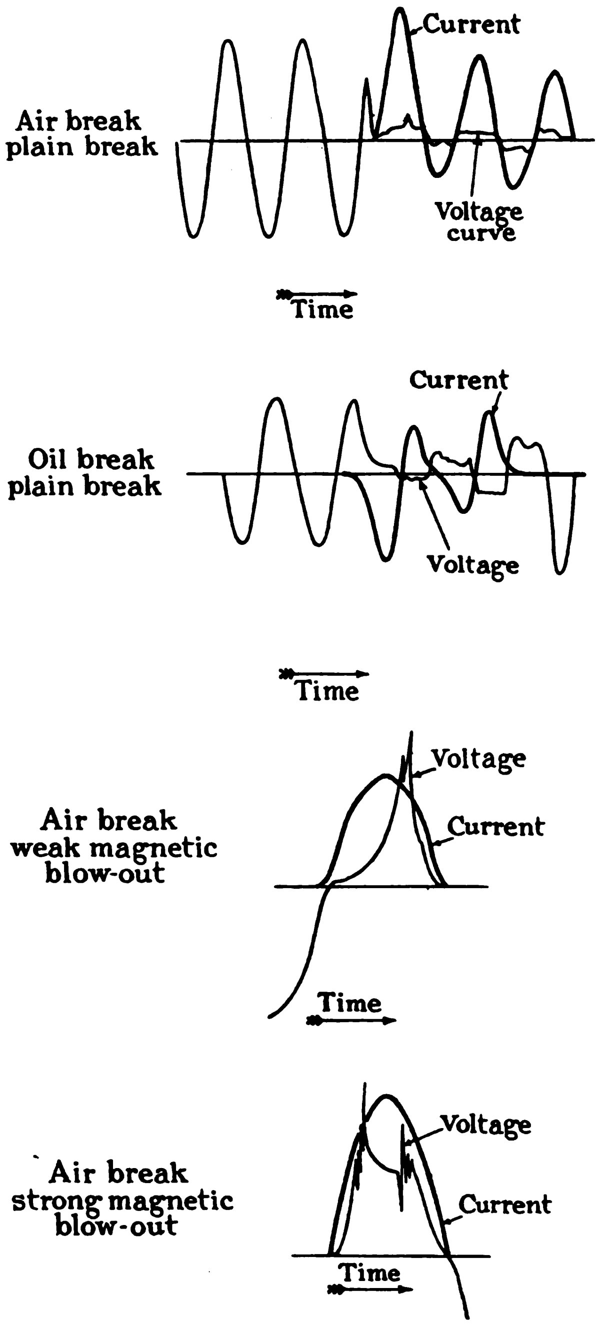

Fig. 1.—Comparison of arc characteristics: (*a*) plain air cut-out, (*b*) oil-immersed cut-out, (*c*) weak magnetic blow-out, (*d*) strong blow-out in air.

to give it a definite significance. Briefly, it may be described as the maximum power which can be safely ruptured by a cut-out. A cut-out may be capable of rupturing large powers, but that alone is not sufficient.

It must clear the fault without a dangerous explosion and without arcing over to neighbouring parts. Thus a plain cut-out of even the most elementary form may be capable of rupturing large powers, but the tests have shown that it cannot be made to do so without a harmful explosion. A more precise definition of rupturing capacity is the maximum kVA which can be cleared by the cut-out without an explosive or other effect which could cause damage to adjacent apparatus.

Magnetic blow-out.—Amongst what might be called external means of assisting the rupturing performance, magnetic blow-out has been extensively employed in various forms. Tests were therefore carried out to determine the value of magnetic blow-out, and it was found that the introduction of proper magnetic blow-out to the arc at the point of rupture has the general effect of decreasing the arcing time but, if misapplied, may produce voltage harmonics. These harmonics have often been found to be of a dangerous amplitude, and the tests indicate that magnetic blow-out may be, and often is, a disadvantage unless intelligently applied. Incorrect form may introduce complex phenomena, resulting in a greater amount of arc energy than in the case of a fusible cut-out not provided with magnetic blow-out. A comparison of arc characteristics to illustrate this point is given in Fig. 1.

If magnetic blow-out be adopted, it should be of simple form. Commercial forms of magnetic blow-out, both for switches and for fusible cut-outs, are far from simple. A common form of magnetic blow-out consists of a horseshoe magnet excited from a coil carrying the main current. The field of such a magnet has several components. There is a simple effect which acts directly upon the arc loop, tending to enlarge it; there is the horizontal field between the cheeks, which tends to move the arc in a straight line, and there are other effects.

The most reliable magnetic blow-out so far tested for heavy-current fusible cut-outs was obtained by bending the main leads at right angles to the fuse element for a few inches, so that there was a tendency for the fuse element to be blown away from the ends of the conductors. This arrangement provides a simple field which keeps the arc away from the contacts and assists materially in the clean extinction of the arc.

With large plain fusible cut-outs, particularly when arranged for magnetic blow-out, there is a tendency for portions of the fusible material to be left in a non-volatilized condition and to be ejected bodily from the carrier. In a number of tests carried out by the author with currents up to 100 000 amperes and employing magnetic blow-out (in some of the tests in the form referred to in the previous paragraph), portions of the fusible elements were blown 300 ft. away.

Oxidation of fusible element.—Unless specially prepared, a copper-wire fusible element will become red-hot at approximately 75 per cent of its minimum fusing current. The temperature at normal full-load current must be below this temperature, and in practice it has been found necessary to limit the continuous full-load current to between one-third and one-half of the minimum fusing current, in order to prevent cumulative oxidation being set up by the heating effect of the normal full-load current.

With certain metals and alloys, the fusible element is liable to oxidize at extremely low temperatures or even under the influence of the atmosphere alone. The oxides can be divided into two classes, namely, those which volatilize at approximately the same temperature as, and those which volatilize at a greater temperature than, the fusible material. When the oxide film breaks down at a temperature near to the fusing temperature of the metal, as with copper, the process of rupturing is not affected to any marked extent by the presence of the oxide; but with metals such as tin, aluminium and zinc the oxides are capable of holding up the molten metal after the current has raised the fusible element to its melting-point.

With open fusible elements of small size the oxidation effect is particularly troublesome. It is found that the oxide skin has the effect not only of increasing the rated minimum fusing current but, what is more troublesome, of exerting upon the fusible element a variable effect which cannot be predetermined.

Powder and similar fillings in cartridge cut-outs.—In cartridge cut-outs it is usually found that oxidation

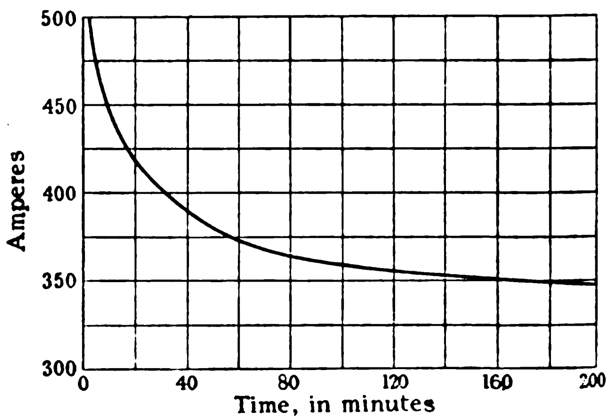

Fig. 2.—Time/current curve of cartridge cut-out with calcium-carbonate compound filling.

troubles are accentuated through the tendency of the filler to support the oxide film. Manufacturers are therefore faced with the alternative of using a loosely packed filling, which avoids to some extent the holding-up action on the fusible element, but introduces a certain amount of oxygen and consequently increases the risk of explosion. A tightly packed filling, although practically eliminating oxygen, supports the fusible element and the oxide film, and the molten material of the fusible element is prevented from being driven into the filler to be cooled.

To be efficient, the filling must be in fairly intimate contact with the fusible element, and, to achieve this, a fine powder is often used. Fine powders pack easily and, assisted by air, heat and moisture, may become solid, which further accentuates the holding-up effect. It will be appreciated that the production of a good filling is no simple matter, there being a sort of Scylla and Charybdis between which a correct course must be steered.

It has been found that a good filling for cartridge cut-outs can be formed by using a calcium-carbonate

base. Calcium carbonate alone is an effective arc damper, but in certain circumstances it is possible for it to assist rather than quell the disruptive agencies, probably through the action of heat on the filler, which results in the production of CO_2. This will tend to extinguish any arcing or burning, but, if produced in excess, will tend to set up a bursting pressure on the container. The introduction of an effective restrainer has been found to be beneficial in controlling this action. Apart from the effect of the CO_2, the action of such a filler seems to be largely a cooling one. On the other hand, it is possible that there is a thermionic effect.

Good results have been obtained with simple inert fillers such as sand, but such a filler introduces other difficult problems, and the best results were obtained from the arrangement described in the previous paragraph. Packing a fusible element affects its characteristic time/current curve, and a curve of a fusible cut-out with calcium-carbonate filling is given in Fig. 2.

Cross-section of fusible element.—The section of the fusible element plays a part in limiting the current on short-circuit, but the effect has been found to be due not so much to the resistance of the element, as is perhaps sometimes supposed, as to the stage in the growth of the short-circuit current at which the element melts.

The element will rupture when the product of watts and time is sufficient to raise the element to its melting temperature. At this point a gaseous gap takes the place of the fusible element and an arc E.M.F. appears. A small fusible element will rupture at an earlier stage in the growth of the current than a large element, and consequently the arc kVA will be less and the duty of the cut-out will be reduced. In other words, it is possible to prevent the current from rising to its full short-circuit value by using a rapidly-acting fusible element.

It is consequently of importance to reduce the amount of metal in the fusible element as far as is possible without introducing risk of oxidation. Expressed in another way, it is desirable to reduce what may be termed the "load/fusing-current ratio," i.e. the ratio of the full-load current to the minimum fusing current. The importance of employing a low load/fusing-current ratio does not appear to be generally recognized in the industry, but an examination of Fig. 3 will show that a low ratio is desirable. In this curve the power ruptured is plotted against the minimum fusing current. The curve is of a general character and embodies the results of a large number of tests on cut-outs of many different types. It is possible to show this effect, perhaps more elegantly, in other ways, but it is doubtful whether it can be shown more strikingly than by the actual test-results embodied in Fig. 3.

The importance of reducing the load/fusing-current ratio is most apparent when the maximum short-circuit power is comparatively heavy. For instance, it has been found by test on a 6 000-volt system with a maximum short-circuit power of 70 000 kVA that a 100-ampere cut-out, if of careless construction, may pass practically the full short-circuit power before it clears. Thus, with a cut-out designed to carry a full-load current of 100 amperes, an examination of the curve will show that with a load/fusing-current ratio of 1 : 2·5 the cut-out will not clear the short-circuit until the power has reached nearly 20 000 kVA, whilst with a load/fusing-current ratio of 1 : 2 it will clear at about 14 000 kVA. With a specially constructed cut-out it is found practicable to reduce the fusing ratio to 1 : 1·2 without introducing oxidation, and it will be

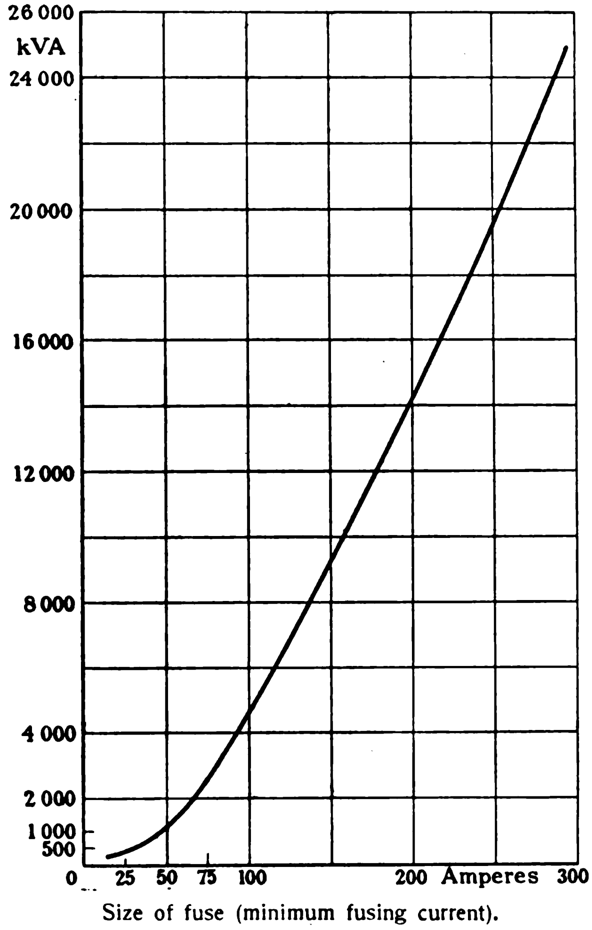

FIG. 3.—Curve showing advantage of reducing "load/fusing-current" ratio.

seen that with such a load/fusing-current ratio the short-circuit power ruptured by the 100-ampere cut-out will be reduced to about 6 000 kVA.

By exercising extreme care in the design of the carrier and by paying attention to factors such as cooling, it is possible to reduce to some slight extent the load/fusing current ratio in a simple form of cut-out, but to obtain the best results it appears to be necessary to make radical changes in the design of the fusible element. Thus in one modern type of fusible cut-out commercially available it is found possible to reduce the load/fusing-current ratio to 1 : 1·2. In this cut-out the functions of melting and heating are separated, and the heat is transmitted to a rupturing point from a calibrated copper neck or restricted portion.

The amount of heat transmitted from the neck is proportional to the load carried by it. When the load reaches a value which causes sufficient heat to be transmitted, the circuit is broken.

Another method is to have a fusible element which will run at a comparatively high temperature, but this introduces other and very difficult problems. Yet another method is described in the next section.

Multiple-element cut-outs.—It has been shown that at the moment of rupture the metallic fusible element becomes a conducting vapour path. It is important to reduce the temperature rapidly in order to reduce the arc energy to the lowest possible value. In cartridge fusible cut-outs the filling cools and condenses the metallic vapour, and the more rapidly the vapour can be driven into the filler, the more rapidly will complete rupture be obtained.

The fusible element should have as small a section and as great a surface area as possible for a given load current, thus giving the filler less work to do and spreading the work over a greater proportion of the filler. Methods of obtaining a small section of the fusible element have been considered in the preceding section. Another method is to employ a subdivided or multiple element or the equivalent, which has the dual advantage of giving a greater surface area in contact with the filler, and of enabling a smaller aggregate section to be used for a given current owing to the increased radiation surface.

It has been shown by Downes that with a five-element cut-out of given capacity the filling will be brought into action twice as rapidly as with the equivalent single-element cut-out. The duration and magnitude of the current will be reduced, with correspondingly lightened duty on the cut-out. The multiple-element arrangement can be formed in various ways. For instance, simple, spaced wire elements, radial strip elements and circumferentially arranged strip elements give equally good results, whilst the corresponding single element gives trouble through explosive rupturing.

Enclosure (general).—It is definitely indicated by the tests that all fusible elements should be enclosed. Many forms of enclosure at present in use are defective. Cartridge cut-outs with weak containers were found to be the rule rather than the exception. Porcelain fuse-carriers are weak mechanically and the porcelain carrier itself is a source of danger. The enclosure of simple fusible elements of the open-arc type in earthed metal, or the enclosure of cut-outs of opposite polarity in a common container, is not a good arrangement, for when clearing any considerable amount of power there is a strong tendency for arcing to be set up to the metal housing and to adjacent poles, and no form of internal insulation so far tested has been found capable of preventing trouble of this nature.

There appear at present to be two satisfactory methods of enclosing fusible cut-outs. One is to make the container of tubular form surrounding the fusible element, as in filled cartridge cut-outs. Such containers are usually located close to the point of rupture and should consequently be of an insulating character. The second method is to immerse the element in oil within a strong metal enclosure. These two methods are dealt with in separate sections.

Enclosures of the insulating type (cartridge cut-outs).—The necessity for employing insulating material for tubular containers limits the choice of materials to a group which includes glass, porcelain, fibre and bakelite, and which have comparatively poor mechanical strength. This is unfortunate, since their proximity to the point of rupture exposes them to high gas pressures, and unless efficient arrangements are made for damping and controlling the explosion set up at rupture, the container is likely to be shattered. When rupturing a power of the order of 30 000 kVA per phase, pressures of the order of 1 000-2 000 lb. per square inch were measured at approximately 1 inch from the point of rupture, and there is reason to believe that higher pressures are set up.

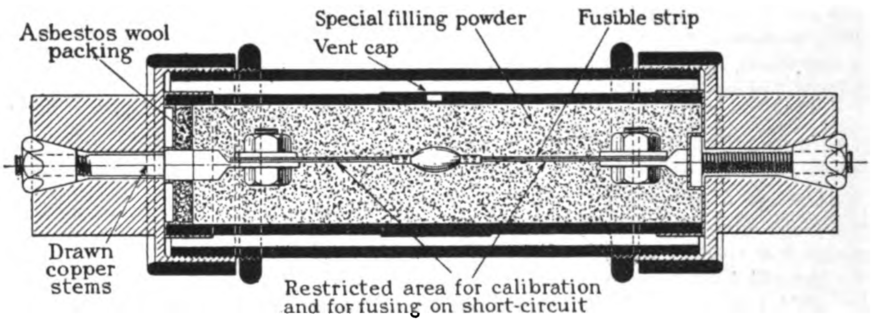

FIG. 4.—Section of filled cartridge cut-out.

Glass and porcelain containers are generally incapable of withstanding anything like this pressure. Bakelite and fibre containers can withstand considerably more pressure than glass containers of similar form, but the enclosure of a plain element in such a container with only air or a liquid does not provide a safe arrangement, since the pressures set up under such conditions are often more than the container can withstand. The tests have not brought to light any substance of liquid form which appreciably reduces the pressure set up at the moment of rupture.

Even with powder-filled cartridge cut-outs high pressures are set up which render glass and porcelain tubes of the usual dimensions unsuitable as the material for the container. Common fibre also is unsuitable, partly

because (although much more tenacious than glass) it is not strong enough to meet the requirements of high-power work, and partly because it is hygroscopic. The latter is a serious drawback, for damp will tend to make the container conductive and will also distort it and cause rapid deterioration, besides reacting harmfully on the filling.

Bakelite has been extensively used for the containers of cartridge cut-outs. It is better mechanically than the materials just mentioned and is almost non-hygroscopic. The chief troubles are the non-uniformity of batches and the conductivity along the laminæ, and it is also somewhat expensive. A combination consisting of a glass external tube and a fibre or bakelite internal tube is also being used. A special form of bakelized fibre has been found to give the best all-round results.

Table 1 shows the results of an absorption test on a number of materials, all of which are capable of standing

TABLE 1.

Absorption Test after 7 Days' Immersion.

Material	Percentage increase in weight

Moulded bakelite tube	1·2
Bakelized fibre tube *	0·05

* After 65 hours, this material withstood a pressure of 3 400 lb. per sq. in.

up to the temperature of the molten fuse elements without damage.

Another important point is the fixing of end caps in cartridge cut-outs, for it is difficult to arrange fibre, bakelite, and similar substances in the form of a closed container. One common arrangement is to pin a screw-threaded brass ferrule to each end of the tube and to screw brass ends and contacts on to the ferrules. With this arrangement the pin fixing is liable to tear out. Another common method is to cut a screw-thread on each end of the tube and to screw the end caps directly on to the tube. In this case the thread is liable to strip. Yet another way is to screw a brass ferrule directly on to the tube and to screw the cap and contact on to the ferrule, but even this arrangement appears to be incapable of withstanding the forces which the tube itself can stand.

An arrangement which proved satisfactory in the tests is illustrated in Fig. 5. This consists of two brass ferrules screwed respectively into the inside and on the outside of the tube, thus clamping the tube between the two ferrules, the end cap being screwed on to the exterior of the outer ferrule.

Enclosure in metal with oil immersion.—The enclosure of fusible elements in metal containers without damping substances has been found to be unsuitable, chiefly because of the unrestricted range of the arc and the explosive effect which results in destruction of the carrier and arcing to the framework. When the fusible element is immersed in oil the arc is restricted to a comparatively small space, but the pressures set up are not reduced; rather are they augmented. This necessitates a strong housing.

To avoid flash-over and creepage over the internal and external insulation, the dimensions of the housing must be greater than with cut-outs of the insulating container type. In the development of metal-enclosed fusible cut-outs with oil immersion, the dimensions of the parts have approximated to those usual for oil switches. This may increase the cost, but it results in apparatus having a rupturing capacity intrinsically higher than in cut-outs of the insulated container type. A fusible cut-out of this pattern must be capable of withstanding explosion pressures of the order of hundreds of pounds per square inch. In tests carried out on a 6 000-volt three-phase pattern when rupturing approximately 50 000 kVA, pressures of the order of 600 lb.

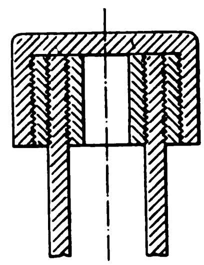

FIG. 5.—Arrangement of end-cap for cartridge cut-out.

per square inch have been measured within 2 inches of the arc, and pressures up to 200 lb. per square inch at the walls of the container.

RUPTURING-CAPACITY TESTS ON SIMPLE FORMS OF CUT-OUT.

Introductory remarks.—If a plain fusible cut-out in air operates under overload conditions, the element melts comparatively slowly, an arc is established and burning vapour is produced. If it operates on short-circuit, the effect is explosive and, in addition to the scattering of hot metal and the heat of the arc, damage is often caused to the carrier and other parts of the cut-out. There is consequently a considerable risk of personal injuries, and the psychological effect on operators is a factor to be considered. Indeed, it may be said that we have now reached the stage when uncontrolled power arcs are inadmissible. They have already been largely eliminated in switchgear by the development of oil-immersed switches, but comparatively little has been done in this direction with fusible cut-outs, and a cut-out which can be relied upon to operate satisfactorily without risk of a dangerous explosion is a recent innovation. Most of the cut-outs at present on the market are defective in this respect.

The present section of the paper gives an account of the tests carried out on plain cut-outs in air and on various commercial forms of cartridge cut-outs, assisted air cut-outs and liquid-filled tubular cut-outs.

Tests on fundamental form of fusible cut-out.—With a plain cut-out consisting of a fusible element mounted in

a carrier in air, an arc is set up at the moment of rupture, with nothing material to assist in its breakdown. There is no essential difference between this and the fundamentally simple arrangement consisting only of a piece of wire stretched between terminals. Indeed it could even be maintained that this fundamental form, as far as its circuit-breaking properties are concerned, is the better arrangement and, moreover, there is not the risk of splintering of the carrier, which is generally formed of a comparatively fragile substance.

Tests were carried out on this fundamental form arranged as in Fig. 6 and it was shown that it will clear short-circuits every time, provided the gap is large enough. On 6 000 volts a 12-inch gap is not sufficient, but moderate results are obtained with a 24-inch gap, whilst with an increased gap the circuit

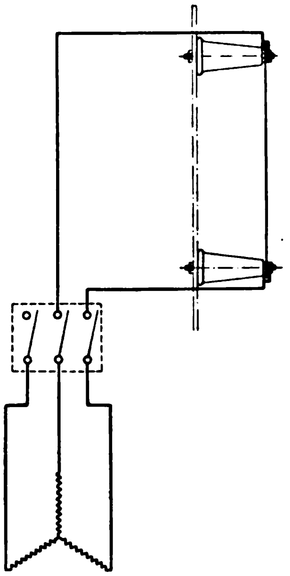

FIG. 6.—Arrangement of fundamental form of fusible cut-out as tested at 6 000 volts.

was cleared every time. Corresponding tests were carried out at and below 440 volts. The important point shown by these tests is that the process of rupturing with such a cut-out is not materially different from that with any of the undamped forms of cut-out, for a tremendous and destructive explosion took place.

Let us consider a specific instance, that of a cut-out connected to a source capable of giving a short-circuit power of the order of 50 000 kVA at 440 volts, a likely condition as was pointed out in an earlier section of the paper. Some engineers would be horrified at the idea of using this fundamental form of cut-out in such circumstances. Others would put the same wire into a porcelain or other carrier—an addition of questionable merit—and would then consider for some obscure reason that conditions were entirely different. Others, whilst neglecting the fundamental insecurity of the arrangement, would go to the trouble of specifying the dimensions of the carrier and the confining case, the size of the contacts and other factors, which from a rupturing-capacity point of view are irrelevant.

The problem must be attacked in a more logical way by investigating the prime causes of the trouble. The rupturing of the circuit produces a certain amount of thermal energy in an explosive manner, and the immediate result is the production of an arc and the explosion of a quantity of vapour. The problem can be solved only by reducing the arc energy and controlling the explosive effect; but efforts to do this with simple fusing arrangements have been unsuccessful, as the tests described below in this section will show. If these effects can be controlled and, in addition, the whole of the disruptive phenomena isolated, for instance by complete enclosure, there should be no external evidence that the internal conditions are undergoing any change even during the rupturing process. Many engineers with experience of heavy-duty fusible cut-outs will doubtless regard this as an ideal which is difficult, if not impossible, to realize. This is true when considering a cut-out in air, whether it be built into a carrier or placed in an iron box or arranged in any of the well-known ways, and it is also true of other well-known simple forms of cut-out, and of many commercial cartridge cut-outs, but entirely different results can be obtained with well-designed cut-outs, as will be clearly shown in later sections of the paper.

Tests on heavy-duty plain cut-out.—The performance of a heavy-duty plain cut-out on short-circuit is described below in some detail in an attempt to present a picture of the performance of the majority of power cut-outs of this type. The tests were a reproduction of the conditions obtaining with the auxiliary supply in a modern power station, and were similar to the conditions to be found to-day on many alternating-current distribution systems.

The cut-out consisted of three separate carriers for three-phase working, with porcelain-shrouded contacts and insulating barriers between phases and to earth. The elements were rated at 200 amperes continuous carrying capacity. The general construction was heavy, the weight of the unit being about 100 lb. As will be seen, the results were disastrous, there being a huge flash and report accompanied by flying fragments, and it is almost certain that any person or apparatus in the neighbourhood would have been badly damaged.

A three-phase transformer bank consisting of two 1 200-kVA transformers in parallel was coupled to a 6 000-kVA three-phase 40-cycle 6 600-volt turbo-alternator capable of giving a maximum of 70 000 kVA on dead short-circuit. The tests were commenced with a pressure on the transformer secondaries of 180 volts between phases, as shown in the oscillogram (Fig. 7). On short-circuit at full voltage the transformer bank was capable of giving a maximum current of about 100 000 amperes (peak). The instantaneous current value actually attained was 8 446 amperes.

In this test, the sequence of events was as follows: All connections were made and current was switched on from the high-pressure side. Before the current had reached its first peak, the elements ruptured with a loud report. Simultaneously, there was a blinding flash, apparently several feet across and lasting no longer than 1/80 second. One-thirtieth of a second after the flash, a cloud of gas 2 ft. in diameter had gathered, having been

forcibly ejected from the bodies of the fuse carriers. One-fifth of a second from the start, molten material was first noticed being ejected, and this lasted altogether for $\frac{1}{8}$ second, at the end of which time the molten material had succeeded in kindling a fire amongst a with the usual intolerable explosion, with flame and burning fragments ejected in all directions, but cleared the fault. At the sixth short-circuit (at 440 volts) a second flash-over between phases took place, with results similar to those of the first test.

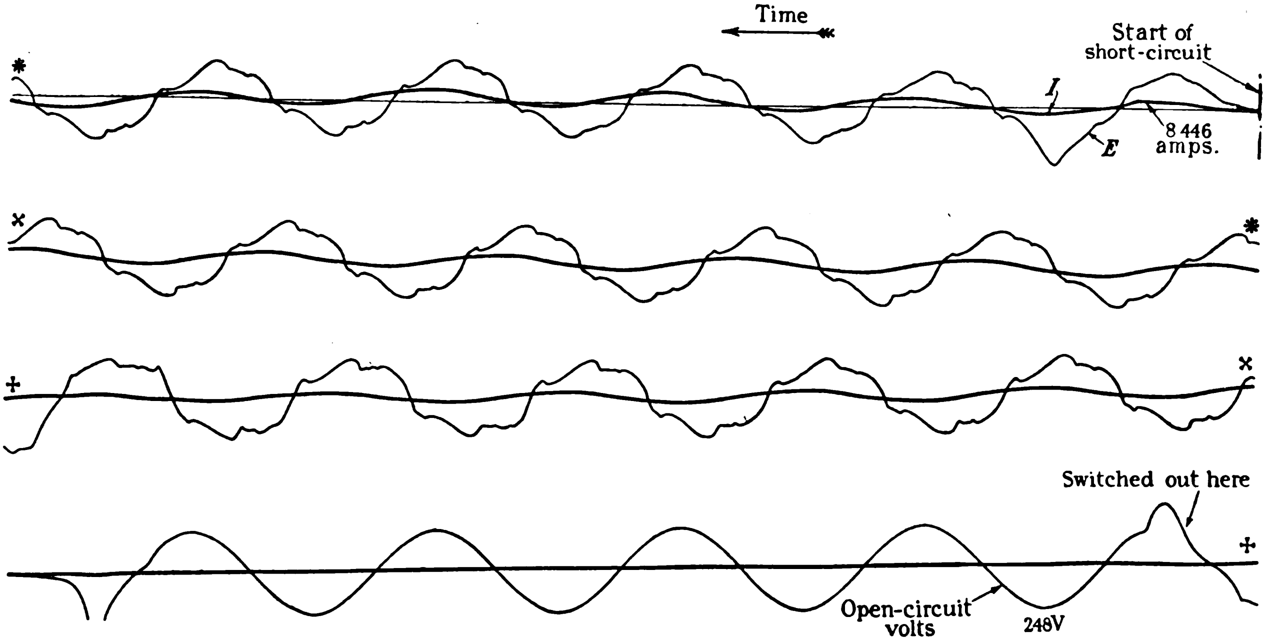

FIG. 7.—Short-circuit test at 180 volts on heavy-duty plain cut-out.

handful of waste on the ground about 3 ft. below the fuse chamber. At $\frac{1}{8}$ second from the start, the smoke and gas cloud was 4 ft. across, and at $\frac{1}{3}$ second, it was 12 to 15 ft. across. The cloud was very dense and came from all sides of the apparatus. It was found on

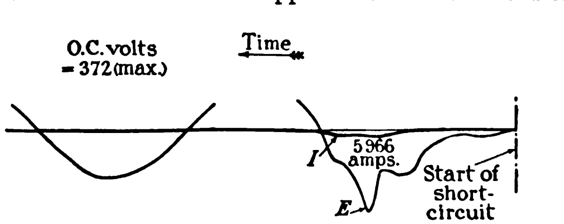

FIG. 8.—Short-circuit test at 265 volts on plain cut-out.

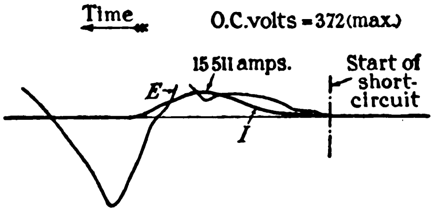

FIG. 9.—Short-circuit test on plain cut-out; voltage = 265.

dismantling the apparatus that there had been an arc-over between phases due to the hot gases given off by the molten fuse elements. Altogether a total of about 1 cubic inch was burnt off the connections in this way.

In four subsequent tests at voltages ranging from 150 to 440 volts between phases, the cut-outs operated

There were two failures out of six tests (oscillograms of four of the five remaining tests are shown in Figs. 8, 9, 10 and 11, of which Fig. 11 shows the sixth test), the better results on the second to fifth tests possibly

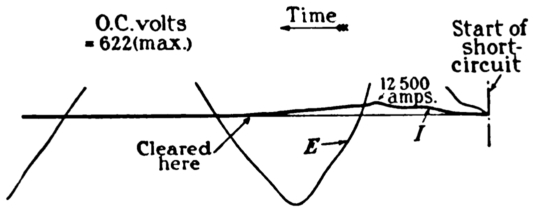

FIG. 10.—Short-circuit test at 440 volts on plain cut-out.

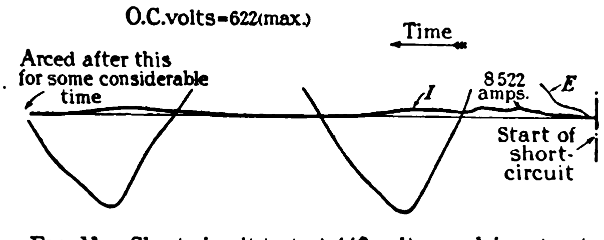

FIG. 11.—Short-circuit test at 440 volts on plain cut-out.

being due to the increased clearance through burning in the first test, but more probably the tests represent a normal average of breakdowns.

These and similar tests serve to show that plain cut-outs, however carefully designed, are inadequate on heavy-duty work and are dangerous alike to the operators

and to all apparatus associated with them. Cinema records in addition to oscillograph records were taken of these tests and also of the comparative tests described in the next sub-section.

Tests on commercial tubular cut-outs.—Similar tests were carried out on many commercial types of tubular cut-outs with liquid, powder and other fillings and at various voltage ratings. The majority of these tests were extremely disappointing and even disquieting; the cut-outs were frequently destroyed, resulting in an open arc between the main contacts. A brief description of a representative selection of these tests is given below. The first group was carried out on low- and medium-pressure cut-outs (500 volts and under), the circuit arrangements being similar to those described for the heavy-duty plain cut-out referred to in the previous sub-section, whilst in the remaining nine tests the high-pressure cut-outs were connected directly across the machine terminals. Oscillograph records of some of these tests are illustrated in the paper, the figure numbers being given in brackets. Many of these tests were carried out at reduced voltage, but this made little or no improvement in the performance.

Test at 350 volts, 40 cycles, on 250-ampere filled cartridge cut-out with zinc element in fibre case: blew to pieces, big flash and report, some smoke.

Test at 350 volts, 35 cycles, on 250-ampere cartridge cut-out in fibre case: blew to pieces, large flash, loud report.

Test at 350 volts, 40 cycles, on 250-ampere aluminium-element cartridge cut-out: blew out at top end cap, rupturing the metal part, cloud of smoke and explosion.

Test at 440 volts, 40 cycles, on 300-ampere pebble-filled cartridge cut-out for network use, zinc element: orange flame, loud explosion, blew to pieces (Fig. 12).

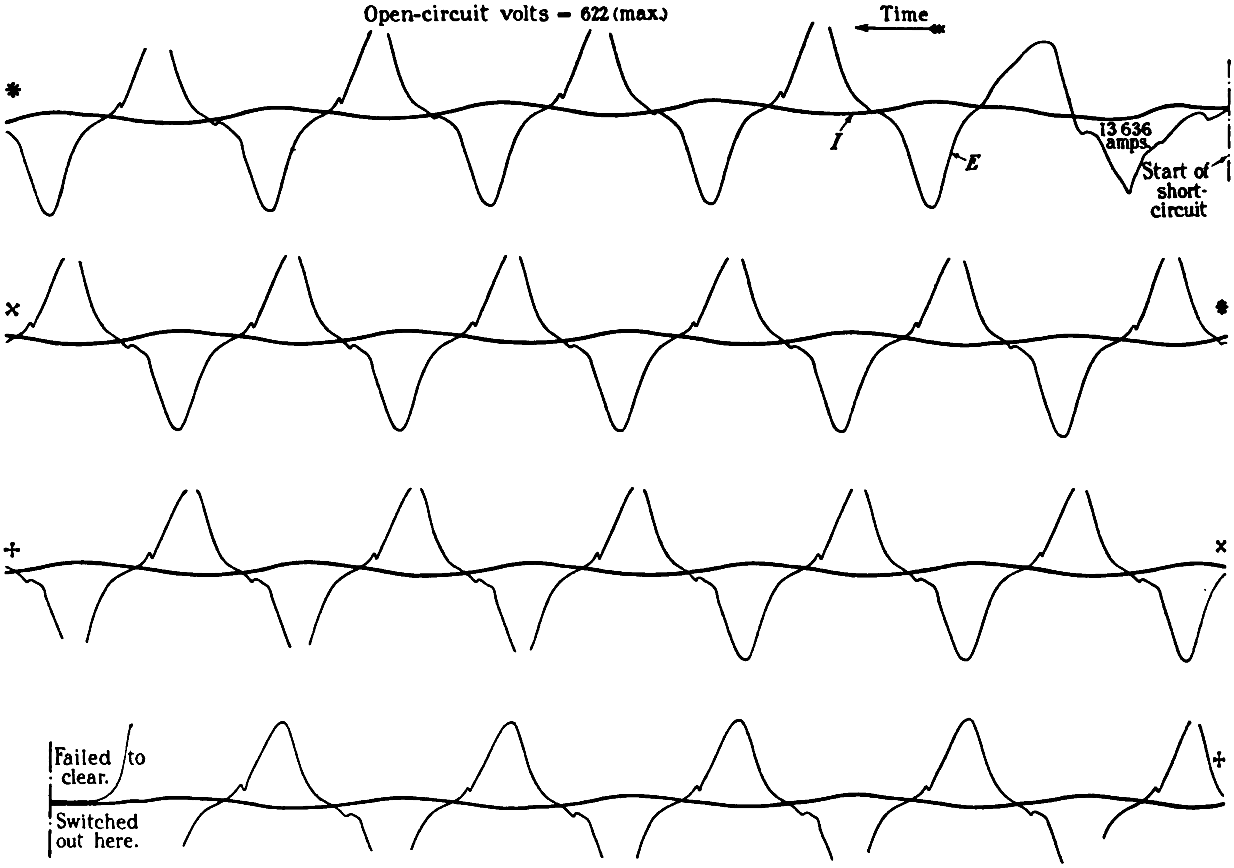

FIG. 12.—Short-circuit test at 440 volts on 300-ampere 500-volt commercial cartridge cut-out.

Test at 350 volts, 40 cycles, on zinc-element inert dust-filled cartridge cut-out rated at 500 volts, 150 amperes: flame blew out at top, fairly loud noise, smoke: noise heard after cartridge had blown, indicating that it had not cleared (Fig. 13).

Test at 250 volts, 40 cycles, on 200-ampere early-pattern cartridge cut-out with unknown filling: end piece blown several yards away, big flash, loud report and smoke (Fig. 14).

Test at 350 volts, 40 cycles, on enclosed 250-ampere cartridge cut-out: flame and a lot of smoke, not much noise, jaws of top contacts burnt (Fig. 15).

Test at 350 volts, 40 cycles, on 250-ampere pebble-filled cartridge cut-out: blew to pieces, big flash, loud report.

Test at 350 volts, 40 cycles, on 250-ampere chalk-filled cartridge cut-out: blew out at top, grey smoke, no flash.

Test at 4 500 volts, 40 cycles, on glass-tube cut-out filled with extinguishing liquid, peak current 4 500 amperes: bottom contact sheared due to force of explosion, fuse cleared (Fig. 16).

Test at 5 000 volts, 60 cycles, on pressure-chamber cut-out: blew to pieces with loud report, smoke, flying fragments.

Test at 6 030 volts, 40 cycles, on 20 000-volt glass-tube cut-out, current 4 800 amperes: failed to clear and arced until cleared by main circuit breaker.

Test at 6 000 volts, 40 cycles, on 11 000-volt bakelite-tube cut-out filled with extinguishing liquid: tube burst and arc set up in air across terminals, circuit cleared by oil switch, current in first half-cycle 7 500 amperes (Fig. 17).

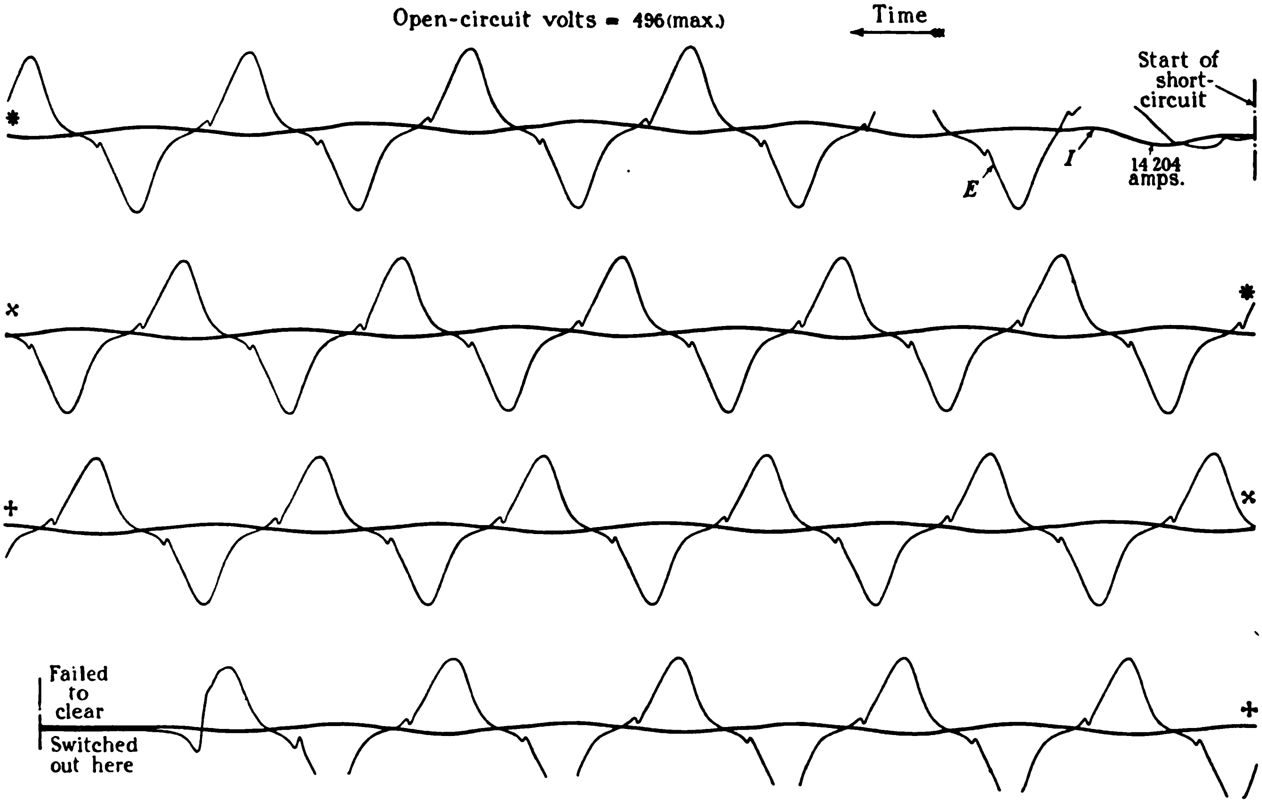

FIG. 13.—Short-circuit test at 350 volts on 150-ampere 500-volt commercial cartridge cut-out.

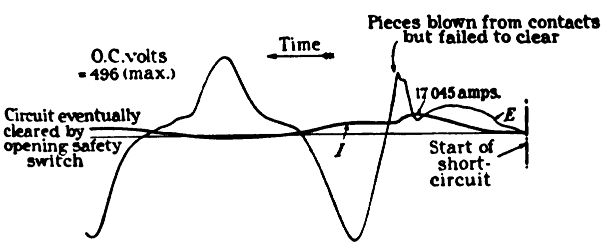

FIG. 14.—Short-circuit test at 350 volts on 200-ampere old-pattern 500-volt cartridge cut-out.

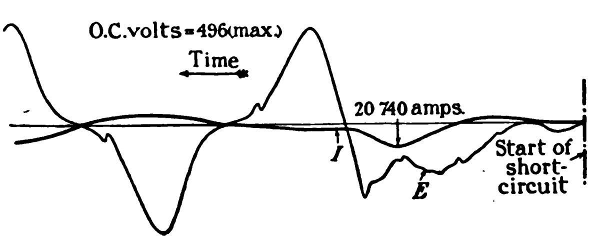

FIG. 15.—Short-circuit test at 350 volts on 250-ampere commercial 500-volt cartridge cut-out.

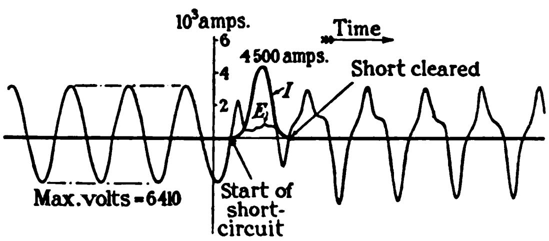

FIG. 16.—Short-circuit test at 4 500 volts on 6 000-volt 25-ampere liquid-filled glass-tube cut-out.

Test at 6 000 volts, 40 cycles, on 11 000-volt glass-tube cut-out with extinguishing liquid: cut-out blew to pieces with bad flash and explosion, but cleared short-circuit (Fig. 18).

Test at 4 000 volts, 50 cycles, on "expulsion" cut out: bad explosion, smoke (Fig. 19).

Test at 5 500 volts, 50 cycles, on " expulsion " cut-out: blew to pieces with loud report; smoke, flash and fragments, portions of fuse carrier picked up 300 ft. away.

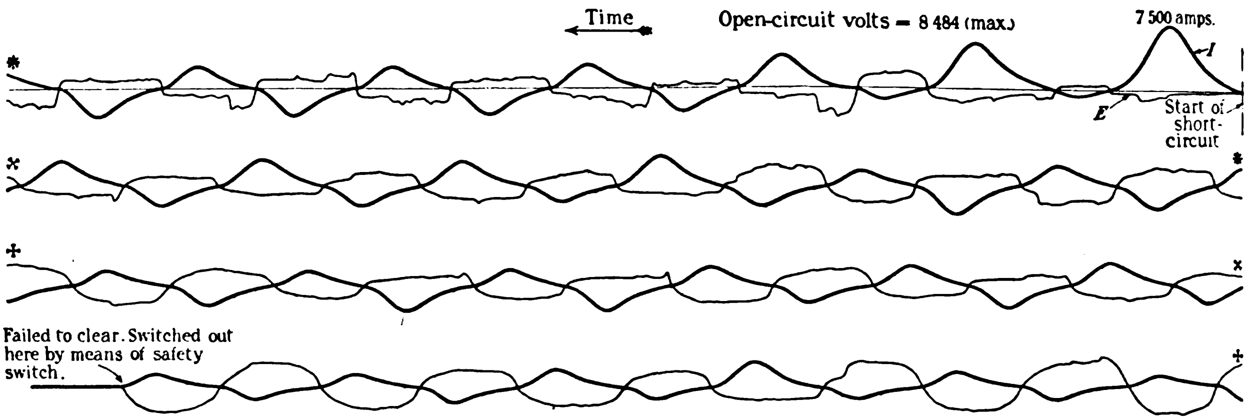

FIG. 17.—Short-circuit test at 6 000 volts on 11 000-volt 20-ampere bakelite-tube cut-out.

Test at 3 300 volts, 40 cycles, on 3 300-volt foreign oil-pot cut-out: half of oil ejected, interior found to be broken up after test; fuse arced for a prolonged period (Fig. 20).

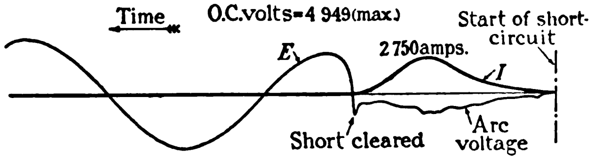

FIG. 18.—Short-circuit test at 6 000 volts on 11 000-volt 20-ampere glass-tube cut-out.

Test at 3 300 volts, 40 cycles, on 3 300-volt oil-pot cut-out: oil, smoke and flame ejected, flashed over to earth internally (Fig. 21).

MODERN TYPES OF FILLED CARTRIDGE CUT-OUTS WITH SPECIAL FILLINGS.

It was found on test that certain recently developed types of cartridge cut-out give a performance entirely different from that of the older types referred to in the last section. They have been tested for low-pressure work and for high-pressure work (up to 6 000 volts) with equally good results.

One design has already been referred to and is illustrated in Fig. 4. It consists of a robust cartridge cut-out with a bakelized fibre container and strong metal ends. For extra-heavy duty a double container is used (as shown in the figure) with a vent arrangement between the inner and outer containers. It is a difficult matter to arrange an effective vent which will operate sufficiently rapidly to relieve the sudden rise of gas pressure. In the present instance a thin paper seal across a hole of predetermined dimensions has proved to be quite effective. The fusible element was evolved after considerable trial and, apart from its rupturing-capacity performance, the calibration for load conditions was found to be exceptionally accurate. The filling, which

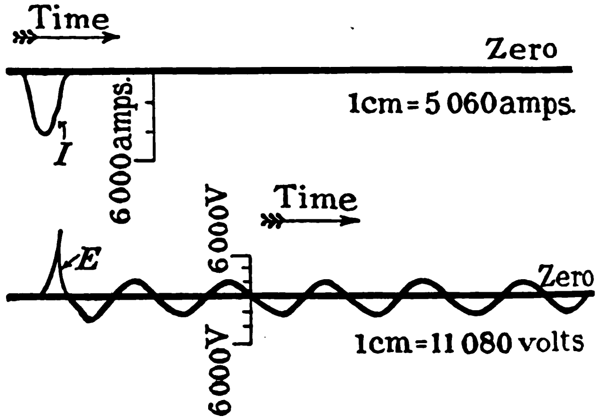

FIG. 19.—Short-circuit test at 4 000 volts on 11 000-volt 25-ampere expulsion cut-out.

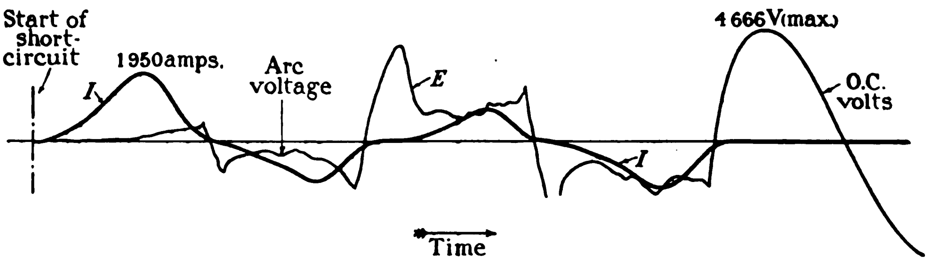

FIG. 20.—Short-circuit test at 3 300 volts on 3 300-volt 25-ampere oil-pot cut-out.

has calcium carbonate as a basis, was also determined by experiment.

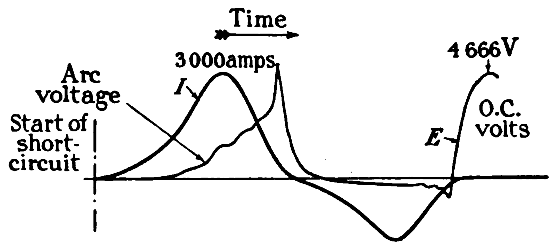

FIG. 21.—Short-circuit test at 3 300 volts on 3 300-volt 25-ampere oil-pot cut-out.

In tests similar to those described in the previous section, which resulted in the destruction of plain cut-outs and commercial tubular cut-outs, the present section, and although the fault current was carried for only a small fraction of a second, there was yet sufficient time to allow the rubber to liquefy and to run out at the ends of the cable, accompanied by clouds of smoke.

Another modern type of cartridge cut-out was also subjected to tests. It had a moulded container of ceramic material and a simple inert filler of clean sand. This cut-out was not so exhaustively tested as those previously referred to, but in medium-pressure tests (up to 440 volts) it was proved to be capable of standing up to short-circuits of considerable magnitude. A characteristic oscillogram for this cut-out is shown in Fig. 24.

The Ironclad Oil-Immersed Cut-Out.

Preliminary remarks.—The ironclad oil-immersed fusible cut-out is a recent development. One of the first difficulties to be surmounted was that of the heating

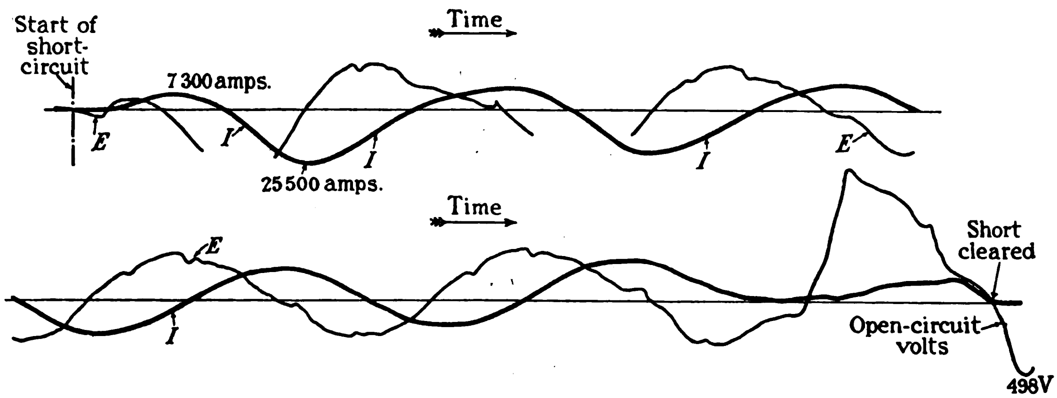

FIG. 22.—Short-circuit test at 350 volts on 500-volt 400-ampere modern, filled, cartridge cut-out.

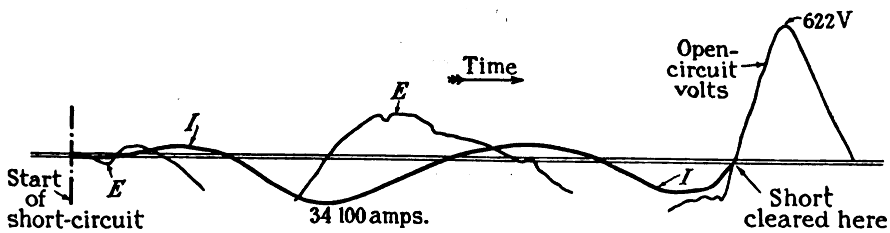

FIG. 23.—Short-circuit test at 440 volts on 500-volt 400-ampere modern, filled, cartridge cut-out.

cut-out cleared the short-circuit satisfactorily with no sign of flash or flame and with no report. Characteristic oscillograms of medium-pressure tests are given in Figs. 22 and 23, equally good results being obtained in the high-pressure tests.

It was perfectly safe to be in the vicinity when this cut-out was opening a "potential short-circuit" of 100 000 amperes. (The term "potential short-circuit" is used to indicate the maximum current which could be fed into a dead short-circuit if there were only the inherent reactance of the system to limit the current; since the fuse exerts a limiting effect, the actual short-circuit current is usually considerably less than the potential short-circuit current.) The only sign of anything happening was the melting of the insulation of the connecting cables, which took place in every test irrespective of the type of cut-out under test. The cables were of approximately 0·25 square inch of the fusible element. This has caused trouble in the past and is one of the reasons why the design has not

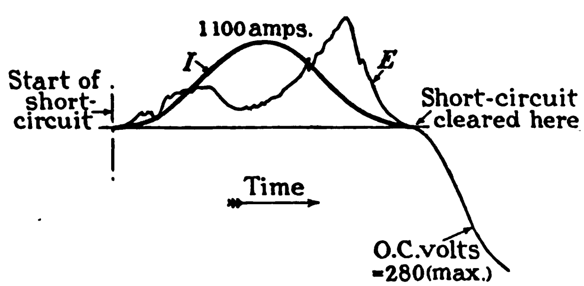

FIG. 24.—Short-circuit test on 500-volt reinforced-container cartridge cut-out with inert filler.

been developed before. In earlier papers on the subject, it is stated that oil-immersed fusible elements must be

run with a large voltage-drop on account of the high current density. It is stated that in such conditions the oil gets hot and that no cut-out should be allowed in which the fuse wire is in contact with or immersed in oil.

With long fuse wires the heating effect is certainly sufficient to raise the oil to a dangerous temperature.

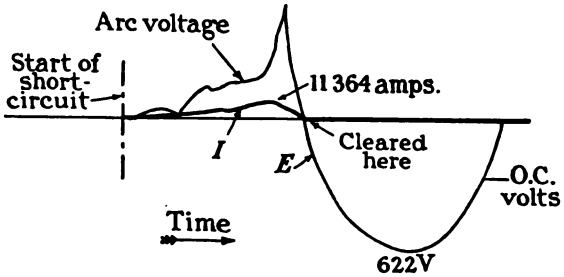

FIG. 25.—Short-circuit test at 440 volts on 440-volt oil-immersed ironclad cut-out.

Length of element and current density are responsible for the energy loss and consequent heating of the oil. Experiments were made to determine whether a reduction in the dissipation of energy could be obtained by considerably shortening the fusible element. As a result, a satisfactory fixed break was evolved for low-pressure work, but for high-pressure work it was found desirable to employ springs to ensure a rapid and long break.

Low- and medium-pressure type.—A number of tests similar to those described in previous sections were carried out on a 600-volt three-phase 200-ampere ironclad oil-immersed cut-out. The three phases were mounted within 2 inches of one another and at a similar distance from the iron case, which was earthed. This cut-out broke, without any sign of operation other than the ejection of a slight spray of oil through a somewhat faulty flange, short-circuits similar to those which destroyed the other types of cut-out. Similar tests on other sizes showed equally satisfactory results. A characteristic oscillogram is given in Fig. 25 for a 440-volt cut-out, and a typical 440-volt installation is shown in Fig. 26.

High-pressure type.—Fig. 27 shows a sectional view of a 6 600-volt oil-immersed cut-out, and Fig. 28 illustrates a typical complete installation. The general construction will be clear from the figures. A large oil volume is provided, primarily for the purpose of keeping up the rupturing capacity and of assisting the cooling process. In reducing the fuse length, a limit is reached when the end connections exert an appreciable effect on the cooling of the fuse wire. A length of $1\frac{1}{2}$ inches was finally adopted. It is true that a certain amount of cooling is exercised by the contacts on a fuse wire of this length, but the effect is consistent and good calibration is possible. As has been mentioned, springs are used to give a long break, and tests were carried out to determine the maximum arcing distance. Finally, the contacts were so arranged that in breaking a 50 000-kVA short-circuit on pressures up to 6 600 volts, the distance between the contacts was about four times the maximum arcing distance.

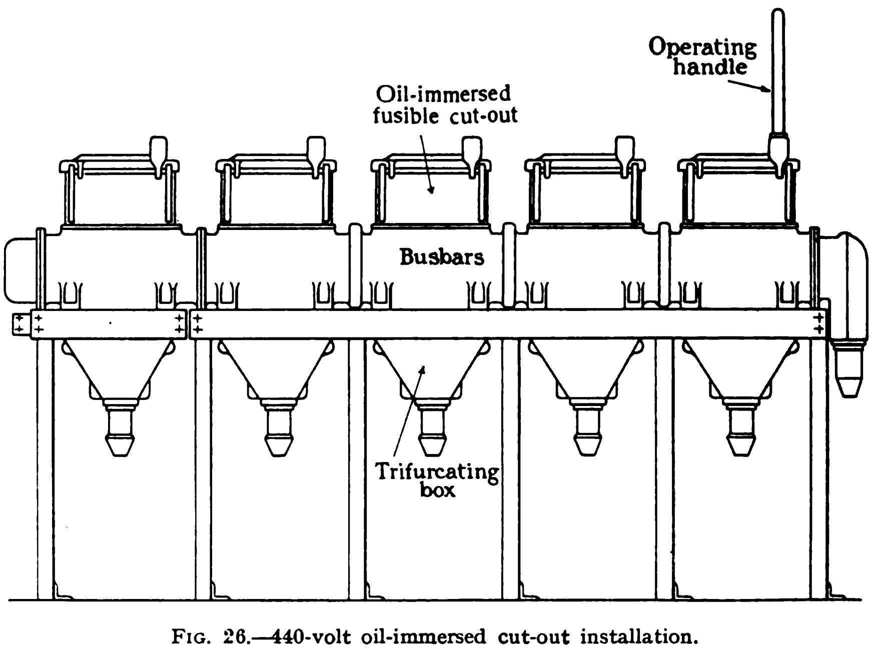

FIG. 26.—440-volt oil-immersed cut-out installation.

The arrangement of springs was also determined by experiment. The normal speed of break in oil-immersed circuit breakers is about 5 ft. per second, and the maximum speed used is from 12 to 15 ft. per second. This is generally considered to be the maximum safe speed. Increased speeds were, however, tested with the object of extinguishing the arc within the first half cycle, which has been shown by test to reduce the shock to plant, mains, etc., to a remarkable extent.

The noise and shock due to plant when subject to short-circuit are well-known, but by the use of fuses with their characteristic quick clearance this noise can be

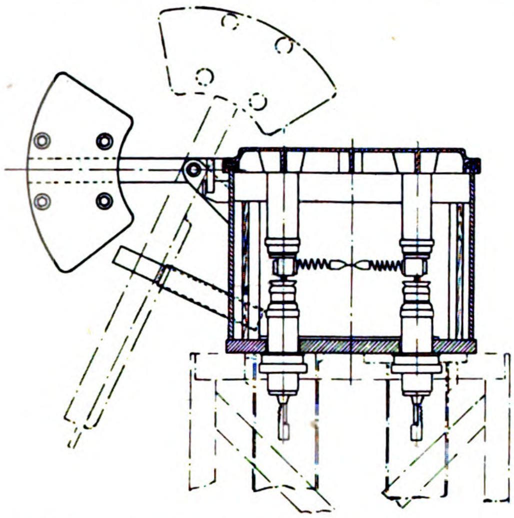

FIG. 27.—Section of oil-immersed fusible cut-out.

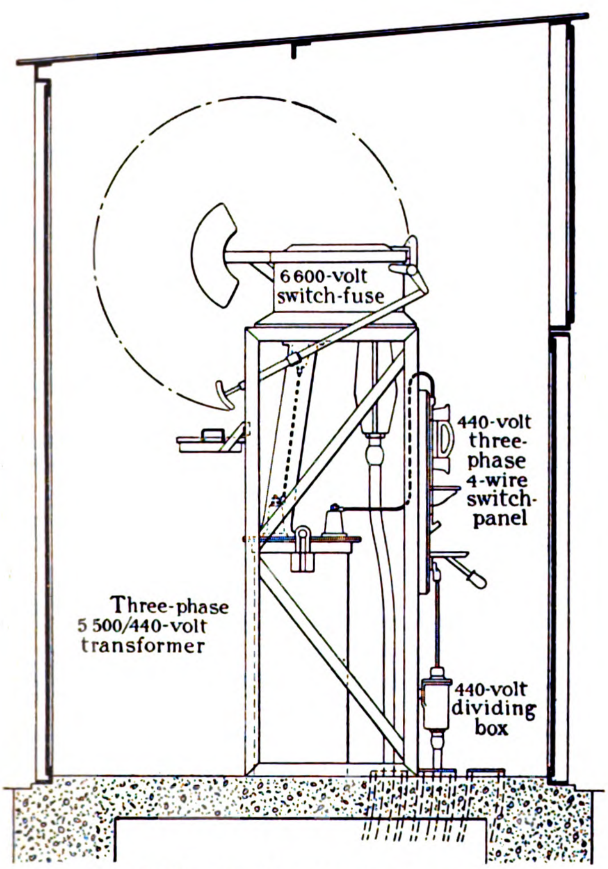

FIG. 28.—6 600-volt oil-immersed cut-out installation.

reduced to a mere click, which is frequently barely discernible. It was found that the increased speed necessitated a speed of break of 30 ft. per second, and the spring arrangement was finally arranged to give 40 ft. per second. This represents the maximum safe speed of break which can be employed (at any rate for work of the class being dealt with) without introducing the risk of pressure-rises through enforced decay of the current—an important point. It is of the utmost importance that the speed of break should not be too high or else the arc will be lengthened too rapidly, a condition analogous to introducing resistance into the circuit, with the aforementioned risk of pressure-rise.

Oxidation troubles.—After oil cut-outs of this pattern had been in service for some time, it was found that an action was taking place on the fusible elements, which gradually became covered with a brown deposit,

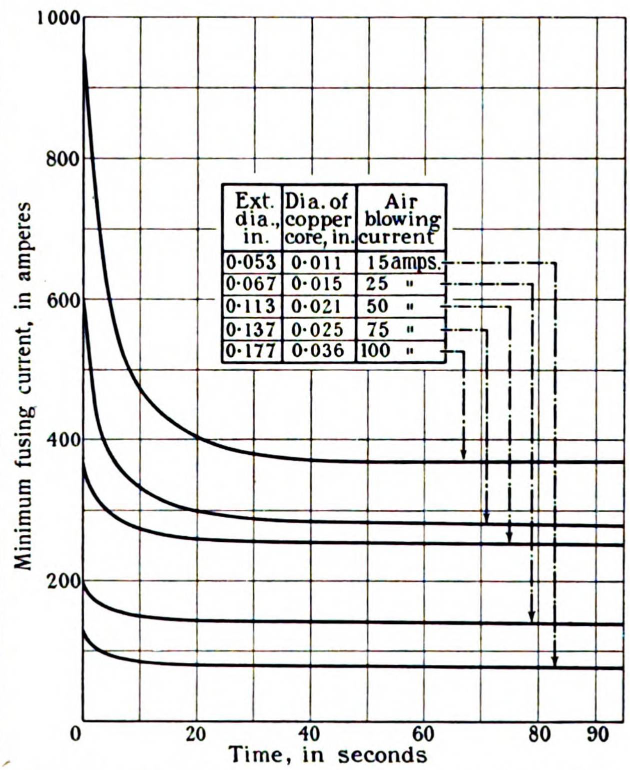

FIG. 29.—Time/current curves of oil-immersed bi-metallic fusible elements.

and the metallic portion appeared to be reduced in section cumulatively, until finally the element would melt on reduced current or even spontaneously. This appeared to be a recrudescence in a new form of the old oxidation trouble experienced with air cut-outs, and in oil the trouble was experienced with any load/fusing-current ratio lower than 1 to 3. In order to avoid this trouble, it was found necessary to adopt a load/fusing-current ratio of 1 to 6, which, of course, gives indifferent protection.

It was believed that the action was at least partly catalytic, but from the very mechanism of the action it was clear that catalytic action was not alone responsible. When copper wires were used, it was found impossible to overcome the trouble while retaining a reasonable load/fusing-current ratio, and bi-metallic

fusible elements having a copper core sheathed with tin or tin-lead were finally adopted. The cumulative deterioration process was thus eliminated, apparently due to the provision of increased radiation surface for a given current density, with consequent reduction of the surface temperature, and perhaps also to the substitution of a comparatively inert agent for copper.

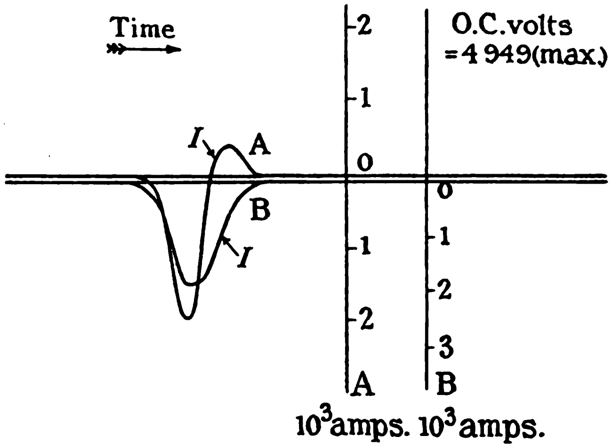

FIG. 30.—Preliminary short-circuit tests on 6 600-volt oil-immersed ironclad cut-out.

With these bi-metallic elements the load/fusing-current ratio was reduced to 1 : 3 and could have been still further reduced.

Fig. 29 shows characteristic time/current curves for fusible elements of this character when immersed in oil under these conditions.

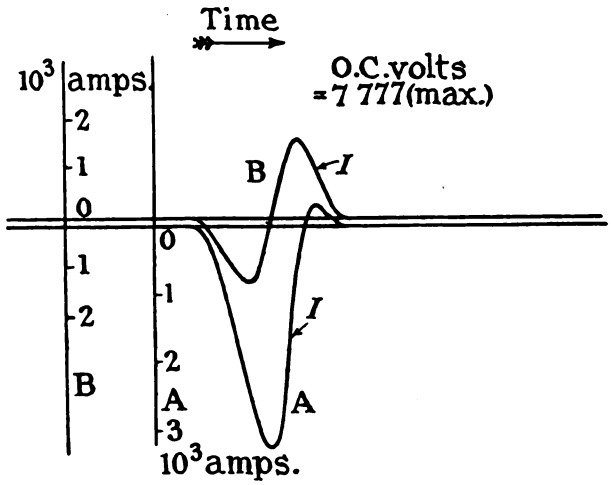

FIG. 31.—Preliminary short-circuit tests on 6 600-volt oil-immersed ironclad cut-out.

Tests on high-pressure oil-immersed cut-out.—Three characteristic oscillograms taken during tests on a 6 600-volt three-phase oil-immersed cut-out are given in Figs. 30, 31 and 32. The first two records were taken on earlier designs operating with a speed of break of about 10 ft. per second, while the third record was taken on the same pattern cut-out after the design had been perfected and the arcing time reduced to the minimum.

Fig. 30.—Three-phase test on dead short-circuit; test volts = 3 500 R.M.S. (line).
Calibration: A = 10·1 mm per 1 000 amps.
B = 7·01 mm per 1 000 amps.
Fig. 31.—Three-phase test on dead short-circuit; test volts = 5 500 R.M.S. (line).
Calibration: A = 9·3 mm per 1 000 amps.
B = 6·5 mm per 1 000 amps.
Fig. 32.—Three-phase test on dead short-circuit; test volts = 6 500 R.M.S. (line).
Calibration: A = 6·05 mm per 1 000 amps.
B = 8·66 mm per 1 000 amps.

The ironclad oil-immersed cut-out is available for higher pressures than 6 600 volts, but no tests have

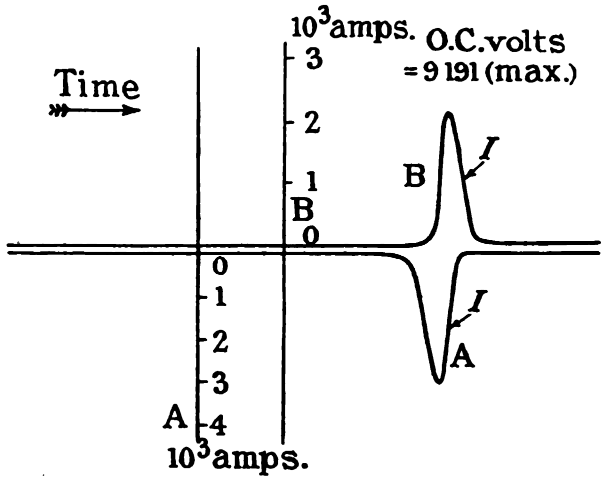

FIG. 32.—Short-circuit test on final design of 6 600-volt oil-immersed cut-out with high-speed break.

been carried out by the author on the higher-pressure cut-outs.

A characteristic time/current curve of a high-pressure oil-immersed cut-out is given in Fig. 33. The feature to be noticed in this curve is the tendency towards flattening of the characteristic from the rather angular form of similar air cut-outs.

Oil and gas pressures in oil tanks.—When an oil cut-out is interrupting any considerable current, pressures are set up which are to some extent a measure of the power being ruptured.

If the power broken is well within the capacity of the cut-out, the effect of the arc is to set up a hot gas bubble in the body of the oil. A steep-front pressure-wave will then be transmitted to the walls of the tank. This wave may or may not be capable of doing material damage. After an interval, the oil will yield to the pressure, which will cause an upward movement of the oil (the only direction possible), but, owing to the power being comparatively small, the air at the top of the tank will be compressed, but only to a small extent. The movement of the oil and air will adjust the pressure sustained after the original explosion.

If a greater power be broken, the high-frequency

pressure-wave will be of greater amplitude. The follow-on effect due to the expansion of the gas bubble will be greater and the oil will be pressed out in all directions against the top, sides and bottom of the tank. The air cushion will be practically obliterated and a pressure will be sustained in all directions. A mental picture of the condition can be obtained by considering the gas bubble to be a core to the oil, the latter being held securely in all directions against further expansion by an iron skin, i.e. the oil tank.

In short-circuit tests at 6 000 volts a number of oil-pressure records were taken. When breaking 10 000 kVA the sustained pressures averaged nearly 20 lb. per square inch. At 20 000 kVA the average

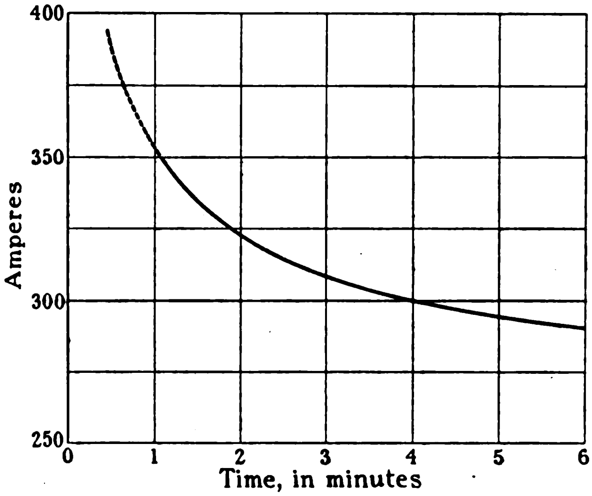

FIG. 33.—Time/current curve of copper fusible element in oil.

of a number of tests gave nearly 30 lb. per square inch, and at 50 000 kVA the pressures reached 150 lb. per square inch several times, but averaged more nearly 80 lb. per square inch. In Fig. 34 are given curves showing comparative results obtained in similar tests. Curve (A) gives the average pressures, whilst curve (B) gives the maximum results recorded. It should be explained that whilst in the majority of instances the pressures recorded are in the neighbourhood of curve (A), yet there is, at present, an ineradicable proportion of pressures recorded of quite a different order. These exceptional pressures are referred to as maximum

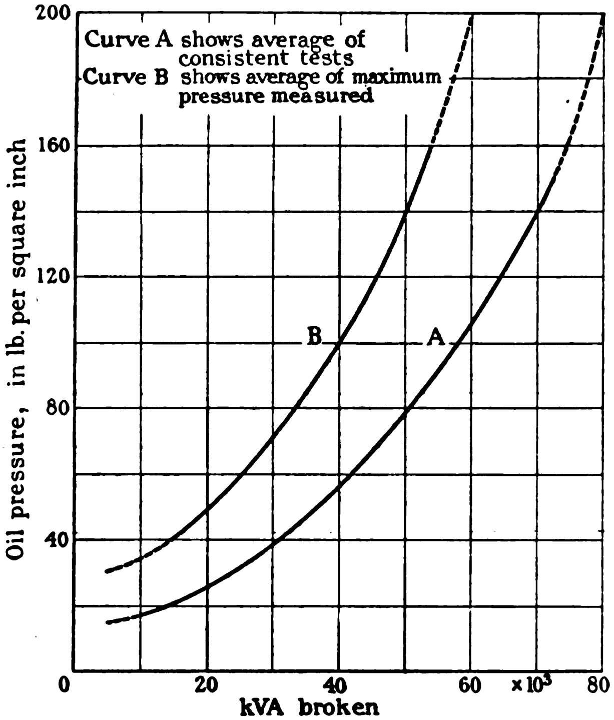

FIG. 34.—Curve showing average and maximum oil pressures set up when rupturing a given power.

pressures and their average values are recorded in curve (B). It is considered that all cut-outs should be designed for at least the average of such maximum pressures. In all tests these pressures were measured at the tank walls or bottom. The curves, it will be seen, do not cut the zero, perhaps because so soon as the gas bubble becomes large enough to press out the

* Assumed.

oil in all directions, a pressure of at least 20 lb. per square inch is set up. Several arrangements were devised in attempting to produce a reliable pressure indicator for this work, and it is believed that the results given are to be relied upon.

Ratings of oil-immersed cut-outs.—The low- and medium-pressure type of ironclad oil-immersed cut-out above referred to is rated for pressures up to 660 volts between phases. This type is also modified for high-pressure work for voltages between 2 200 and 3 300. Both types have been tested many times and are capable of breaking 60 000 kVA satisfactorily. The maximum safe rupturing capacity is probably between 80 000 kVA and 100 000 kVA.

The particulars given in Table 2 are an example of a typical rating system for low-pressure and medium-pressure cut-outs, and are applicable to power station auxiliary motors controlled by voltage-reducing starters or their equivalent, but do not apply to direct-started motors. The figures are based on a motor efficiency of 80 per cent and a power factor of 0·80. The cut-outs are required to withstand the full starting current for 2 seconds without blowing, but should clear a sustained stalling current.

Table 3 contains particulars of a simple fuse-rating system for cut-outs of the high-pressure type and gives for the various fuse sizes the load current and load kVA at various voltages, as well as the rated rupturing capacity at those voltages. For load ratings above those given in the table, it is usually more economical to install oil-immersed switchgear.

The various types of ironclad oil-immersed cut-outs have been proved capable of breaking load current and isolating a high-pressure circuit merely by swinging back the lid, without affecting the fusible elements. It is possible to close the lid, thus making the circuit on full load and on moderate short-circuits with safety.

New Type of Oil-Immersed Fusible Cut-Out.

Fig. 35 is an oscillogram taken during a test on a new form of cut-out. The fusible element is oil-immersed and the arc characteristic can be consistently reproduced. It will be seen that the arc voltage is quite stable, there being none of the vicious harmonics usually found in an arc characteristic. The process of rupture, as shown in the oscillogram, is clean and rapid and the performance quite different from anything previously experienced, the total energy being much less than with cut-outs of the older forms.

In the test illustrated, the cut-out cleared a short-circuit power of 3 673 amperes at 4 666 volts without any visible or audible evidence of its having operated at all. The overall dimensions of the cut-out are comparable with those of many of the old forms of cartridge cut-out in common use, which in the tests described in this paper proved to be inadequate. It is hoped that more information will be available in the near future.

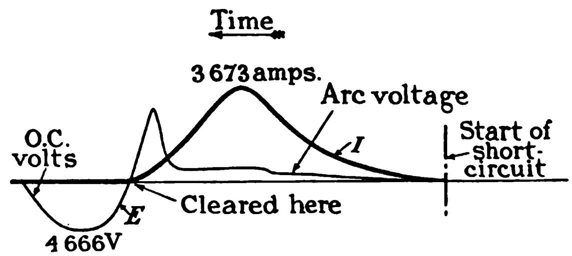

Fig. 35.—Short-circuit test at 5 000 volts on stabilized arc cut-out.

Comparison of Various Types of Cut-Outs.

As the result of the investigations above described, a chart has been prepared with the object of showing a comparison between the rupturing capacities of the

various types of cut-outs tested. This chart is shown in Fig. 36, the ordinates (indicating rupturing capacity) being given on a square-root scale in order to save space. The ninth column (high-pressure oil-immersed cut-outs) has been extended to 300 000 kVA on the evidence of the performance of oil-immersed circuit breakers of similar dimensions. It will be noticed that rupturing capacities above about 5 000 kVA are obtainable only with the modern types of cartridge cut-out with special fillings and with the ironclad oil-immersed cut-outs. One term used in the chart may not be quite clear. In column 4, by "assisted air cut-outs" is meant those cut-outs which consist substantially of a simple element in air and in a carrier or container, this rupturing process being assisted by embodying in the design a pressure chamber or a gas jet as, for instance, in the "expulsion" cut-out.

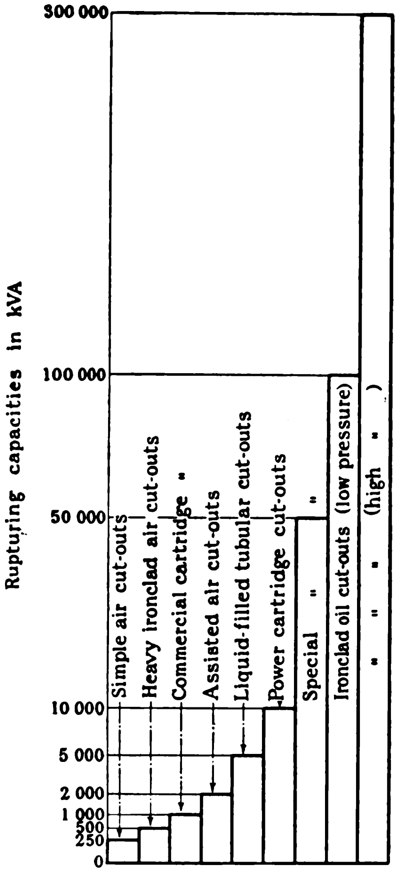

FIG. 36.—Rupturing-capacity chart.

CUT-OUTS FOR SMALL-CURRENT HIGH-PRESSURE WORK.

General remarks.—Experiments were made with a view to finding a fusible cut-out suitable for small-current high-pressure work—for example, for the control of small equipments, the protection of potential transformers and for more unusual services such as the power-line control of "wired wireless" equipment. For this purpose, tests were carried out on tubular cut-outs, many of them similar in form to those already described but using limiting resistances connected in series. It was found that the majority of the better designs could be made to function quietly with a series resistance which limited the short-circuit power to something under 1 000 kVA. These were power cut-outs and relatively expensive. If the value of the resistance be increased to allow lighter cut-outs to be used, the accuracy of the instrument transformers is liable to be interfered with.

Upon reducing the value of the limiting resistance, it was found that two things happened: failure of the cut-outs commenced, and it was found difficult to produce a resistance which could safely be put forward for enclosure in switchgear structures. This is only to be expected as the heating is proportional to the square of the current, and the bulk of the resistance increases in proportion if the resistance is to be capable of withstanding the heating, without damage to itself or neighbouring apparatus. A switchgear enclosure is far from an ideal place for a hot body, such as a limiting resistance when carrying short-circuit current, and there is a real danger of the hot vapour causing flash-over, damage to insulation, etc., or of the resistance itself being destroyed.

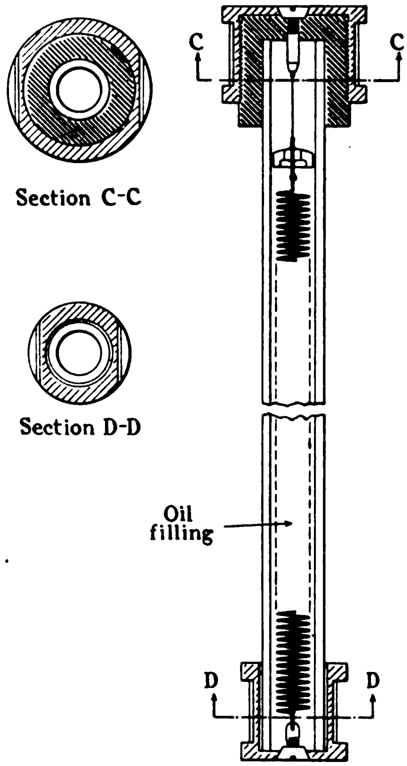

FIG. 37.—Section of resistance cut-out.

Combination resistance-fuse.—As the fusible element would inevitably be destroyed on short-circuit, and as an economical resistance would be in danger of destruction or would rise to a temperature which would be dangerous to other apparatus unless the resistance

were enclosed, it was therefore reasoned that the resistance and fuse could well be enclosed in a single container, thus obtaining a dual advantage. Having a resistance in series, it became possible to design a cut-out of comparatively simple construction which would rupture the maximum short-circuit current and, as the

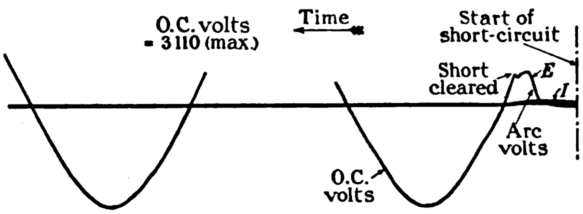

FIG. 38.—Short-circuit test at 2 200 volts on 5 500-volt resistance cut-out.

resistance was enclosed with the cut-out, it was relatively unimportant if this resistance should become overheated.

Following to some extent on the experience obtained on the ironclad cut-out, a short fusible element was used. This was immersed in oil in a tubular

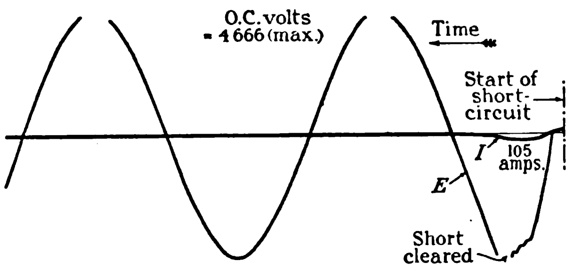

FIG. 39.—Short-circuit test at 3 300 volts on 5 500-volt resistance cut-out.

container as shown in Fig. 37. The resistance wire was made in the form of a spiral to obtain the requisite resistance and to take advantage of the magnetic effect of the turns of the spiral in obtaining a rapid break. A short element was used giving the desirable

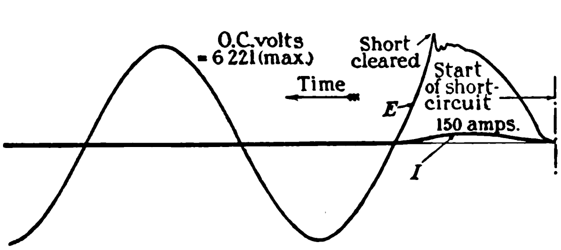

FIG. 40—S.hort-circuit test at 440 volts on 5 500-volt resistance cut-out.

feature of having only a small mass of metal to be melted. Tests were carried out on this cut-out and finally resulted in the production of a workable arrangement which could be connected directly across a high-pressure circuit and which interrupted the resultant power without noise, flash, or other unwanted phenomena. Figs. 38, 39, 40, 41 and 42 are oscillograms showing the performance of this arrangement better perhaps than any other description. These tests were carried out at a frequency of 40 cycles per second.

Tests on small-power high-pressure cut-outs.—Particulars of a series of tests carried out on ordinary cut-outs suitable for potential transformers and small-power supplies at high pressures are given below. The cut-outs were rated for 3 000 to 11 000 volts and were of various forms. Some were small and light, whilst others were quite heavy in construction. Containers were variously of glass (which, in spite of its disadvan-

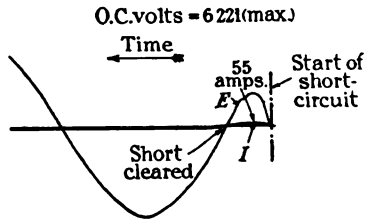

FIG. 41.—Short-circuit test at 5 000 volts on 5 500-volt resistance cut-out.

tages, seems to be a great favourite), bakelite, fibre, etc. Fillings were employed in a great many of the fuses, chalk and marble dust being the most common. The tests are illustrated by means of a representative set of oscillograms.

A feature found to be common to small cut-outs is shown perfectly by these tests, i.e. either the circuit is interrupted in the first half-cycle with extremely low arc energy, indicating good operation, or, in the event of failure of this rapid-extinction process, the arc persists or tends to grow, resulting very quickly in the destruction of the cut-out by the bursting and burning

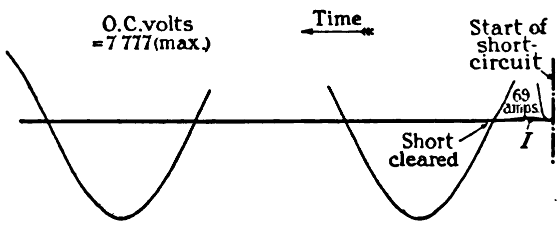

FIG. 42.—Short-circuit test at 5 500 volts on 5 500-volt resistance cut-out.

of container and contact arrangement. It appears to be the rule—and it seems a logical one—that unless such light cut-outs can be designed to clear early in the first half-cycle, they will immediately be destroyed and a dangerous arc across the main contacts will be set up.

Such an arc in the open air persisting for a fraction of a second would result in the destruction of surrounding apparatus and would probably cause a lengthy shut-down. Should the cut-out break up, something is radically wrong with the design—usually the construction is too light.

Tests on Small-Power High-Pressure Cut-Outs With and Without Limiting Resistance.

Small glass-tube cut-out (about 12 in. long and 1 in. in diameter) in air with 380 ohms in series, test voltage = 5 500, frequency = 40: cleared satisfactorily (Fig. 43).

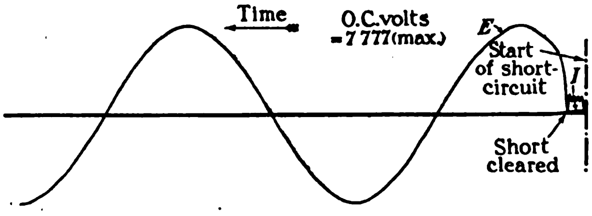

Fig. 43.—Test at 5 500 volts on 5 500-volt glass-tube cut-out with external resistance of 380 ohms.

Element in small-diameter glass tube of switch oil, diameter of tube ½ in., length 14 in., with 20 ohms in series, test voltage = 5 500, frequency = 40: glass burst but cut-out cleared (Fig. 44).

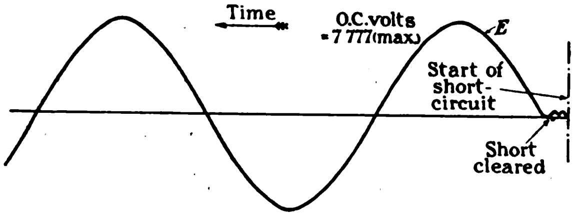

Fig. 44.—Test at 5 500 volts on 5 500-volt glass-tube cut-out with external resistance of 20 ohms.

Element in glass tube filled with marble dust, sealed and immersed in oil tank, no series resistance, test voltage = 5 500, frequency = 40: loud report, tube shattered to fragments, not much gas (Fig. 45).

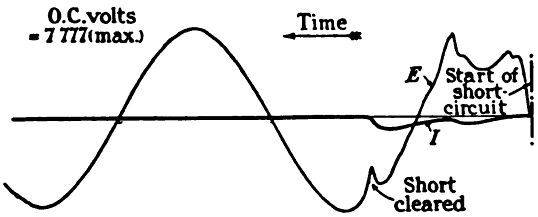

Fig. 45.—Test at 5 500 volts on tubular, marble dust and oil 5 500-volt cut-out without external resistance.

Glass-tube cut-out in mica dust, in air, test voltage = 5 500, frequency = 40: top of tubular container blown through wall, flash and loud report, cleared (Fig. 46).

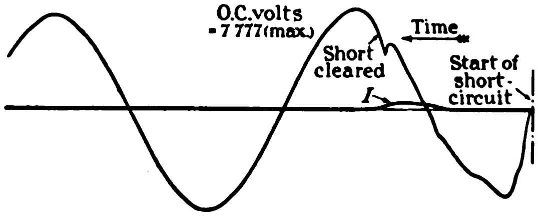

Fig. 46.—Test at 5 500 volts on 5 500-volt mica-filled tubular cut-out without external resistance.

Glass-tube cut-out (small-diameter resistance-wire element) containing marble dust, test voltage = 5 500, frequency = 40: short-circuit cleared (Fig. 47).

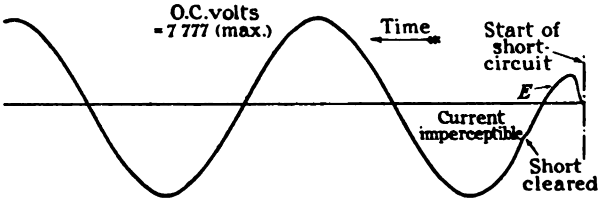

Fig. 47.—Test at 5 500 volts on 5 500-volt resistance-wire marble-dust-filled cut-out.

Small-diameter spring-loaded glass-tube cut-out filled with resin containing element with series resistance of 20 ohms, test voltage = 5 500, frequency = 50: short-circuit cleared, slight noise.

Spring-loaded element in glass tube of small diameter and filled with oil with series resistance of 50 ohms, test voltage = 5 500, frequency = 40: short-circuit cleared.

Glass-tube cut-out in marble dust and sealed and immersed in oil, series resistance of 50 ohms, test voltage = 5 500, frequency = 50: short-circuit cleared.

In the tests with series resistances, the current was so small—probably reaching at the most 100 amperes—that accurate measurements were not possible by oscillograph. Rapid melting of the fusible element is essential if good operation is to be secured. It is not sufficient to ensure that the circuit is cleared in half a cycle, as the current may rise to a maximum in such circumstances. The limiting effect which is so essential is secured only if the fuse is melted on the initial rising-current curve.

Conclusions.

The investigations were commenced because of the confusion of ideas which apparently prevailed as to what was required of a high-power fusible cut-out, and also because of the difficulty of obtaining cut-outs capable of fulfilling all the requirements of the service for which they are intended. It is considered that all cut-outs should be capable of clearing without any explosive effect the maximum short-circuit power of the system or apparatus controlled.

The paper contains an analysis of the factors influencing the rupturing capacity of cut-outs. The load/fusing-current ratio (i.e. the ratio of the full-load current to the minimum fusing current), which depends to a large extent on the cross-section of the fusible element, is found to have an important bearing on rupturing capacity, and great advantage results from keeping it at a low value.

The application of magnetic blow-out appears at present to be of doubtful value, but further tests are perhaps required to settle this matter. The simpler

forms of magnetic blow-out have been found to be the more satisfactory.

The form and strength of the enclosure of a cut-out are of vital importance, and the tests have shown that many existing types of container are not good enough. Fillings for cartridge cut-outs also require close attention in order to be consistently effective. Reliable forms of enclosure and fillings have been tested and are described in the paper.

An elaborate series of tests was carried out, mainly with the object of finding fusible cut-outs suitable for heavy-current work at pressures up to 600 volts, at pressures between 600 volts and 3 000 volts, and also for medium-current and comparatively heavy-current high-pressure work involving the rupturing of powers up to 300 000 kVA. The tests cover up to 70 000 kVA only and were carried out on many different types of cut-out.

Plain fusible cut-outs in air were found to be extremely dangerous for high-power work.

A large number of commercial forms of cartridge cut-out failed to satisfy requirements, but one or two modern forms with carefully designed containers and special fillings were found to be reliable.

Ironclad oil-immersed cut-outs have been developed and are found to be satisfactory within wide limits. Designs have been produced for voltages up to 33 000, and have rupturing capacities beyond the powers available in the tests.

Tests were also carried out on cut-outs intended for small-current high-pressure work, for example for the control of potential transformers and for rural and other small services. The tests showed that the light high-pressure cut-outs available were incapable alone of fulfilling the requirements, but that the majority of them could be made to function satisfactorily if provided with a limiting resistance in series. It is, however, very difficult to arrange a separate limiting resistance in such a manner as to be wholly satisfactory, and a combined resistance cut-out has consequently been developed. This resistance cut-out is described in the paper and has been fully tested with satisfactory results. It is available for all voltages up to 132 000.

As the result of the investigations it has been proved that satisfactory fusible cut-outs are now available for the following requirements (the type of cut-out being indicated in brackets) :—

(*a*) For interrupting powers up to 70 000–100 000 kVA at pressures up to 600 volts (the ironclad oil-immersed cut-out, low-pressure type and the double-tube cartridge cut-out).

(*b*) For interrupting powers up to 60 000 kVA at high, medium and low pressures (single- and double-tube modern cartridge cut-out).

(*c*) For interrupting several hundred thousand kVA at high pressures (the ironclad oil-immersed cut-out, high-pressure type).

(*d*) For small-current high-pressure work (the combined resistance cut-out).

DISCUSSION BEFORE THE INSTITUTION, 18 MARCH, 1926.

Mr. R. W. Gregory: The primary duty of all interrupters, whether fuses or switches, is to protect the system. It is only a secondary duty to prevent damage to the apparatus which has failed. If the interrupters provided perform both duties satisfactorily, so much the better; but the first duty is the more essential. It appears from the author's tests that a properly designed fuse, rated for its job, clears a fault in half a cycle. It therefore produces the least effect on the system and at the same time protects the faulty apparatus to the greatest extent. The author has shown that there is no inertia in a fuse, whereas any automatic switch takes somewhere about 0·2 sec. to operate. Fuses are very similar in behaviour to the high-speed breakers which have become the fashion on traction work. It is found in practice that these high-speed breakers, which break the fault current in a few thousandths of a second after the incidence of the fault, are so useful in preventing flash-overs on machines that the designers of rotary converters for heavy traction work rely on the installation of these breakers to save their machinery. At the same time the use of these high-speed breakers reduces to a minimum the damage to the faulty equipment. The fuse is a high-speed breaker which is applicable to a.c. work at all distribution pressures. The author's work of sorting out and rating the various types of fuses available for industrial purposes is extremely valuable. Every now and again a minor disaster occurs on growing systems which shows that the fuses installed are not suitable for the increased duty put on them by the growth in generating plant. The author's tests and tables help us in the choice of fuses suitable for modern requirements. The author shows that "open type" fuses are very limited in their rupturing capacity. I know they are very dangerous. A recent failure of a porcelain-handled fuse that I know of might easily have killed any person then in the switch room. It is very satisfactory to know that there are now obtainable reliable powder-filled fuses and oil-immersed fuses to meet present-day requirements. It is perhaps fair commercial engineering to take advantage of the infrequency of the worst possible fault. I should say that for rural supplies on second-class high-pressure overhead lines, which are protected by proper interrupters where they are connected to the main system, it is sometimes quite sound engineering to use some of the low-breaking-capacity fuses tested by the author, even though these fuses will blow to pieces when attempting to clear a fault between phases on the transformer terminals. On the other hand, if a small transformer is connected to an important trunk feeder on the main system, I do not think, from the point of view of the system, that it is justifiable to take such chances; either a first-class breaker, or, what may be cheaper, an oil-immersed switch-fuse should be used. The paper records a very great advance in the art of simple overload protection. I think that the development of the use of fuses will be hindered not by the fact that they are unable to deal with short-circuits (I believe that there is no doubt that they can be made able to deal with any short-circuits with which it is practicable to deal by a circuit breaker) but by the lack of knowledge of what can be done in the way of discrimination. If two or three fuses are in series, it is very undesirable for No. 1 to blow when only No. 3 should blow. I think that this side of the subject of fuse design is worthy of continued research, and I suggest that the author should undertake it. The characteristics of the oil-immersed switch-fuse are worthy of note. I feel that this piece of apparatus is a decided help in the problem of dealing with small powers on important high-pressure systems, a problem which has to be faced by many of us in the power-supply industry at the present time.

Mr. P. D. Morgan: In the past the scientific study of

fusible cut-outs has been very much neglected, and, as a result, engineers in general have been led to assume that such apparatus could not be relied on as a safeguard where large amounts of power were to be controlled. The test-results given in the paper show clearly that the foregoing is an erroneous conclusion, and demonstrate that fusible cut-outs, when designed from data obtained as a result of careful research, can be made to operate in a safe and reliable way under heavy short-circuit conditions. The first point I should like to raise is that of nomenclature. Before any considerable advance can be made in the study of any scientific subject it is well recognized that all the terms used to denote the various quantities to be dealt with must be clearly defined. I noticed in this connection that some of the terms used by the author differ, somewhat from those used by other investigators. For example, his term "minimum fusing current" corresponds to the term "normal fusing current" as used in B.S.S. No. 88 of 1919, and to the term "minimum blowing current" as used by the Electrical Research Association. Similarly, the author's term "load current" corresponds to the B.E.S.A. term "working current," and to the Electrical Research Association's term "rated carrying current." Although those differences may seem relatively unimportant, they have been found to create a great deal of misunderstanding. This point was very clearly demonstrated some three years ago, when the E.R.A. prepared and issued to its members a critical résumé of published information on fusible cut-outs from British, Continental and American sources. As a result of the study of this information, it was found necessary to revise completely the nomenclature on this subject; and, consequently, the E.R.A. report contains a list of most of the quantities and their definitions likely to be met with in a study of this subject. Those definitions are now under consideration by the Editing Committee of the B.E.S.A. and it is hoped that they will be adopted as standards in the near future. The second important point raised by the author is the question of the deterioration of the fuse links of cut-outs under working conditions, and its influence on the subject of rating. He states that the influence of factors such as mechanical vibration, changes in temperature due to load variation, air draughts, etc., are fairly well understood and have been dealt with by other investigators. I think that this statement is only true to a limited extent. It is common knowledge that these factors do influence deterioration; but, despite careful study, the E.R.A. was not able to find any really reliable test-results which showed the exact percentage for which each factor is responsible in a given case. The study of the rating of fuse links from the standpoint of deterioration under working conditions is one in which the E.R.A. is highly interested. In the past few months a great number of tests have been made on this subject; and the results are now being embodied in a report. Much interesting and useful information has been obtained; and further tests will be put in hand shortly. Considering now the question of rupturing capacity of fusible cut-outs, the limit of rupturing capacity of a cut-out is reached when it fails to open a circuit in an "efficient" manner, that is to say, without causing damage by arcing, explosion or otherwise. In dealing, therefore, with rupturing capacity, it appears necessary to define what exactly is meant by "failure." For example, the Bureau of Standards in 1916,* when carrying out extensive short-circuit tests on cartridge fuses, recognized six types of failure, namely: (*a*) Rupturing of the fuse cartridge, (*b*) Blowing off of the cap, or blowing out of the ends; (*c*) Mechanical injury to the cut-out; (*d*) Ignition of cotton placed around the cartridge fuse; (*e*) Holding of the arc for an appreciable length of time; and (*f*) Remaking of the circuit after it had once been opened by the cartridge fuse. It seems, therefore, that the results of the author's tests on cartridge fuses would have been much enhanced if some such criteria had been adopted. In judging the behaviour of the oil-immersed ironclad cut-outs developed by the author, it is to be remembered that the tests were made on alternating current only; whether, in the case of low-voltage tests, similar results would have been obtained in a direct-current circuit under otherwise similar conditions, is open to question. Under existing regulations in Germany, America, Switzerland, France and England, the rupturing capacity of a fusible cut-out for operation at pressures up to 750 volts is based on its behaviour under short-circuit test in a direct-current non-inductive circuit, the current being supplied by a battery of stated capacity. The generally accepted view, therefore, is that these are the most severe conditions for test. As an example of the behaviour of similar cut-outs on a.c. and d.c. circuits, Dr. E. B. Rosen, in the Bureau of Standards tests to which I have already referred, states, as a result of oscillograph tests, that cartridge fuses which are uniform in behaviour on a d.c. circuit vary widely in their behaviour on alternating current. This violence depends on whether the current is broken when there is a large or small amount of energy in the a.c. circuit, that is to say, "it is a matter of chance as to whether the current or voltage is large at the moment that the fuse melts and is interrupted; or whether it has an intermediate value or a zero value." For this reason I think it would be interesting if the behaviour of the cut-outs could have been compared on both alternating and direct current. The E.R.A. is fully awake to the possibilities of the development of fusible cut-outs. By the courtesy of the London, Midland and Scottish Railway the Association has obtained the loan of a large battery at Stonebridge Park power station, capable of giving about 10 000 amperes at 600 volts. A suitable building has been erected, and the work of equipping it with what is undoubtedly the latest design in this country of oscillographs and other apparatus is now proceeding. Starting with tests on existing designs, it is hoped to make an exhaustive study of the various factors underlying the successful design of fusible cut-outs, and to develop a new and improved product.

Mr. H. W. Clothier: The author has been fortunate in having at his disposal a large plant for short-circuit tests. The absence of this in the past has been a great obstacle to the full study of breaking capacities of large fuses, and optimistic ratings have therefore often gone

* "Investigation of Cartridge Enclosed Fuses," *Bureau of Standards Bulletin* No. 74, 1916.

by unchallenged and unchecked. Another obstacle has been the lack of uniformity in demand. The user has failed to state concisely his requirements in respect to breaking capacity. He has been in the habit of merely stating the normal current-carrying capacity without specifying the work to be done or the amount of power behind a short-circuit which is to be cleared. I agree that a cut-out fuse is not satisfactory if in clearing a short-circuit it is shattered or damaged beyond repair for further use, but after all it is a renewable part and not very expensive and so if it does its primary function of isolating the fault it should be pardoned if in the process its condition befits it only for the scrap heap. It is another matter, however, when, as so frequently happens, the original disturbance is spread in an attempt to clear the fault to another more serious fault such as arcing at the terminals or to framework or between busbars. This disability of the ordinary commercial fuse when used on heavy power circuits for which, if the designer only had particulars of testing, he would have known it to be unsuitable, has aroused the author to action. As a result, improvements have been made and a greater expenditure of care and material on the fuse as a protective device is now justifiable. In future I believe we shall endeavour to obtain the isolation of a fault without pyrotechnical displays or secondary damage to neighbouring parts. It will probably become more usual to inquire about the required circuit-breaking capacity before installing a fuse. The author's tests have brought about the necessity for greater care in the smaller power fuses, and he has found that the fuses may enter into the realms of the larger oil circuit breaker, thus providing a more economical form of protection capable of dealing with short-circuits in important locations on large power supply systems. Economies thus effected should more than compensate for the increase in initial expenditure which will probably be caused by bringing to light the defects of the other devices. The meaning of the breaking capacity of a fuse must be properly defined. A general understanding of it is as important as in the case of the ordinary circuit breaker. It introduces a new kind of rating—the author calls it a "potential" power. For example, he refers to a fuse being perfectly safe when opening a "potential short-circuit" of the order of 100 000 amperes. On examining the curve of the performance of this fuse the maximum short-circuit current is shown to be only 25 500 amperes. This is also implied in Table 3, where rupturing capacities are given which are apparently based not on the actual current at which the several sizes would break, but on the amount of potential short-circuit occasioned by a fault in the vicinity of the fuse. In other words, the fuse has a fault-current limiting effect which is not possessed by the ordinary circuit breaker. Advantage may in a measure be taken of this effect by using a smaller form of enclosure for an oil fuse than would be necessary for the ordinary circuit breaker in a similar position on large power-supply systems. A fuse, therefore, requires three power ratings, (1) its normal load, (2) the actual power it breaks, and (3) the potential power that would be available were it not for the restricted effect of the fuse. Bearing on this, the author in Fig. 3 draws attention to the value of a low ratio between the fusing current and the load current. This is all to the good in widening the margin between the actual breaking capacity and the potential breaking capacity, but I am not convinced of the practical value of a ratio so close as 1·2 to 1. I understand that this is obtained by the construction shown in Fig. 4. A fuse may be looked upon to give protection in two ways, (1) as an overload device to protect the plant from excess current, and (2) as a protection for the system by isolating a faulty plant. A low fusing-current/load-current ratio may be useful in the former case, but I am suspicious about so sensitive a margin. It is like using too sensitive a relay on protective gear, as it may tend to cause the plant to be interrupted unnecessarily. If one must have thermal protection to prevent injury to the plant by excessive temperature, then it would seem to be better to provide the plant itself with some simple thermostat device. Moreover, I am not satisfied that in this particular form of fuse there is the advantage which the author claims. As I understand the fuse, it has two main elements, (1) a fusible strip to operate on short-circuit by current, and (2) a fusible bulb of low-melting-point metal to operate on small overload. The device has therefore two time characteristics, but it is on the short-circuit characteristic that its merits as a short-circuit current-limiting device must be gauged. The fusible strip, which is of copper, has, I believe, a fusing-current/load-current ratio of at least 2 : 1, in which case the power ruptured, according to Fig. 3, would be 14 000 kVA and not 6 000 kVA as taken by the author on the overload function of the fuse. As a matter of nomenclature, I doubt whether the author's definition "potential" short-circuit is the best. The word "potential" is apt to be confused with "voltage." The "potential" short-circuit as I understand it is the maximum that would be available in the vicinity of the protective apparatus. A title implying this might be quite as appropriate and less confusing. I suggest "vicinity" short-circuit. I notice that the author uses the word "rupturing capacity," whereas in the British switchgear specifications it is termed the "breaking capacity." The author has in most cases adhered to the B.E.S.A. term "fusible cut-out," but I think it must be admitted that it is a clumsy title and that the word "fuse" comes more naturally to us. It would be interesting to have particulars of the pressure indicators used to record the impulse pressures on the walls of the switch fuse tanks. The most convenient commercial means of testing the strength of tanks is by using an ordinary hydraulic pressure test. Some comparative basis is required to associate the impulse pressure with the steady hydraulic pressure. It is probable that a tank which would withstand the ordinary hydraulic pressure test of 15 lb./sq. in. would be competent to withstand the impulse pressure of 150 lb./sq. in. The author mentions that the oil switch-fuse can be used as a switch to open and close while carrying full load, and can also be switched in on *moderate* short-circuits. As a safeguard against the possibility of closing this isolating device on a heavy short-circuit I prefer to equip the lid with a separate isolating switch

in those cases where there is no other isolating switch in the circuit. This improved type is provided with an interlock which prevents the isolating device from being in a closed position when the operation of closing the lid is in process, and guards against the possibility of contact being made on a short-circuit before the lid is completely closed. It must be observed that it would be risky to an operator who happened to close the lid on a heavy short-circuit in the arrangement shown in section in Fig. 27 and in the elevation in Fig. 28. It is noteworthy that over 30 years ago the oil-break fuse was made by Dr. Ferranti. Comparing the features then and now, the old oil fuse obtained isolation by withdrawal of the fuse from fixed contacts (but not on load), it had the spring break, and the moderate blow-out now recommended by the author was obtained by taking the fuse at right angles to the two parallel conductors which lead to it. It had the advantage of having the actual fuse wire normally in air, the contacts being drawn down into the oil. What it lacked as compared with the present-day device was the strong metal-clad enclosure, oil-tight joints and sufficient clearances between terminals to avoid arcing over terminals after the fuse had blown. I think that the author's work will in the future be of great service to electric supply distribution, particularly in the control of small supplies to rural districts and to outlying consumers where the cost of the more expensive forms of switchgear with circuit breakers would be a handicap to extensive developments on supply undertakings.

Mr. A. Hooker: There would appear to be a considerable field for fusible cut-outs in connection with rural supplies from high-tension systems which are, very probably, often inadequately provided for with respect to short-circuits. I recently examined some of the high-power cut-outs on the market, and was impressed with their design and structure. The container is made of glass filled with CCl_4, and there is a separate fuse chamber. The fusible element is connected by a wire which passes through a nozzle-shaped piece of wood, and is attached to a spring, the latter being held in tension. The fuse chamber has a lid-like cover, sealed with a soft composition. When the fuse blows, the cover is blown off, thus avoiding explosion, and a spring is released, speedily opening the gap. Damping fluid is forced through the vents into the fuse chamber and any arc is extinguished. The makers claim that their fuse is capable of rupturing over 25 000 kVA on the first half cycle with absolute safety. It seems to me to be desirable to have a transparent container wherever possible, if only for inspection purposes. I should like to ask the author whether containers composed of silica containing Cl_4 or tri-chlor-ethylene have been tried? Silica is transparent and is capable of withstanding higher pressures and temperatures than is glass.

Mr. P. Dunsheath: The paper leaves one with the impression that the author, in his enthusiasm for his subject, has rather overlooked the necessity for logical treatment, and in my opinion it would have been of advantage if he had added definite conclusions to be derived from some of the tests. Several speakers have already referred to the questions of nomenclature and fundamentals, and I think that the value of the paper would be considerably enhanced if the author could deal with that point a little more fully in his reply. For instance, if he had properly defined the ratio of the fusing current to the working current the subject would have been more easily understood. Again he speaks first of all of the necessity for reducing a load-current fusing ratio, and a few lines later he talks of reducing the fusing-current/load-current ratio. Both cannot be right. I suggest that the name of "ultimate current ratio" should be given to this quantity. The author does not appear to deal with the 1-minute fusing current in the paper. I think that is rather a serious omission in view of the fact that many people are working on it to-day, and the "1-minute current ratio" is another important quantity. Fig. A demonstrates these two current ratios and illustrates two points that the author, if I may be allowed to say so, makes rather laboriously, namely, the effect of altering the ratio. He says that if the ratio of minimum fusing current to working current is increased for a given working current, the load to be broken on the fuse is increased. It is quite clear from Fig. A that when the ratios are increased the fusing current curve is raised and this increase naturally increases the current at any particular time. In the same way, the author says that if the same ratio is decreased, the fusing current being kept constant, the working temperature is raised. The diagram again shows in a very simple way that to reduce the ratio with a constant fusing current simply raises the working current load, and so increases the temperature of the fuse under working conditions. In the same connection Fig. B shows some other results which have

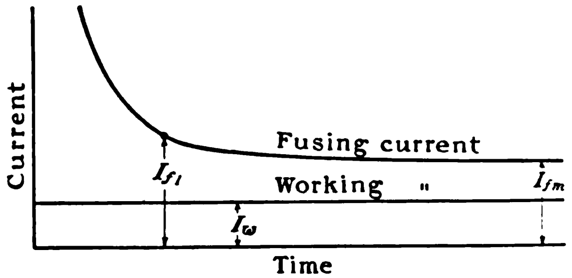

FIG. A.—Current ratios.

$$\alpha = \text{1-minute ratio} = \frac{\text{1-minute fusing current}}{\text{working current}} = \frac{I_{f1}}{I_{\omega}}$$

$$\beta = \text{ultimate ratio} = \frac{\text{minimum fusing current}}{\text{working current}} = \frac{I_{fm}}{I_{\omega}}$$

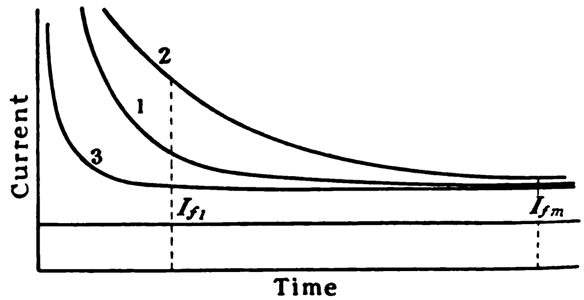

FIG. B.—Effect of material and conditions on shape of fusing-current curve.

been obtained from experimental work and brings out the effect of different materials and different conditions on the shape of the fusing-current curve. The inner curve is of a copper wire in air. It will be seen that the 1-minute current ratio and the ultimate current ratio are practically the same. If the wire is replaced by a low-melting-point metal, we get curve 2. If the ratio in the first place is something of the order of 2, the supposition made in the Institution Wiring Rules, the substitution of tin for copper brings up the ratio to 4 under certain conditions. At the same time the ultimate ratio is not affected. Curve 3 shows the effect of lagging the wire in any way. If, for instance, wire is put in an asbestos tube or a holder of any kind which will retain the heat, then this neck appears in the curve and the 1-minute current ratio is equal to the ultimate ratio. The second main point which I should like to raise goes right to the root of fuse design. I suggest that the author, in common with all previous investigators, has overlooked a vital principal affecting the rupturing capacity. By the application of a very simple physical principle, the rupturing capacity of a cut-out can be enormously increased. An arc is, after all, simply a space which is rendered conductive by ionization. We know that the potential required to ionize is closely connected with the actual mechanical pressure of gas. If the pressure of gas is increased, the requisite voltage is increased at the same time. The rupturing capacity of the fuse is closely connected with the quenching of the arc. From those considerations it follows at once that in order to increase the rupturing capacity, all that we have to do is to increase the pressure of the gas formed when the wire is vaporized. As it happens, air pressure or pressure on the gas is very easy to produce; all that is necessary is to restrict the expansion of the volatilized metal. Many designers have appreciated this factor of pressure due to the restriction of the expansion of the gas, but, so far as I can see, in every case where the characteristic has been made use of it has been accidental. Some designers have introduced vents to enable the gas to be dissipated; others have produced cartridge fuses with fillers for cooling the gases; but, generally speaking, the pressure generated has been deplored rather than made use of by the author and by all previous investigators. Nobody so far has done the obvious thing, i.e. to produce a tubular container for the wire of internal dimensions very little greater than the wire and mechanically designed to withstand the pressure generated. I have not been able to carry this idea beyond the very elementary stage; but, so far as I have gone, this principle has proved to give a better rupturing capacity than has any other principle adopted to-day. I have here a small fuse which consists of a fibre rod or tube with a hole down the centre. It is about $\frac{5}{8}$ in. in diameter and $1\frac{1}{2}$ in. in length, and the hole down the centre is about $\frac{1}{8}$ in. in diameter. On each end is screwed a strong brass cap and between the caps there is a piece of copper wire. That fuse will break consistently every time without failure on 250 volts a current of more than 6 000 amperes, which is the maximum battery current available. It will rupture about 1 500 to 2 000 kW with ease and those who have experimented with fuses will be aware that the results obtained with this small fuse are about four times better than can be obtained, using the same dimensions, with any other types. All that is required, then, is a mechanical design to withstand the high pressure generated. In this particular fuse the pressure generated is of the order of 1 ton per sq. in. The author mentions the importance of quick rupture. This little fuse, when breaking a load of 1 500 to 2 000 kW, only burns away $\frac{1}{2}$ in. to $\frac{3}{8}$ in. of the copper wire. By the time this amount of copper has disappeared the pressure generated is sufficiently great to break the arc, so producing what must be a very rapid rupture.

Mr. Vernon Hope: I should like to refer to Mr. Clothier's point with regard to the fuse element in the Aeroflex fuse. The tin pocket in the Aeroflex fuse is not correctly considered as a second fuse in parallel with the copper main fuse. This tin pocket has a carrying capacity very much greater than the carrying capacity of the copper fuse, and it may be best considered as fulfilling to some extent the function of the lead seal in the Grinnell sprinkler used for the fire protection of buildings. When the temperature of the copper rises above the melting point of the tin, the tin pocket is melted out. The advantage of this arrangement is that the copper portion of the element is run at a low temperature; consequently there is no oxidation of the element, and it is for this reason that the time/current curves take the form they do. With this type of element the fuse can be run at 1 500 amperes for 8 hours, and with an increase of load of 25 per cent the same fuse will blow in less than 5 minutes. With regard to potential-transformer fuses, the general practice of using large limiting resistances seems to be carried to excess and little attempt is made to use a fuse with a high rupturing capacity. Where these limiting resistances are used they occupy a very great deal of space which can be avoided if attention is turned to getting a high rupturing capacity in the fuse itself. We have obtained on test a very high rupturing capacity indeed without any limiting resistance, by the simple expedient of using a silk ribbon in the warp of which is put one strand of very high-resistance wire, obtaining in this way 200 ohms resistance in the fuse itself. In obtaining a high rupturing capacity in a fuse, it is not generally appreciated that there are what one might term two sources of energy. There is the thermal energy due to the melting of the element, and there is what might be called the secondary pressure due to oxidation of the vaporized metal. Uncertain results in fuses are largely due to a want of appreciation of the pressures set up due to this secondary explosion. The primary energy is probably definitely proportional to the rupturing capacity, and the secondary energy is controllable. The secondary energy in the case of oil fuses is a chemical action due to the breaking up of the oil and has given rise to great pressure. The difficulties of isolating and analysing the gases formed are very great, and therefore this rather points to the fact that oil is not really an ideal liquid to use. Probably the solution will be found in the adoption of some other liquid. With regard to pressure fuses, I have done some experiments on the lines indicated by the last speaker, and have obtained surprisingly good results

with very small fuses, but the difficulty is not in small fuses but in large ones. It is not only a question of rupturing capacity but also one of avoiding oxidation and heating troubles. A fuse on the lines suggested might be workable up to 20 amperes, but would be quite impossible if 1 500 amperes is considered. In connection with oil fuses, the maximum pressure to be obtained due to thermal energy at the arc does not exceed 150 lb./sq. in., but in oil fuses pressures ranging up to 100 tons/sq. in. have been found, due to the chemical action, and this points to the necessity for very massive construction. What is really needed is a liquid that will damp out the explosion without any secondary or chemical pressure being set up.

Mr. H. Brazil: It may be of interest if I make a few remarks in regard to a supply undertaking's experience with fuses. For the past 20 years we have been using oil-filled fuses on our 10 000-volt three-phase circuit, and are still using them in connection with motor-generators. These fuses consist of a silver wire enclosed in a brass case which is lined with insulation and open at the bottom. To the bottom end of the silver wire is attached a spring, and the whole of the apparatus is enclosed in a glass tube about 12 in. long, filled with oil to about half-way up the brass case. When the fuses blow, the silver wire is drawn down, and the arcing therefore takes place under the oil. At first, glass tubes about 1½ in. to 2 in. diam. were used, and we had some trouble owing to these bursting, but when we increased the size to 3 in. diameter and about ⅜ in. thick to enable them to stand the pressure, they behaved very satisfactorily. It seems to me that this fuse is somewhat akin to Mr. Dunsheath's pressure fuse, as a considerable amount of oil has to be moved before the pressure is released. With regard to low-tension cartridge fuses, I have used these for a working current of 2 000 amperes on 200- and 400-volt circuits, and they have broken circuit so successfully that it has not been possible to know they have done so until a test has been made with the detector. In this case quite a number of fuses are in parallel, say 20 in the case of the 2 000-ampere size. These fuses consist of stout copper wires joined together in the centre by a small length of silver wire which is brazed to them, the whole being enclosed in a cartridge filled with marble powder. The length of the fuse is about 6 in. I am inclined to agree with Mr. Hope that, while Mr. Dunsheath's pressure fuse may be quite satisfactory with small currents, he would experience serious difficulties when he tried to use them for larger currents.

Mr. A. W. Isenthal (*communicated*): The author mentions several materials used in the construction of fusible elements, but does not mention silver. As is well known, silver oxidizes very slowly, and my experience has shown that silver wire, used in correctly designed tubular holders, forms a very good high-tension fuse. What is the author's opinion of silver fuse wire ?

Mr. J. M. Scott Maxwell (*communicated*): On page 920 it is stated that "At the time the investigations were commenced, the author could not find any cut-outs capable of rupturing, with reliability, heavy currents at medium or high pressures, or any reliable cut-outs suitable for small-current high-pressure use." The "S. & C." fuse, called by the author a "liquid-filled glass-tube cut-out," was well established in the United States before the war. This fuse was invented by power-station engineers to get over many of the troubles mentioned in the paper. It has been submitted to many tests, both in this country and America, and the test data in my possession indicate much better results than those given in the paper. This fuse was originally designed for the protection of potential transformers, thousands of them being installed all over the world, and to the best of my knowledge there have been no accidents due to their use, such as have happened with simpler forms of fuses. The fuses are used without any external resistance, and as almost all potential transformer breakdowns are due to insulation weakness in the transformer and take some time to develop, the fuse clears the circuit before any damage can be done to the system. The operation of these fuses with potential transformers was so satisfactory up to 132 000 volts that they were also developed for power purposes. It is not intended that the power fuse should be installed in the power station, where there is the minimum of impedance between the fuse and the generator. The fuse is intended to be installed on transmission lines and distribution systems, and the latest design of power fuse will break a greater kVA than is indicated in the paper. The following tests were made by the Duquesne Light Co. at the end of 1923, at their North Substation on the 66 000-volt ring, stepping down to 22 000 volts, the fuses being connected across the 22 000-volt side of the step-down transformers. The figures in Table A are from oscillograms.

It will be noted that only in the last test did the

TABLE A.

Test	Fuse rating	Voltage across fuse	R.M.S. current (initial)	R.M.S. current (broken)	Load (broken)	Cleared in
	amps.	volts	amps.	amps.	kVA	cycles
9	50	13 500	3 060	2 080	28 000	2
10	50	13 600	4 910	3 620	49 000	2
11	50	13 500	5 980	5 380	72 000	2
12	50	13 700	5 395	4 980	68 000	2·5
13	50	13 100	?	5 240	68 000	2·5
14	100	13 100	7 260	6 150	80 000	1·5
15	200	13 200	?	5 880	77 000	2·5
22	50	12 800	7 240	6 430	82 000	failed to clear

fuse fail to clear. The same test was repeated with the 100-ampere and 200-ampere sizes of fuse and these fuses both cleared. The tests show that the rupturing capacity of the 50-ampere size is above 5 000 amperes at 13 000 volts across the fuse, or over 65 000 kVA. The 60- to 200-ampere fuses are of larger diameter and have a rupturing capacity of at least 80 000 kVA. Oscillograms of two of the above tests are given in Figs. C and D. Tests were carried out at Carville Station, Newcastle, during 1922, the fuse in this case being connected across the generator with the minimum of impedance on the line. The figures which I have of these tests are given in Table B.

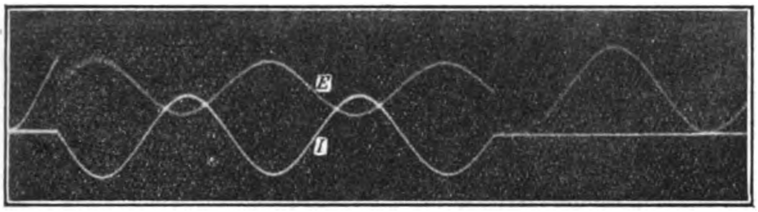

Fig. C.—Test No. 12 (50-ampere fuse).
Voltage across fuse = 13 700.
R.M.S. current { Initial = 5 395 amperes. Interrupted = 4 930 amperes.

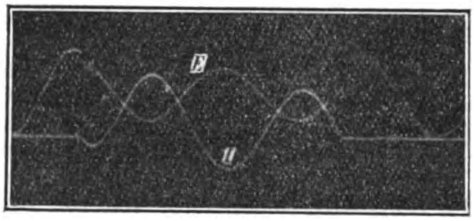

Fig. D.—Test No. 14 (100-ampere fuse).
Voltage across fuse = 13 100.
R.M.S. current { Initial = 7 260 amperes. Interrupted = 6 150 amperes.

Table B.

Fuse rating	Voltage across fuse	R.M.S. current (broken)	Load (broken)	Remarks
amps.	volts	amps.	kVA	
20	6 000	5 300	31 800	failed
20	5 000	4 400	22 000	cleared
20	5 500	4 850	26 600	cleared
20	4 000	3 550	14 200	cleared
20	5 500	4 850	26 600	cleared
20	6 000	5 300	31 800	failed

The fuses which cleared did so in the first half-cycle. They were of the same type and diameter as the 50-ampere size in the American tests, and cleared over 25 000 kVA. The only difference involves a constructional detail, but rather an important one. The top ends of the fuses tested at Carville were sealed with a flat copper disc, soldered at the edge to the brass cap. The pressure required to blow off this disc under a short-circuit, thus relieving the internal pressure, varies according to the soldering. In the latest design which is described below and which was the design used in the American tests, no solder is used. The disc or vent cap is pressed into the brass top, and by using a special paste the joint is made air-tight. This design is more reliable than the older design and requires less pressure to remove the disc, thus raising the effective rupturing capacity of the fuse. The maximum current cleared is approximately the same in both tests, the higher kVA in the American tests being due to the higher voltage. This indicates that with still higher voltages the kVA rupturing capacity will also be higher. In the " S. & C." fuse (see Fig. E) the fusible element is of very small dimensions so that it fuses rapidly and produces the minimum of metallic vapour, and thus the ratio of fusing current to load current is not important in this fuse. As the fuse is hermetically sealed and filled with a liquid and its vapour (CCl_4) in which there is no oxygen, the fuse element is not subjected to oxidation or corrosion. The tension of the strong spring, which is extended twice its length, is taken by a nichrome-steel wire. There is no strain on the fuse element, which in the smaller sizes is of silver wire and in the larger of tin strip. As the steel wire has a high resistance it melts

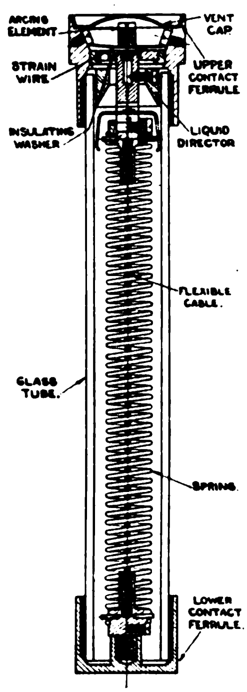

Fig. E.

practically simultaneously with the fuse element and the spring thus draws the live terminal very rapidly into the liquid, the moving parts having very little inertia. The liquid both cools and extinguishes the arc due to its dielectric property, which is over 100 000 volts per inch. The container is a glass tube, as used for

steam gauges, but the pressure does not rise to the high values given by the author. The initial explosion takes place in the brass explosion chamber, the top of which is a saucer-shaped disc, pressed into the end and made airtight by means of a special paste. No solder is used, and the disc is blown off immediately the pressure reaches about 50 lb. per sq. in., whilst the pressure required to break the glass tube of the 50-ampere fuse (1 in. internal diameter) is over 1 100 lb. per sq. in. The amount of liquid in the fuse is small and, as very little is ejected when the fuse blows, no damage is done to other plant nor is there any danger to station attendants. The brass ends are fixed to the glass tube with a special alloy, and the coefficients of expansion of the brass, glass and alloy are such that no leakage can occur at the lowest temperature or in the hottest tropical sun. The fuse requires no protection of any kind, and can withstand every climate. It has been submitted to several competitive tests in America by different official bodies and has given better results than every other make.

Mr. J. B. Rudkin (*communicated*): There can be no doubt that the conclusions drawn by the author are in favour of introducing a new make of oil-immersed fuses. These have, in fact, already been anticipated by similar designs of other makers. Amongst others may be mentioned the Union Switchgear Co. (Voigt & Haeffner), who manufactured a design in 1914 which is practically similar to the one shown in Fig. 26. Many of the introductory criticisms in the paper of existing types of fuses are quite correct, but they are not, however, entirely correct in that certain makers have been able to eliminate many of the weak points referred to. It is claimed that the type of fuses which are now being manufactured in England by the firm with which I am associated, possess very few of the points criticized. There is no question that our low-voltage tubular or switch-handle-pattern fuses are not made for a breaking capacity larger than about 10 or 20 times the rated current. I am of the opinion that in places where the breaking capacity is as high as 50 000 kVA or even above 10 000 kVA, the oil-immersed circuit breaker is the more convenient type of apparatus to use. Regarding potential-transformer fuses, for a number of years we have manufactured these with a series resistance to limit the breaking capacity to values that the fuse can easily deal with. For voltages above 33 000 a weak point, which has not been mentioned by the author, in many existing types of fuses is the deterioration of the fuse wire of very small diameters by radiation. This has been avoided in our designs to such an extent that we can easily guarantee fuse wires to remain intact for voltages as high as 200 kV without any visible sign of deterioration. The use of pure copper has been abandoned on the Continent for high-voltage fuses, on account of instability of section as the result of oxidation. They have been replaced by non-oxidizing metals, silver being mostly used and, in some cases, tungsten. The author strongly criticizes fuse carriers made of porcelain. Up to a certain limit I agree with him, but I must strongly object to his conclusions that no suitable porcelain fuse carrier can be made. My firm has designed and supplied in large numbers a porcelain fuse carrier which will safely break a load of 10 000 kVA under 15 000 volts and even more. We would not hesitate to design air-break fuses of similar characteristics for 2 or 3 times this breaking capacity. On page 925 the author states that an open-type fuse is superior to an arrangement confining the wire in a carrier, but our tests show that this is not generally true. The values given in Fig. 36 do not apply to our types of fuses. Oil fuses have been in practical use in so many different forms that every possible experience has been gained with them, and, as I have already mentioned, the type of fuses shown in Fig. 26 are no exception. The cost of installation and space required for this type of oil-immersed fusible cut-out would be about the same as that in the case of an automatic oil switch; in fact oil switches for 6 600 volts and breaking capacities between 50 000 and 100 000 kVA occupy about the same space and can be bought for the same price. The decision as to which device should be used does not depend entirely on the initial cost. There are many inherent deficiencies in fuses. Of these the continual cost of spare fuse replacement parts, difficult service control by reason of the delay in restoring the service, and electrical shut-down by single-phase interruption producing high-voltage surges, are amongst the most commonly known. The above drawbacks of fuses are mentioned in full appreciation of the many advantages possessed by these devices, but in my opinion the application of fuses in electrical installation must necessarily be limited to cases where continuity of service is not seriously impaired by their action. Even if the fuse, in common with other apparatus, is constantly subjected to improvements in design to enhance its electrical qualities, the service engineer will in every case have to discriminate carefully at which point of the installation fuses may be used, and where circuit breakers are preferable or indispensable. Fuses have up to the present in a general way stood up to their service and given satisfaction, due to the fact that they have been installed in places where the breaking capacity imposed on them is certainly very much below 70 000 kVA for low and medium voltages, and equally below 30 000 kVA for pressures over 3 000 volts. These figures can be easily calculated from the layout and dimensions of the network in any particular case. In installations where breaking capacities of the above magnitude enter into consideration, the question of the resumption of service is of such vital importance—as every engineer who is in touch with relay problems knows—that it is quite impossible to utilize fuses where a scientific system of protection by means of discriminating relays is called for. There is a large demand for high-tension fuses on the score of their low cost for installation and operation. The standard types manufactured by my firm have been fully proved by a large number of engineers both on the Continent and in Great Britain.

[The author's reply to this discussion will be found on page 954.]

North-Western Centre, at Manchester, 16 March, 1926.

Mr. Vernon Hope: There are a few points on which I cannot see eye to eye with the author. In the chart showing the comparative maximum rupturing capacities, he puts the rupturing capacity of the oil fuse at a considerably higher value than the rupturing capacity of what he has called the special cartridge fuse. The rupturing capacity of this special cartridge fuse is arrived at by actual tests which he has carried out himself, but my contention is that the maximum rupturing capacity of the fuse was not reached, and I have a good reason for this contention. We have approximately measured the pressures in these cartridge fuses and the fuses have successfully cleared circuits with a pressure of 10 times the amount that was actually obtained on the particular tests on which the author bases his maximum rupturing capacity, and therefore it is reasonable to contend that there was a very wide margin to spare and that the rupturing capacity of these fuses is very much higher than the figures given in the paper. With regard to the rupturing capacities given for the oil fuses, these are only approximate figures and are based on assumptions founded on results obtained from oil switches, which may not necessarily be correct. In comparing the powder-filled fuse with the oil fuse, it is important to remember that the correctly designed powder-filled fuse has a high rupturing capacity with very little pressure in the fuse case, but the oil fuse has a high rupturing capacity with a very great pressure in the case. The pressure in oil fuses has been found to be thousands of lb. per sq. in., and this pressure is due to the chemical action and not to the thermal energy of the arc. I have therefore still to be convinced that the oil fuse has a higher rupturing capacity than the powder fuse. The oil fuse has many attractive features and in design it is comparatively simple compared with the difficulty in producing a powder-filled fuse with a high rupturing capacity. No doubt some people will disagree with the very low rupturing capacity which the author has placed on the ordinary commercial fuse, but there is not the slightest doubt that in this he is perfectly correct. The ordinary commercial fuse produced to-day is apparently designed without any knowledge of the subject and is a very inadequate means of opening a circuit, but no doubt the time has come when designers will have to pay a great deal more attention to research in the matter if fuses are to be produced with some reasonably high rupturing capacity.

Mr. S. R. Mellonie: The curve shown in Fig. 3 presumably refers to fuses with a ratio of fusing current to load current of 1·2 to 1. If the author has the data available it would be interesting to amplify this by the addition of another curve for fuses wired for a 2 to 1 ratio. The author is to be congratulated upon the development of a satisfactory high-tension oil-immersed fuse of high rupturing capacity, but the pressures shown in Fig. 34 certainly require a design which provides for closing the circuit after the cover is bolted or latched in position. Has the author's fuse any device to give external indication when the circuit is ruptured? Recent tests confirm the author's conclusion (on page 937) that the most economical arrangement for light-power circuits is a simple fuse of cheap construction and a series limiting resistance. The ohmic value required to keep the power within the limit of the fuse is so low that the effect on the accuracy of instrument transformer circuits is negligible. Tests have recently been made on a new design of semi-enclosed wire-wound resistance of robust construction which is quite suitable for use in a high-tension switch cubicle. No danger need be anticipated from the fact that the resistance may, for a fraction of a second, become red-hot, as the heat is quickly liberated. The design shown in Fig. 37 is certainly a neat solution of the resistance cut-out, although the sudden increase of temperature of the mass of the spring in a limited quantity of oil must produce pressures which are absent when the resistance is air-cooled and the fuse a separate piece of apparatus. In view of the author's suggestion that the fuse should break circuit in the first half cycle, the oscillogram shown in Fig. C should be interesting. This may be taken as typical of a number of tests of an expulsion-type fuse

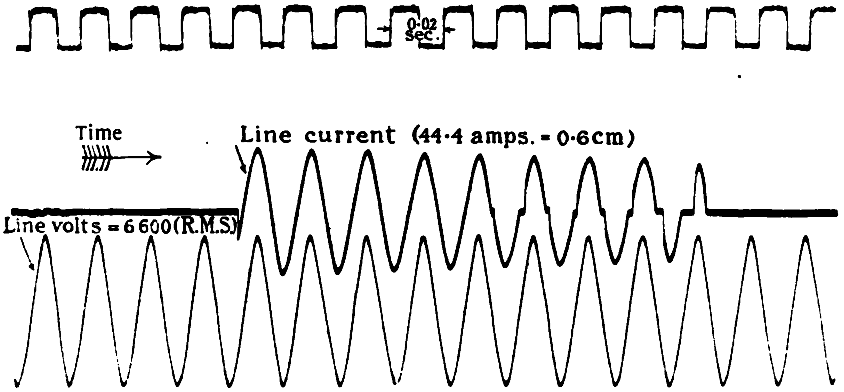

Fig. C.

in series with a limiting resistance; in every case the fuse cleared the circuit quietly and efficiently although the current persisted for several cycles.

Mr. A. B. Mallinson: I have for many years been prejudiced against the fuse, but the development of the cartridge fuse has astounded me. If the author's experiments are carried out on the scale that he has outlined I can understand the need to make tests in the open air. It is only by experiments of that character that we can provide for the practical development of the fuse or any other piece of electrical apparatus. I see one great objection to the fuse and I do not yet see how it will be overcome. The circuit breaker opens and it is re-closed; but what is going to happen to the fuse in industrial areas where the man in charge has not a full knowledge of the subject? I should like to see a fuse so designed that it is not possible to put a metal strip across it. I was very impressed with the way in which the circuit was cleared by the Aeroflex fuses. These blew exactly as the lantern slide showed. I was particularly impressed by the state of the Aeroflex fuses after being short-circuited across a 460-volt 6 000 ampere-hour battery with no resistance in series. I understand the resistance of the circuit was 0·006 ohm and that the fuses, wired for 38 amperes running load, blew at about 1 000 times full load. There was absolutely no sign inside the inner bakelite sleeve, or on the small terminals at the end, of any splashing. That test conclusively shows that a fuse of this character is really a good fuse; it will not be necessary to have a new cartridge complete every time a fuse blows, on a short-circuit. This is an important factor, as the cost of the complete cartridge replacements is high, but the spare fuse element complete with the powder is not a big item. Referring to the oil fuse, how far is it going to be elaborated? Is not the reason for the fuse being developed one mainly of capital cost? If we are going to get massive construction similar to that shown on the lantern slides, I suggest that it will approach the circuit breaker in capital cost, without any step in advance being made.

Mr. B. M. Burt: I think that the most important point in the paper is the claim that a well-designed fuse will clear a short-circuit a considerable time before the current has reached its peak value. In Fig. 3 the author shows that the extent to which this can be done is increased by reducing the ratio of fusing current to load current. It has hitherto been thought that the reduction of this ratio increases the breaking capacity by reducing the amount of metallic vapour; surely the author will still agree that this is a factor and that for this reason alone a copper wire will have a higher breaking capacity than, say, a lead wire having the same minimum fusing current. Whilst agreeing that a wire of very small section can reach its fusing temperature well before the current has attained its maximum value, I do not agree with the author when he states that on a 6 000-volt system having a maximum short-circuit capacity of 70 000 kVA, a 100-ampere fuse with a fusing current of 120 amperes will have to deal with only about 6 000 kVA. No commercial fuse with this blowing current could melt more rapidly than 0·002 sq. in. of copper. For this to deal with only one-tenth of the potential short-circuit it would have to reach its fusing temperature, assuming a frequency of 50, in something like 0·0005 sec. Assuming no cooling and a specific heat of 0·095, this would require a current having an R.M.S. value for the 0·0005 sec. of 14 500 amperes, which at 6 000 volts is many times greater than 6 000 kVA. Again, I do not see how the potential short-circuit of 100 000 amperes could be limited to 8 446 amperes as shown in Fig. 7. In Fig. 22 the author shows an oscillogram of a 400-ampere modern fuse successfully clearing a potential short-circuit of 100 000 amperes. The maximum current shown is 25 000 amperes, but approximately 5 cycles were occupied in clearing. This presumably shows that the element fused in something like 0·001 sec., thus introducing the limiting resistance of an arc, and that this arc persisted for 5 cycles. Why is the arc voltage 90° in advance of the current? In this case again it does not appear possible to fuse so early in the growth of a short-circuit. When, however, the load current is very small compared with the possible short-circuit current, and provided that the section of fuse wire is made as small as possible, I agree with the author that the wire will melt very early in the growth of the short-circuit. For a given metal, the time required to fuse is inversely proportional to the *square* of the current density and therefore there is a very great advantage in keeping the section at the smallest possible value. For potential-transformer fuses and the like, I advocate more attention being given to the supporting of the wire so as to permit the use of extremely fine wire. Referring to tests with limiting resistances, the author states that the maximum current was about 100 amperes, whereas without resistance it would have been 600 to 1 000 amperes, and he says that this tends to prove that rapid melting of the fuse is essential. The advantage of the resistance is not due to this; in fact, resistance will increase the time taken to fuse. The author claims that more consistent protection can be obtained with a fuse than with a circuit breaker, because the former has a thermal characteristic. A breaker can be provided with fused trips which will have a thermal characteristic. Moreover, these time-limit fuses can be so chosen as to give the desired time-lag, and for this reason a lead-tin alloy is generally used, whereas the design of a main fuse is determined by breaking-capacity considerations. Frequently, however, a fuse characteristic is considered quite unsuitable and in those cases a breaker lends itself to the addition of other time-delay devices. For dealing with small, normal loads there is certainly a field for high-tension and low-tension fuses, but I think that it would very seldom be good policy to install fuses for dealing with normal loads of 3 000 and 4 500 kW as is advocated in Table 3. A limiting resistance is of course only permissible when the normal load current is small. I prefer the fuse and resistance as separate items, as the former has to be renewed, whereas the latter should never require renewing. As the load current is always small in these cases, the fuses can be of very small section and therefore rapid in operation. The resistance is therefore only in circuit for an extremely small fraction of a second and there is no difficulty in designing one which will be of small dimensions, and which will

yet have no serious rise of temperature under short-circuit conditions.

Mr. W. Fennell: Air-break fuses are not referred to much in this paper, and one special type, viz. the "horn break" fuse, has not been mentioned. I think this type has some good points. The fuse, as used outdoor in Mid-Cheshire for controlling transformers up to 300 kVA at 33 000 volts, is enclosed in a glass tube about 2 ft. long provided with type-metal ends, and were supplied by Messrs. Metropolitan-Vickers. These are fixed in substantial clips, the fuse being horizontal. Horns are attached to the clips, so that when the fuse blows the glass is destroyed, the arc rises up the horns and goes out. The glass tube allows very thin fuse wire to be used by protecting it from birds and weather. I have tried these on "short circuit" and they have always worked satisfactorily. We have also some oil switch type fuses which have recently been designed by the New Switchgear Co., perhaps an improvement on those referred to in the paper. The fuse is fixed to contacts suspended on a rod passing through the lid. When the cover is closed a lever is operated externally, the fuse is lowered into the oil and engages with contacts fixed to the bottom of the case. There is a very simple locking gear which prevents the fuse contacts from engaging the live contacts until the cover is closed. I think this is a very convenient and safe form of fuse for controlling the small transformers. It has the advantages of a hand-operated oil switch as well as being free from the risk to which the types described in the paper expose the operator should the cover be thrown into contact position on a short-circuit. I have a rough-and-ready method of testing medium-pressure fuses which are submitted to me as being suitable for use on distributing mains, by connecting them through a massive switch to the leads close to a substation battery. There is practically no inductance in the circuit. Most of the fuse carriers explode in the way shown on some of the lantern slides exhibited by the author. In a number of cases the fuse terminals are burnt so badly that the carrier cannot be used again, and in other cases the whole assembly has been destroyed. The Aeroflex fuse under these conditions operated quietly, and the carrier was undamaged. I trust that the makers will consider bringing down the prices of Aeroflex fuses to a figure which will allow of their use. A drastic reduction in price would result in such a demand that manufacturing costs would be much lower than on the present small output, and the firm's total profits would increase.

Mr. N. E. North: Whilst such developments as Aeroflex fuses are certainly very interesting, are we on the right lines in making such developments which, in order to attain successful operation, make for a more complicated design? I feel that in the majority of applications the replaceable element feature of a fuse condemns it as being the ideal protective device. Should not the line of thought be to produce a safety interrupter which, either automatically or by hand operation, re-establishes the circuit? Some may say that cost will be the great objection to such a piece of apparatus, but if we refer to the catalogue prices of some of the newer and more elaborate fuses discussed, we certainly have a figure at which circuit-protecting devices of the type suggested could be manufactured. The design will doubtless have to be on entirely different lines from what we have previously experienced, and the circuit may have to be broken and established under conditions similar to those obtaining with the present alternatives in fuse construction. In making these remarks I have in mind industrial and household applications, because I feel that we should really divide the paper into two sections, and consider the fuse protection in connection with higher voltages and currents separately. I cannot agree with the author when he talks of the rupturing force of a fuse being the product of the current and the voltage. I think that most of us will agree that, quite apart from insulation considerations, the effect of rupturing, say, 5 000 volts at 5 amperes is quite different from that of rupturing 5 000 amperes at 5 volts. Moreover, the character of the circuit, i.e. whether it is inductive or not, is of major importance. In speaking of the high-powered fuse, we must remember that to rupture the circuit quietly and in the quickest possible manner, is not always ideal or good for the circuit which we are protecting. Experience with magnetic blow-out fuses has led us to reduce considerably the magnetic density in certain traction applications. Moreover, there are numerous cases, particularly at higher d.c. voltages, when it is essential to open the circuit in stages, the blowing of each succeeding fuse inserting greater resistance prior to the last fuse finally opening the circuit under small-current conditions. For this reason I must support the author and disagree with Mr. Hope when he complains that the Aeroflex fuse should come next to the oil fuse on the author's chart. Mr. Hope says that it is essential to exclude all the air for satisfactory operation, but tests which I have made on air fuses, using wire strand, prove that they can be entirely satisfactory (and it is much simpler to replace the element), provided that the fuse is designed to deal with the conditions which arise as a result of the expansion of the gases and surrounding atmospheres, and provided also that suitable cooling and expansion devices are incorporated in the design of such a fuse. Fuses of this type are in satisfactory operation on recent 3 000-volt d.c. traction schemes. I suggest that the value of the paper would have been slightly increased if the periodicity of the circuits shown on the oscillograph records had been given.

Mr. J. D. Peattie (*communicated*): The author has cleared up many misconceptions regarding the phenomena accompanying the operation of fusible cut-outs. It would have added to the value of the paper if he had extended his arguments a little further, and tackled the definition of "rupturing capacity" itself. A great deal of the uncertainty of the whole matter seems to originate in the definition and use of the term "rupturing capacity." It is by no means clear what relation the number (which incidentally has no direct physical significance) defined by the B.E.S.A. specification as "rupturing capacity" bears to the actual physical phenomena inside the circuit-breaking appliance during the interruption of the circuit. The way in which it is generally used, coupled with the introduction of constants applicable only to steady conditions, tends to obscure

the fact that, for the most part, transient phenomena are involved. It seems to me that four main factors are involved. On the one hand, we have the energy which is liable to be released at the circuit-breaking appliance and the rate at which that energy can be released, and, on the other hand, we have the amount of energy which can be absorbed by the circuit-breaking appliance and the rate at which it can be absorbed. The satisfactory operation of the appliance depends on the balance between these factors. The author deals with the last two, but is somewhat vague in his references to the first two. In this connection, it must be remembered that the energy is derived from two sources. One, the more important in transient phenomena, is the store of energy —electrical, magnetic, mechanical and otherwise—in the system itself, and the other the prime mover which is continually replenishing that store and maintaining the potential of the system. I think, therefore, that it will be necessary to extend the definition of rupturing capacity to cover the question of energy absorption or dissipation, and also to introduce the time element. In the meantime, the quantity defined as "rupturing capacity" does not appear to provide a full specification, any more than the product of open-circuit volts and short-circuit amperes would provide a complete specification of the capacity of a generating set. In Fig. 36 the author gives rupturing capacities in kW,* but I suggest that kVA is a more suitable term. I also notice that he frequently refers to short-circuit powers of so many kVA. I think that the word "power" should, as far as possible, be restricted to denote rate of change of energy, especially in considering this particular question, where much of the existing confusion arises from the use of numbers having no physical significance as a measure of actual physical quantities, such as energy or rate of change of energy.

[The author's reply to this discussion will be found on page 954.]

* Since corrected.

North-Eastern Centre, at Newcastle, 22 March, 1926.

Mr. P. G. Ashley: The paper is particularly appropriate at the present time when the prospect of a considerable increase in electrical supply is contemplated in accordance with the scheme recently outlined by the Government. If such a scheme is put into operation we may anticipate that a primary transmission system operating probably as high as 132 000 volts would be erected with secondary systems at 66 000 and 33 000 volts. Main tapping points, and tapping points where the consumption of energy was large, would probably be controlled by outdoor type oil-immersed circuit breakers, but on the secondary systems at small tapping points where the monetary return from the energy consumed was not sufficient to justify the installation of oil circuit breakers, another cheaper type of apparatus would be required. It would therefore appear that there will be a demand for apparatus capable of controlling energy supply at high voltages with low current rating and with a high rupturing capacity. The author has shown that two forms of such apparatus are available—the metal-clad oil-immersed switch fuse, and the resistance-type fuse with spring tension. Both these pieces of apparatus are simple and can apparently be made more cheaply than an oil circuit breaker for the same duty, and the author has shown that they are reliable under short-circuit. The resistance type of cut-out illustrated in Fig. 37 is very interesting, particularly in view of the satisfactory operation of this cut-out on short-circuit as shown by the author. The cut-out seems to be very similar to the liquid-filled high-voltage cut-outs which have been on the market several years and which are extensively used in America. The main difference is that the author embodies his limiting resistance in the spring, whereas with the other type of cut-out the limiting resistance is external to the fuse itself. The idea of embodying the resistance in the fuse is not new. One very good form of resistance cut-out, of which thousands are at present in service, employs a very fine-gauge resistance wire, wound spirally on an insulating core, the whole being embedded in marble dust. The spiral construction enables a long wire to be used in a small space, and short-circuit tests on this cut-out in comparison with an exactly similar construction, using oil in place of marble dust, showed that the latter was more effective in quenching the arc. These short-circuit tests also showed that for satisfactory service the value of the resistance could be as low as 3 ohms per 1 000 volts and that under all conditions this was quite satisfactory. American engineers in general recommend 4·5 ohms per 1 000 volts, although I believe that in one type of cut-out the actual value was found to be only 0·3 ohm per 1 000 volts. One inherent difficulty with the cut-out illustrated in Fig. 37 would appear to be that of satisfactorily combining the resistance with the spring. Assuming the figure previously given of 3 ohms per 1 000 volts, the spring would need to have a resistance of about 400 ohms for a 132-kV cut-out. There would appear to be considerable difficulty in obtaining this, while also retaining the resilient characteristics of the spring. I should therefore like to ask the author what value of resistance he recommends for his fuse, and how he proposes to embody this resistance without weakening the spring. It is gratifying to note that the troubles experienced with the early copper fuse wires in oil have now been overcome by adopting bi-metal fuse wires. These early troubles were very disconcerting and one suggested method of overcoming them was to use an oil having a very low sludge value, as it was thought that the action was equivalent to carrying out a sludge test on the oil. This was disproved when results were available on a series of tests with different classes of oil. A copper fuse wire of a definite size was loaded with its normal full-load current for long periods in different grades of oil and it was seen that the oxidizing effect was practically constant and did not appear to be a function of the sludge value of the oil. The author suggests that the improvement which was effected by

adopting bi-metal fuse wires in place of copper was due to the increased radiation surface obtained. This theory is confirmed by the fact that a similar improvement has been obtained by using copper fuse wires threaded with closely-fitting glass tubes. This device entirely prevents oxidation troubles, but it is not sufficiently robust for apparatus which may receive rough handling. Table 15 of Report E/T23 published by the British Electrical and Allied Industries Research Association, gives interesting figures in regard to the relative action of various catalysts. In this table it is shown that the catalytic action of lead is almost exactly the same as that of copper, and that zinc has an action

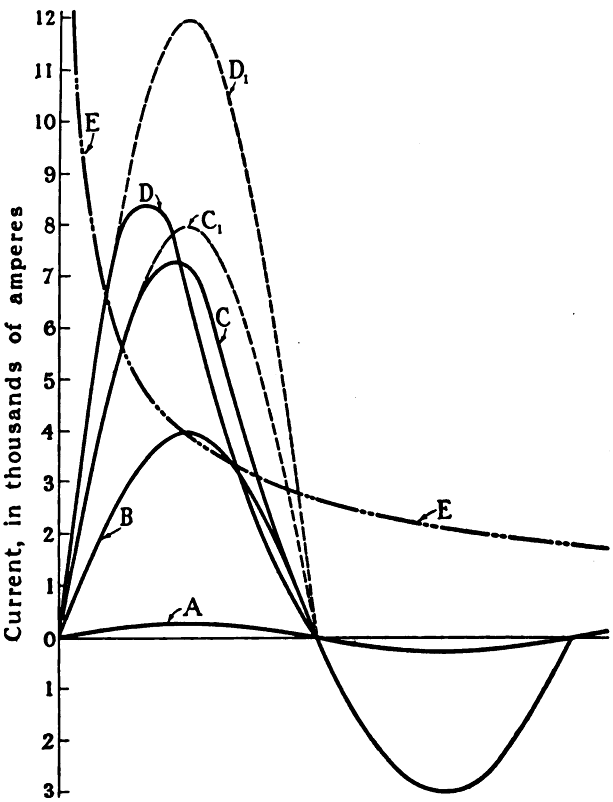

Fig. G.—Inherent current-limiting effect. Copper fuse-wire in oil.

only slightly less. The bi-metal employed being an alloy of lead and zinc, it will be seen that there is very little difference between the catalytic action of this metal and that of the copper previously used. For this reason I cannot agree with the author that the prevention of oxidation was due to the substitution of a non-catalytic agent for copper. Reference is made in the paper to the limiting effect of a fuse on short-circuit. This is particularly interesting as it is a point which is not often realized by users of fusible cut-outs. This phenomenon is mentioned on page 922, but it might be of interest to show a diagram which may be used to illustrate the point further. In preparing this diagram (Fig. G) no attempt has been made to draw the curves very accurately, as it is intended purely as an illustration. The heat generated in a fusible element when carrying current is proportional to I^2R. Normally this heat is dissipated by conduction, convection and radiation, but under short-circuit conditions the time of current-flow is so small that these dissipating factors become ineffective. We may therefore assume that all the heat imparted to the element is absorbed in increasing its temperature. If the short-circuit occurs at zero value of the normal current wave, the expression for the short-circuit wave becomes $I_0 \sin pt$ and the heat generated is proportional to $\int_0^t R(I_0 \sin pt)^2\, dt$, which on integration gives the expression $RI_0^2(\frac{1}{2}t - \frac{1}{4p}\sin 2pt)$. For any given element there is a definite value of heat which will raise its temperature above the melting point and cause it to volatilize. The expression $RI_0^2(\frac{1}{2}t - \frac{1}{4p}\sin 2pt)$ can therefore be equated to a constant. If the values of current and time which satisfy this equation are plotted, a rectangular hyperbola is obtained which is shown at E in Fig. G. This curve becomes asymptotic at a current value equal to the minimum fusing current of the element, but the equation given above does not hold over the whole range of time, owing to the complicated factors introduced by dissipation of heat. Curve A is the current wave which, if prolonged for 7 or 8 minutes, will cause the fuse element to blow. Curve B is an actual short-circuit current wave taken when this copper fuse wire was subjected to a short-circuit from a 6 000-volt turbo-alternator. The kVA value of the short-circuit was in this case limited by the size of the machine and the series impedance. Curve C_1 shows a hypothetical short-circuit current wave, assuming the cut-out to be used on a system where the available short-circuit corresponds to the value shown for the peak of the curve C_1; in other words, at a place where the potential short-circuit is 8 000 amperes. Actually, the fuse will not rupture this kVA, as a limit is introduced by what we may call the inherent current-limiting effect. As the value of the current increases from zero, as shown by curve C_1, at a certain time, the current rises to such a value that the heat generated is sufficient to melt the fuse and to volatilize it. The metal vapour which replaces the fuse element is still capable of supporting an arc, and the current therefore continues to increase with time until the arc becomes unstable; in other words, the volatilization of the element prevents the current from increasing to the value which the constants of the system would otherwise allow. Curves D_1 and D illustrate the same effect for a position where the available short-circuit or the "potential" short-circuit is greater than in the case of C_1. The practical effect of this phenomenon is that the short-circuit kVA rupturing capacity of a fuse link is fundamentally dependent upon its section and material, in relation to the available short-circuit; and if this phenomenon is to be utilized in service the relationship between these factors must be carefully considered and adjusted. It would therefore appear desirable that the curve shown by the author in Fig. 3 should have kVA plotted against minimum fusing current rather than current-carrying

capacity,* since the limiting effect and also the current-carrying capacity, is dependent upon the minimum fusing current.

Mr. H. W. Clothier: The predominating feature of all satisfactory designs of circuit-breaking devices appears to be the mechanical strength of the enclosure. It was the feature lacking in the early Ferranti oil-break fuses. The cartridge fuse shown in Fig. 4 has a double enclosure of strong fibrous tubing. This has more to do with its high short-circuit breaking capacity than the low fusing-current/load-current ratio, or any other constructional feature. A comparison of tensile strength of the several materials recorded in Table 1 would be of interest, and might to advantage be added if the author has available records. I understand that the "bakelized fibre tube" which has the lowest absorption test is similar to material known as "bakelite dielects," a form of wound paper compressed in a split mould after winding. The author has drawn attention to the important difference between the maximum energy which might pass through a short-circuit as determined from its location on a system, and the actual energy of the circuit broken by a fuse which intercepts it, the fuse having a current-limiting characteristic. An extreme case in practice is a fuse on a potential-transformer circuit. A fuse having a comparatively small breaking capacity can be used on a power station switchboard alongside of main circuit breakers of very large breaking capacity. When acting on heavy short-circuit the fuse has a very much shorter time-lag than a circuit breaker; it may break circuit on the first wave of a short-circuit and before the current reaches the maximum that it would attain through a circuit breaker in a corresponding location. Thus an oil-break fuse may be of lighter construction than a circuit breaker in the same vicinity. This is one factor leading to economy in the use of the oil-break switch-fuse, and it is just possible that it might be applied for linking up sections on large bulk supplies where the current-limiting ability might be used as a substitute for reactances.

* Since corrected.

Mr. Vernon Hope also took part in the Newcastle discussion. The substance of his contribution to the discussion is contained in his remarks in the discussion before the Institution (see page 945).

THE AUTHOR'S REPLY TO THE DISCUSSIONS AT LONDON, MANCHESTER AND NEWCASTLE.

Mr. L. C. Grant (*in reply*): Before attempting to reply in detail to the remarks of those who took part in the discussions, I would point out once more what I have said in the paper and emphasized at the meetings, namely, that the paper is intended to deal with rupturing capacity and the factors having an immediate bearing upon it. It has been said, for instance, that I have not dealt with certain time and current ratings: these and some other subjects mentioned are outside the scope of the paper, but I would mention, in passing, that I have been investigating the question of rating, and am inclining more and more to the belief that such arbitrary ratings are of little value and the really important things are (1) the minimum fusing current, which can be obtained definitely in practice on a properly calibrated cut-out, (2) the ratio of maximum or sustained full-load current to minimum fusing current, and (3) the full rating characteristics of the cut-out, which I consider can be obtained only from an accurately produced time/current curve.

Another point which has been brought up by one or two speakers is the question of the degree of goodness or badness of a given cut-out. I am afraid that I am sufficiently exacting to recognize as good only one class of cut-out. I consider it to be a satisfactory circuit-breaker only when it interrupts its maximum rated short-circuit current without developing any symptoms such as flashing or burning, or even excessive noise, and certainly without causing any damage whatever to the container or surrounding apparatus. Therefore, while I appreciate the reasons underlying Mr. Gregory's plea that it is sometimes sound engineering to use low breaking capacity cut-outs even though they may be blown to pieces when attempting to clear a fault, I would point out that a performance of this class can be simulated and possibly improved upon by the simple expedient pointed out in the paper, i.e. that of using an open wire strung between terminals and without any enclosure. Inexpensive apparatus is essential in the development of economical rural schemes, but if a cut-out worthy of the name is required, it is possible nowadays to obtain one which is a good circuit-breaker at a cost comparable with that of cut-outs which are such in name only.

With regard to Mr. Gregory's closing remarks, I agree with him that the subject of fusible cut-out design and discrimination is worthy of continued research. Properly conceived, a fusible cut-out is a scientific and reliable piece of apparatus; in some respects, perhaps, more so than an oil circuit-breaker.

I agree with Mr. Morgan's remarks with regard to nomenclature and have endeavoured to embody standard terms as far as possible, but I would point out that the standardization of terms used in fusible cut-out work has not yet been settled definitely, consequently, it is not possible to use standard nomenclature, except up to a point. As Mr. Morgan himself states, the nomenclature of the subject is at present under consideration by the Editing Committee of the B.E.S.A., and the recommendations may be adopted as standards in the near future. With regard to Mr. Morgan's remarks on the failure of fuses, he states that it appears to be necessary to find out exactly what is meant by failure. I have already endeavoured to define what I mean by successful operation, and I do not agree to the American Bureau of Standards 1916 Catalogue of types of failure being used in any way except to *describe* the type of failure. The cataloguing of failures in this way seems to imply that certain types of failure may be recognized as successful operation. I maintain that if a cut-out is properly designed—and it can be done—there will be no need to discriminate between such failures as, for instance,

rupturing of the cartridge, blowing off of the caps or ends, ignition of cotton placed around the cartridge, remaking of the circuit after it has once been opened and so on. I would suggest that any engineer who considers that such failures may be forgiven should place himself in the vicinity of a cut-out when it is operating in such a fashion.

With regard to the comparative performance of a fusible cut-out on alternating current and direct current, I have carried out a number of comparative tests of this nature and have not discovered any material difference in the performance. Furthermore, if the cut-out is properly designed and correctly applied to its duty, it should, under fault conditions, operate on the initial rising-current curve, the rate of rise of which depends on the time-constant of the circuit and not on whether the supply is from a battery or an alternator, etc. There is certainly a difference in the inductance of the circuit with direct as compared with alternating current, but there should be no difference in the performance of the cut-out. I am not endeavouring to lay down difficult or impossible conditions or to theorize without foundation; it has been my experience that a properly designed fusible cut-out will operate equally well on alternating and direct current, with no noticeable difference in its performance. There seems to be a great deal of misapprehension about the theory of interrupting circuits and about the performance of cut-outs and circuit-breakers, and there seems to have been a lamentable amount of misdirected effort; so much so, that when I first set out to investigate fusible cut-outs I wondered if what appeared to be hard facts had in reality been refuted at some previous time and had resulted in some of the curious views held on the subject of fusible cut-outs.

Mr. Clothier repeats in substance Mr. Gregory's perhaps weak support of the defectively designed cut-out, when he states that the cut-out is a renewable part and not very expensive, and consequently, if it does its primary function of isolating the fault, it may be pardoned if, in the process, its condition becomes such as to fit it only for the scrap-heap. My reply to this and to Mr. Gregory's remarks is that this is not the performance of a fusible cut-out at all, and an incomparably better performance could be obtained by a properly designed cut-out at little if any extra cost. I am glad that Mr. Clothier is with me in looking forward to the time when we shall endeavour to obtain the isolation of a fault without either pyrotechnical displays or secondary damage. The question of the ratio of actual power broken to "potential short-circuit power" is, of course, vitally important, and I can assure Mr. Clothier that the ratio of 1 to 1·2 is quite practical and is obtained with safety and simplicity. I do not, however, agree with Mr. Clothier that so sensitive a margin, as he terms it, may be likely to cause trouble, and his comparison with the relay protected gear is, I think, in some respects a false one. The integration of time and current, which is basic in the performance of a fusible cut-out, is absent in the usual protective relay arrangement, and it is possible to take advantage of the time/current curve to a remarkable extent. I agree that purely a current setting of such a ratio would indeed be a bad thing. I am afraid that I do not see the argument for a thermostatic relay in the place of a fusible cut-out when the latter provides the thermostatic device and the circuit-breaker in one.

Mr. Clothier raises the same question—although in a different sense—as Mr. Morgan, i.e. nomenclature. I agree that the word fuse "trips lightly from the tongue" and that "switch-fuse" for instance is a very descriptive term, whereas "oil-immersed fusible cut-out" is clumsy, but our Standardization Committees agree upon these terms and are always ready to criticize an offender. Various types of pressure indicator were used in the tests, and I think that Mr. Clothier has seen at least one of them. Two of the impulse type which were tried utilized a lead or copper anvil screwed to the fuse container and gave quite good results. A third was a device which combined the functions of electrostatic condenser and contact-making device. This was calibrated hydraulically and gave results comparable with the others. Another device was a small high-speed engine indicator modified for the tests. It was thought at first that the inertia of the moving parts of this would be such that no useful results would be obtained, but the figures which were obtained have been comparable with the results obtained with the other devices mentioned and with other apparatus which I have seen used for this purpose.

With regard to Mr. Hooker's remarks, the fusible cut-out is, of course, very suitable for controlling rural supplies. The cut-out he mentions has been tested and is duly dealt with in the paper, and I cannot add anything useful to the information therein given. With regard to the suggestion to use silica instead of glass, silica is similar in some respects to glass in its characteristics, except that it is possible to make thicker containers and so obtain increased mechanical strength in that way. Transparent silica, however, is rather expensive, and if used for fusible cut-out work it will probably be of the opaque variety. I have tested many types of liquid filling for fuses and have not yet found one which in any way reduces the energy or explosion set up in interrupting the circuit, or is in any way an advantage over switch oil or, for that matter, pure water.

With regard to Mr. Dunsheath's opening remarks, I have endeavoured to give in the schedule of tests a useful description of some of the cut-outs tested and have indicated whether they are useful or otherwise. This, together with the remarks in another part of the paper wherein the requirements of a good cut-out are set out and wherein the performance of a bad one is described, are surely definite conclusions. I have already made some observations on the question of nomenclature and fundamentals, and later refer again to them, so that I will make no further reference here. Mr. Dunsheath's remarks with regard to the discrepancy between load-current/fusing-current ratio and fusing-current/load-current ratio refer to a typographical slip —since corrected. With regard to Mr. Dunsheath's and another speaker's methods of showing the effect of altering the ratio, there are several ways of doing this and I considered using a somewhat similar alternative to the curve showing the power actually interrupted, but decided on the latter, which, I hope, is a more effec-

tive way of demonstrating the point so that he who runs may read.

Mr. Dunsheath's second point is interesting, but I do not think that I am guilty of the omission he mentions. There is shown in the paper an oscillograph record and a description of tests on a cut-out similar to that he mentions. The principle has been tried quite extensively, and some of the very latest tests which I carried out before completing the paper were bearing on this very point. In practice, it is extremely difficult to design a container capable of withstanding a useful pressure. Again, there is the difficulty of developing this cut-out to any size, as mentioned by Mr. Hope and Mr. Brazil. This is an apparently insurmountable obstacle and in the design and rating of fusible cut-outs is a fundamental problem which must be overcome equally with that of obtaining high rupturing capacity. Thirdly, a cut-out of this pattern operates with a display of phenomena which I consider to be undesirable and quite unnecessary, and which would be considerably augmented if the 2 000 kW mentioned by Mr. Dunsheath were raised to anything like 50 000 kW, as used in the tests described in the paper.

The silk-ribbon element which Mr. Hope describes is of the resistance type and its performance depends, at any rate to some extent, on the resistance embodied in the fusible element itself. With regard to Mr. Hope's remarks on pressure set up, apparently there is something wrong with his figure of 100 tons to the square inch. I quite agree with him that what is really needed is a liquid which will damp out any explosion without setting up any secondary pressure.

Mr. Isenthal states truly that silver is a good material to use, but I do not think that the material of the element would appreciably help the rupturing performance of a tubular cut-out of the open type to which, I take it, he refers.

With regard to Mr. Scott Maxwell's remarks, I would again emphasize the point that the manner in which a cut-out clears a fault is of great importance—I mean whether it does it properly or otherwise. Again, I consider that even one failure out of eight tests, as in the tests of the Duquesne Lighting Company, is avoidable if the cut-out is operating consistently. The further tests to which he refers and which I carried out during 1922—and subsequently to this date—are shown in Table B, which refers to six tests on cut-outs rated at 6 000 volts. It will be noted that there were two failures out of six tests, these two failures taking place at the rated voltage of the cut-out. The four remaining tests were carried out below the rated voltage of the cut-outs. I agree, to some extent, with his remarks that the higher the voltage, the higher will be the kVA rupturing capacity. This is substantially true of most circuit-opening apparatus, and the Duquesne tests tend to show that the performance on higher voltages may be somewhat better than on lower voltages. I think that Mr. Scott Maxwell is perhaps treading on rather dangerous ground when he commences to discuss pressures. There are pressures of different natures, as we know, and the fact that the end disc is blown off at, say, a pressure of 50 lb. per square inch may not prevent the pressure rising to very much higher values than this. The nozzle effect alone is sufficient to produce such a condition, while the behaviour of a steep pressure wave is very peculiar indeed and, I think, it can safely be said is not thoroughly understood. I have known instances where a strong material was entirely destroyed during the rupturing of a circuit, while a very much weaker material in a similar position was entirely untouched. An instance of such a vagary occurs to me. An explosion due to a high-tension breakdown took place in a large power station. A window frame was lifted completely from its fastenings and deposited some distance away while the glass panes remained intact. I think that while we have instances of this sort it is as well to proceed cautiously when considering explosion pressures.

If I read them correctly, Mr. Rudkin's opening remarks seem rather confused. He appears to be mixing two ideas. I quite agree that for rupturing capacity as high as 50 000 kVA the oil-immersed circuit-breaker is a more convenient piece of apparatus to use, but it is also a much more expensive piece of apparatus and the oil fuses costs less than half that of a corresponding oil circuit-breaker. I note that Mr. Rudkin objects to my conclusions that no suitable porcelain fuse-carrier can be made. I am interested to hear that he would not hesitate to design air-break cut-outs of the porcelain-carrier type for 30 000 kVA at 15 000 volts. It has been sufficiently demonstrated that high powers can be broken by a simple wire in air and, providing sufficient space is allowed, this can be done quite reliably. The effect of enclosing a plain fusible element in a porcelain or other carrier is to make it into something comparable with a bomb. Neither this nor a plain element in air forms an efficient cut-out, for the reasons enlarged upon in the paper. I am aware of most of the deficiencies of fusible cut-outs, but I do not think that cost is one of them when the latter is compared with the alternative circuit-breakers. Spare elements are of nominal cost in the fusible cut-out to which he refers, as common fuse wire is used for that purpose. The delay in restoring service is, of course, one of the deficiencies which must be taken as part of the price to be paid when the cost of an oil circuit-breaker cannot be borne by the job. Experiences cited in the paper, which are examples of everyday practice, bear out the assertion that 50 000–70 000 kVA is a short-circuit power to be met in a large proportion of present-day installations. For pressures above 3 000 volts experience on high-power systems has shown that at least 50 000 kVA has to be handled except on the most remote portions of the system and small secondary networks.

With regard to Mr. Rudkin's closing remarks, many small supplies have to be taken from comparatively high-power lines where the short-circuit power is certainly of the order which I have indicated and where the revenue to be derived from the small supplies is so small that a circuit-breaker is economically impossible. If the term "radiation" refers to oxidation—apparently resulting from surface voltage-gradient—I think this has been covered by the paper. I do not think that there is much chance in practice of the respective cases for fuses and protective apparatus being confused.

MANCHESTER.

I agree with Mr. Hope that the cartridge cut-outs to which he refers were not broken down in the tests, therefore it is legitimate to assume that the breaking capacity is something over the figures given. His remarks regarding oil cut-outs require, I think, some qualification. The results were derived from tests, with one exception, namely, those for the high-pressure oil cut-out and, as I have said in the paper, the latter results were obtained by comparison with oil switches of similar dimensions which are known to have performed similar duty. Referring to pressure in oil-immersed cut-outs, it should be noted that although the pressures in oil containers may rise to high values, the commercial form of the oil-immersed cut-out is so designed that the container and other parts are able to withstand the pressures set up. I endorse Mr. Hope's closing remarks to the effect that the ordinary commercial fusible cut-out produced to-day is apparently designed without any knowledge of the subject, and that the time has come when designers will have to pay a great deal more attention to research if fuses are to be produced with reasonably high rupturing capacity. The information for which Mr. Mellonie asks can be obtained from Fig. 1. This chart was not made from any particular ratio of load-current/fusing-current. Assume, for instance, that one has a cut-out of 100 amperes carrying capacity. If this be wired for a ratio of 1 to 1·2, it will become a 120-ampere cut-out. If, on the other hand, it be designed for a ratio of 1 to 2, it becomes one of 200 amperes, and so on. I agree with Mr. Mellonie that the most economical arrangement for low-power circuits seems to be the use of a simple cut-out with a series resistance, but I do not agree with him that a highly rated resistance may be used or that the resistance may be allowed to become red hot for a fraction of a second. The emission of a hot gas is likely to cause a flash-over in adjacent high-tension apparatus, and it is known that trouble has been caused in this way. Toward the end of his remarks, Mr. Mellonie suggests that the sudden increase in temperature of the mass of the spiral in the resistance cut-out shown in Fig. 37 may produce oil pressures which are absent when the resistance is air-cooled and the cut-out a separate piece of apparatus. This was anticipated and provided for in the original design. Mr. Mellonie and other speakers have perhaps not entirely understood my suggestion that small fusible elements should be arranged to break the circuit on the initial rising-current curve. I think it is stated without ambiguity in the paper that "a feature found to be common to small cut-outs is shown perfectly by these tests, i.e. either the circuit is interrupted in the first half-cycle with extremely low arc energy, indicating good operation, or, in the event of failure of this rapid-extinction process, the arc persists or tends to grow, resulting very quickly in the destruction of the cut-out. . . . It appears to be the rule . . . that unless such light cut-outs can be designed to clear early in the first half-cycle, they will immediately be destroyed." A properly-designed rapidly-acting fuse is not assisted by the limiting resistance so far as current interrupted is concerned, but the resistance is a desirable second line of defence. The present value of the resistance, however, lies in controlling the current passed by the usual type of fuse employed, so that it is enabled to clear the relatively small current, whereas alone it would be incapable of clearing it. If a limiting resistance be used, the current cannot rise to a dangerous value, but the time taken for the cut-out to operate is obviously a function of the current value reached. This is illustrated, not refuted, by Mr. Mellonie's oscillograph record. The tables of tests and oscillograph records given in the paper show that some small cut-outs without limiting resistance operate on the rising-current curve. Clearly, if a limiting resistance is introduced it may be of such a value that insufficient current is passed to melt the fusible element in the first half-cycle, so that the limiting effect is absent, but the energy is kept by the resistance to a value which can be handled safely by the cut-out. This is bound up with the question of size of fusible element, and I would recommend Mr. Mellonie and others who took part in the discussion to consider the various points in their relation to one another.

I agree with Mr. Mallinson's remarks that it is only by full-scale experiments and a thorough analysis of all the factors involved that practical developments of any class of engineering can be obtained. There certainly exists the criticism which has been raised by other speakers as well, that the oil circuit-breaker provides greater switching flexibility than the fusible cut-out, particularly in the closing of the circuit. Also the replacement of the fusible elements takes a little time. These details will probably be overcome in part, and they are being dealt with in some apparatus. Of course we can hardly expect the fusible cut-out to develop the flexibility of the circuit-breaker. It is an intrinsically cheaper device and has limitations which must be paid for and which should be offset against the difference in price. Nevertheless, the possibilities of the efficient fusible cut-out are enormous and I hope that the situation has been cleared to some extent by the tests described in the paper. The cost of replacements are surely only nominal; they cost a fraction of a penny for the oil-immersed cut-out and a few pence only for the cartridge cut-out referred to by Mr. Mallinson. I think that Mr. Mallinson's further criticism has been met to some extent because there are designs wherein it is impossible to insert elements of incorrect rating, while the recharging of cartridges of any importance should be a matter for a responsible person, spare cartridges being carried to take the place of other cartridges while they are being rewired. I do not think Mr. Mallinson need be unduly perturbed about the massive construction to which he refers and which is more apparent than existent. The dimensions of the tank are, no doubt, responsible for this impression, but there is very little complication inside.

Mr. Burt's statement that a reduction in the quantity of metallic vapour will bring about an increase in breaking capacity is, of course, true and I think he will agree with me that reduction in the amount of metal melted in breaking the circuit is in effect the same thing as reducing the load-current/fusing-current ratio. In considering different materials it should be remembered that there are more factors than mass of metal

to take into account; the physical constants of the material used have an important bearing. There must be something wrong with Mr. Burt's calculations when he criticizes the result he refers to, namely, that the 120-ampere fuse would handle only about 6 000 kVA. He should remember that this curve is made up from test-results and is not based on calculations. He should remember also that there are more factors contributing to the melting of the fuse than the heat liberated in the portion volatilized. He has, apparently, not read my statements very carefully. He says he does not see how the "potential" short-circuit of 100 000 amperes can be limited to 8 446 amperes as shown in Fig. 7. It is clearly stated in the paper that Fig. 7 refers to a test at 180 volts on a transformer bank which at full voltage (440 R.M.S.) would give a maximum current of 100 000 amperes. It should be remembered that the illustrations are direct reproductions of the oscillograph records. Fig. 22 is not intended to show limiting effect; the test illustrates only the rupturing performance of this cut-out under rather a bad condition. This cut-out was not suitable for this purpose for two reasons: (*a*) it was too large, which is shown to some extent by exterpolating Fig. 3; and (*b*) the tests on this cut-out were carried out at 350 volts, whereas the full short-circuit current of the transformer bank was not obtained until the terminal pressure was raised to the normal value of 440 volts. I do not quite understand what Mr. Burt means when he asks why the voltage is 90° in advance of the current. The oscillograph record shows that the phase angle is constantly varying from approximately 90° lag until at the moment of clearance it is in phase. Mr. Burt's remarks with regard to limiting effect and limiting resistance has, I think, been dealt with in the reply to Mr. Mellonie's criticism. The case for the fused time-lag switch is usually defined, and so is the case for the fusible cut-out. In these days of hard finance it is unlikely that, in a properly managed system, there will be made mistakes such as the wrongful installation of a switch in place of a fusible cut-out, or vice versa, even for loads of the order of 3 000–4 500 kW. This is referred to again in another portion of my reply.

My chief criticism of Mr. Fennell's suggestion to use the horn break is that such a course is a reversion to the old type of air cut-out, which the tests have shown to be unreliable and dangerous. Mr. Fennell himself says that, when the fuse blows, the glass is destroyed and the arc rises up the horns and goes out. Given sufficient space, the most rudimentary apparatus will serve to clear a short-circuit, but the real problems are to clear without any outside phenomena or danger to other apparatus. I have carried out some tests on horn breaks and these are not at all reassuring. The arc across a horn break is an unreliable factor, it varies in its position and it varies to an extraordinary degree in length. Also, it is blown like a feather by the least puff of wind, and it requires an almost unbelievable amount of space if interference with adjoining apparatus is to be avoided. I am interested to hear that Mr. Fennell has been carrying out short-circuit tests on his own account, and to note that his results are similar to my own, namely, that most of the carriers explode and that the terminals are burnt and the carriers rendered useless, while accurately designed cut-outs operate quietly and without doing any damage.

I do not think Mr. North can divide up my paper into the sections he proposes. As stated in the introduction, I did not propose to enlarge upon the simple lighting or industrial power cut-out. The paper is obviously, I hope, intended primarily to deal with high powers. I do not consider the rupturing capacity of a cut-out or circuit-breaker to be the product of current and voltage, as Mr. North implies. I simply used this convention in dividing up the paper. The rupturing power of a fusible cut-out or circuit-breaker depends primarily upon the current passing through the arc, the voltage across the arc, and upon the time during which the arc is maintained. The product of the first two in properly designed apparatus is much less than the product of open-circuit voltage and short-circuit current, although there are instances where the design has been so bad that the product has been greater. The voltage across the arc is dependent upon many things, not only upon the open-circuit voltage as stated by Mr. North, but upon the type of break, the class of contacts, speed of break, timing of the arc, method of damping or immersion, and so on. This was touched upon to some extent in the remarks upon powder-filled and oil-filled cut-outs, but the subject is such a large one that it is impossible to go into it in detail in the present paper. I agree with Mr. North that it is not always good to rupture the arc in the quickest possible manner. This is definitely stated in the paper in the sections dealing with "Magnetic Blow-out" and "General Design of Ironclad Oil-Immersed Cut-out." It is stated in the latter section that tests were carried out with increased speeds—finally arranged for 40 ft. per second, as this gives the maximum speed of break without introducing the risk of pressure-rise. I do not think, however, it is necessary with a properly designed cut-out to open the circuit in stages, at any rate with such cut-outs as come within the scope of the paper. Such an arrangement is very complicated and cumbersome and in some installations where it has been installed it has been replaced with a single cut-out. The arrangement referred to by Mr. North, in addition to its complication, has the disadvantage that it operates disruptively and with risk of damage to the surroundings, and in the installation to which he refers was not considered entirely satisfactory. The periodicities of the circuits in which the tests were carried out were deleted from the advance copies of the paper through a misunderstanding but have since been re-inserted.

With regard to Mr. Peattie's remarks, the definition of "Rupturing Capacity" has occupied the attention of several committees for a number of years and even now is not satisfactorily determined. In the printed version of the paper, I have endeavoured to make clear what I mean by "rupturing capacity" in so far as it applies to fusible cut-outs. On the question of the energy liberated at the moment of rupture, I have endeavoured to deal with this—at any rate briefly in the paper—and Mr. Peattie should remember that the space allowable for the paper had to be allocated, as fairly as possible, between the different sections, and that the question of

arc energy and power is very complicated. It has been and is being investigated, but it is hardly possible, without becoming involved in a lengthy dissertation, to enlarge upon the point more than has been done in the paper. The transient effect is, I agree, very important: it will be found that there is a certain amount of information in the paper bearing on this point. The term "kVA" has been embodied in the final draft of the paper for the *Journal*.

Mr. Ashley remarks that the resistance cut-out described in the paper is very similar to the liquid-filled cut-outs so extensively used in America. I am afraid that I do not see the resemblance, nor do the Patent Office examiners. The principles and construction of the two are entirely different, while the tests described in the paper show that there is no comparison in the performance of the two. Again, I think he rather misses the point when he states that the idea of introducing the resistance in the fuse is not new. The undesirable features of the other form of resistance cut-out which he describes are that the whole of the resistance spiral forms the fusible element, which means that there is a large mass to be volatilized on short-circuit—an obviously undesirable state of affairs—and, secondly, there is a considerable length of heated wire in contact with marble dust, which results in an unstable combination. The long fuse element is not a desirable feature. Furthermore, I have pointed out in the paper that such a rudimentary marble-dust arrangement is not a reliable circuit-breaker. None of these objections are met with in the oil-immersed resistance-controlled cut-out referred to in the paper and mentioned by Mr. Ashley. The resistance cut-out referred to in the paper is a practical embodiment of up-to-date information. It has been exhaustively tested on short-circuit, while Mr. Ashley's fuse has been subject only to a solitary short-circuit. The tests described in the paper have shown that the figures he mentions for the ohmic value of limiting resistances are not safe. For the resistance of the 6 000-volt cut-out to which he refers, I would suggest a value of 30–50 ohms—preferably even higher—but I think that the most accurate way is to specify the current passed on dead short-circuit, as is recommended in the paper. I would also suggest that Mr. Ashley is in error in assuming that there is a linear connection between the voltage and value of limiting resistance required, and his conclusions with regard to the 132 kV cut-out referred to should therefore be made on a different basis for the two reasons first explained. The question of designing a suitable resistance for this fuse is surely one for the manufacturers of the fuse referred to. With regard to his further remarks, I would point out that the phrase to which he refers reads *in extenso* in the paper: "It was believed that the action was at least partly catalytic, but from the very mechanism of the action it was clear that catalytic action alone was not responsible. When copper wires were used it was found impossible to overcome the trouble while retaining a reasonable load/fusing-current ratio, and bi-metallic fusible elements having a copper core sheathed with tin or tin-lead were finally adopted. . . ."

DISCUSSION ON

"ELECTRO-FARMING, OR THE APPLICATIONS OF ELECTRICITY TO AGRICULTURE."*

THE AUTHOR'S REPLY TO THE DISCUSSION.

Mr. R. Borlase Matthews (*in reply*): On account of the fact that the paper has been discussed at a number of Centres, the various sections of the subject have been dealt with in parallel. However, as a matter of record, it is more useful to arrange the reply in the same serial order as that of the original paper; and this has therefore been done.

The discussions generally are indicative of the very real interest that is taken in this subject nowadays, while there is much useful constructive criticism. This constructive criticism follows two distinct lines: (1) It is suggested that experimental work should be undertaken to a much greater extent than has so far been done; and (2) there is a strong feeling in certain quarters that the whole problem is bound up with legislation, the view being held that the greatest hindrance to rural electrical development is obstructive legislation, sometimes national and sometimes local.

The experimental work, mentioned as necessary, is a recommendation which it is not difficult to make, but when it comes to working out the details, such as by whom this work is to be done, one comes up against the first great problem, namely, that the science of electro-farming appeals to, and should be of benefit to, two undoubtedly different classes of men—the engineer and the farmer. Mr. Atkinson states that the electrical manufacturers should finance research work, it being greatly to the advantage of the electrical industry that advance should be made, and his suggestion is endorsed by other speakers. In this connection, reference should be made to Mr. Wedmore's offer to put the resources of the Electrical Research Association at the disposal of this new science. On the other hand, there are signs that research work might be financed to a certain extent by farming interests.

Throughout the discussion it is observed that the traditional attitude, that the farmer is too conservative-minded to bother with electricity, does not apply to the farmer of to-day. Prof. Gilchrist is confident that experimental work on a large scale would meet with practical support from the branch of the National Farmers' Union in his district; and this opinion bears out the experience of other countries, where, as Mr. Francis stated in connection with Bavarian farmers, Farming Associations have been known to bear the expense of the distribution lines. It also appears throughout the discussion that experimental work has been spoken of, not merely as a necessity to discover in what way electricity can be applied to agriculture, but also as a means of convincing the farmer and the engineer of the practicability of the whole scheme. This is not surprising, for other countries are so much more advanced than ours in the matter of rural electrification, that there is no problem which has not already been tackled, as far as the engineering side is concerned; but on both sides conviction and steady purpose are lacking.

Mr. White raises the question of the suitability of wind-driven electric generators for the production of power for agricultural purposes. Such generators are certainly being used in this country and on the Continent, though not on a very large scale. The windmill can be used successfully for small lighting plants in isolated districts remote from any power scheme. Where electric power is required for driving a number of farm machines, the use of windmills is not to be recommended, on the score of capital investment, since the outlay on the batteries would be too great, especially where the winds are as uncertain as they are in such a country as Great Britain. Incidentally, in wind-swept countries like Denmark and Holland, electric motors operated from the public supplies are now being installed in the bases of many of the windmills.

Mr. Robson asks for more details with regard to the temporary tapping of 33 000-volt lines. It is customary on many parts of the Continent to do this for temporary thrashing and ploughing loads, using cables provided with special bare hook-ends having insulated handles. By means of the latter the hooks are simply hung on the lines and the transformer is thus connected to the circuit. In theory it may not appear safe, but in practice it works quite well. It must be borne in mind that there is never any load on the transformer when the connection is made; in fact, interlocking safety switches are often provided. An illustration of the connection to 30 000-volt lines of a 5 000-volt portable transformer for a 125-h.p. electric plough, at Versailles near Paris, is given in another paper by the author, entitled "Rural E.H.T. Distribution," mentioned in the Appendix on page 812. This work is, of course, only done by one of the electricians of the electricity supply undertaking.

Mr. Creedy and Mr. Minton raise the question of the different types of current. At present there is nothing more suitable and simple for the farmers' use than the three-phase squirrel-cage motor. Hence, for this purpose, a three-phase supply is favoured. Nearly all the farms at present supplied with electric current are on this system. The study of alternative methods of supply is a very fascinating subject, but there are so many other electro-farming problems to be solved, that the temptation at present is to follow the accepted lines of supply. Mr. Minton also asks if I have had any experience in laying tramlines over my farm. While there are none actually laid, they have been seriously considered. Two overhead ropeways have, however, been installed. At present, rails are only employed on farms where a considerable quantity of potatoes, sugar beet or sugar cane is grown. The fields are then usually connected to the factory by tramlines.

Mr. Anderson asks if the method of electro-silage cited in the paper prevents the considerable amount of

* Paper by Mr. R. Borlase Matthews (see p. 801).

waste which was experienced by the old method of merely applying pressure to the fodder. The answer to that is that it does, because the material is entirely enclosed and, except the top layer, is protected from the atmosphere.

Colonel Crompton refers to the industry of enriching the soil in Germany by producing nitrates from the air, and asks for further information. In addition to Germany, it is also a big industry in Norway. Large quantities of nitrates produced in this way are employed in this country. The manufacture can only be carried out on a large scale. I have investigated the process to see if it is feasible with water-power on my own farm, but I found it to be impracticable on such a small scale.

Mr. Turnbull raises a practical point in the wiring of cowsheds. He is thinking of devising a simple vulcanized-rubber system on porcelain cleats, as being preferable to steel tube. The latter is useless, unless protected by an impregnated hemp covering. Ordinary vulcanized rubber cable is not much better and, if employed, should be supported upon insulators as if it were a bare conductor. Reference should be made to the paragraph entitled " Wiring system " on page 805.

Apart from the purely engineering problems of supply, etc., interest in the paper centres chiefly around the questions of poultry-house lighting, intensive illumination for greenhouse plants, bee-house or apiary heating, ploughing and the treatment of crops.

Mr. Robson asks if mechanical milking is satisfactory, as a friend of his, an electrical engineer, once used it, but eventually gave it up. Like everything else, practical experience is necessary in the use of these machines, as I have found to my cost. Having gained that experience, they are most satisfactory. There is now no doubt about this; and one maker alone has 50 000 equipments in use to-day. There are over 19 000 installations of various makes in New Zealand. The reason that dissatisfaction is so frequently expressed with mechanical milking-machines is because it is not realized that such machines need special care, in properly cleaning and using them. Provided that such care be taken, it is no uncommon thing for grade A milk to be produced in dairies where mechanical milking is the rule.

Sir Daniel Hall evidently does not quite appreciate one economic side of the question, when he speaks of dairy farming. It is true that it does not matter whether any kind of a machine be driven by electricity or by hand, provided that both are equally efficient. The worker has yet to be found, however, who can separate 300 gallons of milk or yet churn 180 lb. of butter, as can be done by a machine using one unit of electricity at a cost of but a few pence.

Mr. Grant inquires if there is any recent information in regard to the economics of milk treatment by ultra-violet rays. So far the methods are only experimental, not having reached the commercial stage, though a plant of Dr. Lulofs's design is in use in Amsterdam.

Sir Daniel Hall is sceptical as to the financial advantage of electricity in poultry farming. If, however, the value of the extra eggs hatched and the extra chicks reared, plus the labour saved, is taken into account, the electrical method is cheaper. It is the overall costs that count. Electric light in the laying house means at least 15 per cent more eggs in the winter time, when prices are high, at a nominal cost for electricity.

Mr. Carter raises a more unusual point and arouses a different train of thought, when he suggests that the universal electrification of poultry farms would lead to universal lowering of prices and, consequently, the economic advantages detailed in the paper would not become a general advantage. It is no doubt true that if all poultry farmers were to adopt the lighting method at once, there would be a universal lowering of the price of the egg. This would naturally follow from the law of supply and demand. But all the poultry farmers in England together do not produce sufficient eggs for our own requirements. In fact, last year we imported 1 475 million eggs valued at £9 216 000, so that it would be necessary for the poultry farmers of other countries to adopt the lighting method on a large scale if the prices of eggs in this country were to be appreciably affected. We shall no doubt see the day when this practice will be universally adopted and eggs can be purchased at a standard price all the year round, since the cost of electric lighting for the whole season amounts only to about the value of one egg per bird per annum. By that time the poultry farmer who is enterprising enough to step in now will be taking advantage of some further new scientific practice to help lower his cost of production, such as applications of ultra-violet rays, in which interesting experimental work has already been done.

Mr. Moffett refers to the efficacy of the heating of poultry houses. Hens being of sub-tropical origin, it is more than probable that they would appreciate the comfort of extra warmth, although carried beyond a certain point it would render them liable to chills. It does not, however, seem to be an economical proposition, for it would probably be more profitable to increase the maize in the ration. The increase in egg production brought about by artificial lighting is not a matter of warmth or comfort. It is a feeding matter, the idea of which is to enable birds to have a longer day; instead of getting on to their perches at dusk, it provides them with additional time in which to scratch and feed.

In reply to Mr. Atkinson, who contends that I have been somewhat misled by the rate of growth of plants at night, the point is that, though of course it is fully realized that night is the normal time of growth, the growth under artificial conditions of intensive light has been expedited out of all comparison with normal greenhouse or hot-house growth.

Several speakers are interested in Mr. Sayers's idea for the warming of the soil by means of circulating the hot water from electricity generating stations in pipes through the soil, and the difficulties have been pointed out very thoroughly. There does not seem, however, any reason why such pipes should not be utilized, not under the ground but in greenhouses erected nearby. The heavy capital investment required is the chief objection. Mr. Owen D. Young, speaking in America, has made the suggestion that there should be closer co-operation between the farmer and the engineer, suggesting that each station should have its own agricultural department, and so it seems to be only

common sense that greenhouse cultivation should be a by-product industry of electricity generation.

A practical solution of one of the difficulties in the spread of electricity has been offered by Major Rich and others, in the suggestion that something should be done to reduce the retail prices of lamps. Certainly such a reduction would be of very great advantage. The average prices on the Continent are less than one-half of those that prevail in this country. Still the paradox exists that British lamps can be purchased here at similar prices if the buyer undertakes not to sell or use them in this country. The Electric Lamp Manufacturers' Association has assured me that they will reconsider the prices of lamps in this country in the coming autumn.

As might have been expected, the price of current is a point which the electricity supply engineers have seized upon, and their comments upon this and upon the legislative aspect of the question are decidedly enlightening. Mr. Carter is of the opinion that a farmer would prefer a fixed charge plus a low rate per unit, and he fears that the farmer would grudge the cost of electricity. The reply to this is that it is not so much a matter of the cost of the current as of the return which the farmer is to get out of it. Upon the Continent the farmer does not object to an average charge of 4d. per unit for power and 8d. for lighting, since any other form of power costs him much more. Inquiry upon the Continent has led to the conclusion that psychologically it is better to charge a low rate per unit, plus a fixed sum as a service charge, than to do away with service charges and make the rate per unit higher.

While the figures given in the paper on page 802 were intended rather as an indication of the enormous potential load that is represented by the farming industry, they have been taken rather more seriously by Mr. Jenkin and Mr. Heslop. The ultimate figures of 1 000 and 1 295 million units per annum respectively, that are the outcome of their calculations, exceed, however, my more moderate estimate of 800 million units. Still, the smallest of these figures represents an output that is well worthy of most serious attention.

During the discussions much has been heard concerning the sins of the Post Office, and the point of view of Post Office engineers has also been expressed. Above and beyond those difficulties, however, it does seem that until more helpful legislation than at present exists is put into force, the obstacles in the way of rural electrification in this country are unnecessarily large. Mr. Fennell's exposition of these difficulties might well be pondered upon by those who have influence in Parliamentary matters. It should, however, be pointed out that those engineers who have had the least experience in the construction of overhead lines find the greatest difficulty in complying with the existing regulations.

Another big question upon which a good deal of comment has been aroused is electrical ploughing. Sir Daniel Hall puts the case in a nutshell when he asks, "What prospect is there of doing the ploughing so much more economically by the application of electrical power that horses will be largely displaced ?" Already it is much cheaper than horses and has the advantage of being much quicker and more powerful, thus permitting better cropping. Electrical methods of harvesting and crop treatment will, however, have to be developed, as horses are largely kept for this purpose and therefore can also be economically employed for ploughing, though at the expense of the crops. On my farm of 600 acres there are only two horses; even these could be dispensed with if a light creeper track vehicle such as is at present on the market were substituted.

I was among those who had the good fortune to study under the late Prof. John Perry. It is interesting to call to mind one of the Professor's comments concerning the qualifications of an engineer. Among other things, he said, one of the most important qualities is imagination. Now this whole subject of electro-farming needs a very healthy imagination, for so much of it is in the future. It has often occurred to me that if I were to suppress a great deal of data of which I am fully aware, what a big case I could make out *against* electro-farming. I venture to suggest, therefore, that probably most of those who do not believe in its future as strongly as I do, possibly do not know as much about it as it has happened to be my good fortune to learn. Unfortunately, too many English people use their intellect to create difficulties, instead of to overcome them.

Agreement must be expressed with Mr. Montague Fordham and others who have spoken upon the subject of rural electrification, not from the engineering or agricultural point of view, but rather as a social problem taken in its broadest sense, which is what the whole question resolves itself into. At the same time the social situation is accompanied by most interesting engineering problems which are calling loudly for solution.

SOME NOTES ON THE EARTHING OF METAL OBJECTS OTHER THAN CONDUCTORS.*

By L. HENSHAW.

(*Paper received 7th January, 1926.*)

SUMMARY.

The importance of earthing metal bodies other than conductors is stressed by all electricity law-makers and is denied by few, if any, engineers. At the same time rules, regulations, etc., covering the installation and maintenance of electric plant and equipment strictly avoid specification beyond that vague expression "satisfactory." The paper suggests a starting point for investigation having as its objective the defining of conditions which will preclude all possibility of dispute.

This paper is the outcome of difficulties experienced in operating an Electricity Act under the existing divergence of opinion as to what conditions are essential to a satisfactory earth. The impossibility of developing a clear definition appears to increase in direct proportion to the amount of study applied to the subject. It seems possible, however, and very desirable, to include in all relevant enactments definite conditions with which an earth must comply before it can be declared to be satisfactory, such conditions being, of course, capable of relaxation by the enacting body. In countries in which electrical development is still in its infancy, and especially in those—and there are many—in which the popular mind is discursive rather than analytical, and agrarian rather than mechanical, such action is not only desirable but essential.

The author does not claim to have any special knowledge on this subject, and hence those who read this paper with the object of acquiring such information will be disappointed. Unfortunately, his time and facilities for conducting research are not commensurate with his inclination and field. The intention of the paper is, however, to encourage discussion on this most important question and, if the discussion so encouraged advances the issue of the specification referred to in the last paragraph of Regulation 127 in the Eighth Edition of the I.E.E. Regulations for the Electrical Equipment of Buildings, the author will deem his work well done.

The object of earthing metal objects other than conductors being to "ensure at all times an immediate discharge of electrical energy without danger," we may first consider the nature of the dangers contemplated. They appear to be shock and fire. In view of the small amount of current required to produce shock, and the fire-resisting properties of most conducting bodies, we may, for all practical purposes, assume that elimination of the former will include the latter. It is therefore necessary to provide equipment which will ensure at all times an immediate discharge of electrical energy without danger from shock. This is supposed to be carried out in practice by ensuring that, on the occurrence of a fault of a predetermined magnitude, sufficient current to operate the tripping device shall flow through the earthing system.

Let us now consider the path of the fault current and the obstacles it meets *en route*. Members are here referred to an interesting series of articles which appeared in the *Electrician* in 1915–16, beginning with Prof. Marchant's article in the issue of the 17th September, 1915. In these articles formulæ for the resistance of earth connections in terms of the resistivity of the soil and the nature, location and dimensions of the earth, are discussed at length. Much research has also been carried out and many valuable articles have been written on the nature and dimensions of earth-plates, rods and tubes and earthing leads.

The scope of this paper, however, is limited to consideration of the fault effects met with in general practice and against which protection from shock must be ensured; and we cannot, for obvious reasons, take into consideration the specific resistance of the various substances which lie between the neutral earthing equipment and every protective earth on the system. Omitting this and taking the simplest case—a 3-wire d.c. system with earthed neutral—our obstacles are composed of measurable resistances in series, collectively tending to restrict the flow of the fault current from the fault to the neutral point of the distributing system. Starting from the fault, they are :—

(1) the fault resistance,
(2) the resistance of the earthing leads,
(3) the resistance of the earth,
(4) the resistance of the neutral earth,
(5) the resistance of the neutral earthing leads,
(6) any resistance inserted between the neutral and earth.

Since it is necessary to guard against the occurrence of a dead earth, (1) may be omitted and, assuming the earthing leads to have been correctly designed and installed, (2) and (5) may be ignored. It has been argued that, in view of the probable existence in parallel of innumerable neutral earths of moderately low resistance, (4) and (6) should also be omitted from calculations, but the author sees no reason why a licensee or an owner who maintains, except at one point, the

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

insulation of his neutral should be penalized in this respect or, conversely, why a premium should be put on poor maintenance. (It should be remembered that we are dealing with the earthing of metal objects *other than* conductors.) Hence we have three resistances in series, as shown in Fig. 1, in which B is the earthed body, r_1 represents the resistance of the earth connected to the metal body, r_2 the resistance of the neutral earth, and r_3 the neutral limiting resistance. Assuming a dead earth on B, the fault current will be limited to $E/(r_1 + r_2 + r_3)$, and this, irrespective of tripping or fusing values, is the maximum current with which the earthing system will be called upon to cope, even momentarily. Assuming that this current will be sufficient to operate the tripping device—we shall return to this point later—it is necessary now to decide whether the possibility of shock contact being coincident with the short period of time between the occurrence of the

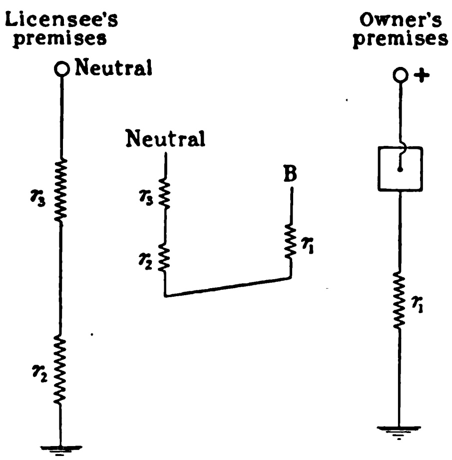

FIG. 1.

fault and the opening of the circuit should be taken into consideration, or whether the current required to open the circuit should form the basis of our calculations. There are, on record, instances of fatal accidents occurring during that period, and for this reason alone the author is of the opinion that the maximum current should be considered. The author's experience may be unfortunate—though by no means unique—but in his jurisdiction the majority of the plant operating on earthed systems relies for protection entirely upon its main fuses or breakers, and hence the circuit is not opened until a current equal to twice (or thereabouts) the full-load current is permitted to pass. Hence, in the case of plant of any magnitude, the value $r_1 + r_2 + r_3$ is required to be very low.

In the case most frequently met with, i.e. an owner's plant operating on a licensee's system, r_2 and r_3 are fixed by the latter, with the knowledge and approval of the licensing authority, and the owner is therefore able to control only r_1 in his earthing problems. And in the plains of India, in the dry season—say 9 months in the year—r_1 is most difficult and expensive and often impossible to maintain, and hence it is not surprising that the current of value $E/(r_1 + r_2 + r_3)$ is seldom sufficient to open the circuit. In fact, many attempts have, for experimental purposes, been made to open circuits by dead-earthing an outer conductor and these have, in spite of good earthing, met with success in only very rare instances.

In this connection it may be of interest to note an unusual case of fatal shock received from a stay wire. The licensee was not aware of the fault on the line, the pole was earthed and the stay wire was securely anchored in the ground. Apart from the pole and the stay wire there was no metallic path to the ground in the vicinity and the ground was dry. The stay wire was not directly connected to the earth wire but, the fault being on a cross-arm, it was obviously in good electrical contact with the pole. It is not known what the fault current was—the voltage across the outers was 440 a.c.—but apparently it was not high and yet, in spite of the nature of the ground, a fatal current was able to flow through the shock circuit. What are we to do about it? Are we to follow regrettable precedents and retard development by insisting that all earthing systems shall include costly protective devices? The answer to that, most emphatically, is not in the affirmative. "An immediate discharge of energy without danger." Discharge to what? Infinity? No, the sole object of earthing the neutral being to provide an adequate return for fault current we cannot get out of it that way. And we cannot compel an owner to fuse down to $E/(r_1 + r_2 + r_3)$. We can eliminate r_3 by shunting it with a light fuse, but we are not much better off, and certainly we cannot rely upon the manual opening of the circuit immediately this fuse blows and the circuit being kept open until the fault is cleared. Nor can we penalize a licensee by making him shut down, even temporarily, a section of his system on account of a fault on a consumer's premises. The author regrets that he has no solution of this problem. If he had, this paper would not have been written, since its object is to obtain information.

It will be obvious, however, that the maximum current which may—or should—flow through the earthing equipment is a most important factor in our problems concerning the earthing of metal bodies other than conductors, and hence it is necessary first to develop rules for its computation. And then, having decided by what means the fault is to be made known and isolated without detriment to other consumers on the same distribution, we may pass on to the consideration of the shock risks due to that maximum fault current.

We have so far dealt with the earth circuit, but our object, it must be remembered, it not only to discover faults but also to prevent those faults from causing harm to animal life. In this sense the earthing system may be looked upon as an *added* circuit for the purpose of taking from an *existing* circuit—the shock circuit—sufficient current to render the latter innocuous. In other words, the function of the earthing system is to eliminate, or at least to limit, leakage current in undesirable directions. It is therefore incident to the shock circuit and should be treated as such.

Acceptance of this view demands consideration of a

circuit which divides into two branches and unites again, one branch being the earthing system and the other a combination of a body touching the earthed member and the medium between that body and earth—the reuniting medium being earth. Our indisputable aim is to eliminate shock from the latter. Let us consider how our object can be attained.

Referring to the circuit diagram in Fig. 2, B is the earthed member and Y is the resistance between the earthing system and earth. Let us use y as the value of this resistance—usually the only test applied. Neglecting the resistance of the leads, this forms the total resistance of that side of the circuit. On the other side, K is the contact-making body the resistance of which is k, and X is the medium between that body and earth, the resistance of which we will denote by x. For all practical purposes the resistance of the two contacts may be included in k.

Assuming for a moment that k is a constant, it will be obvious that shock varies inversely to the value of x/y or, in other words, the greater x is with respect to y the less the shock will be. x and y therefore demand attention. Let us again refer to Fig. 2.

If I = maximum leakage current,

I_y = current in y,

and I_{k+x} = current in K and X,

then
$$I = I_y + I_{k+x} \quad \ldots \ldots \quad (1)$$

and
$$\frac{I_{k+x}}{I_y} = \frac{y}{k+x} \quad \ldots \ldots \quad (2)$$

Now let us assume the maximum current permissible through the contact-making body to be t amperes, then from (1) we get

$$I = I_y + t$$

or
$$I_y = I - t \quad \ldots \ldots \quad (3)$$

and substituting in (2) we get

$$\frac{t}{I-t} = \frac{y}{k+x} \quad \ldots \ldots \quad (4)$$

or
$$y = \frac{t(k+x)}{I-t} \quad \ldots \ldots \quad (5)$$

and for safety
$$y < \frac{t(k+x)}{I-t} \quad \ldots \ldots \quad (6)$$

If this condition is maintained under all circumstances the earthing is, from the shock point of view, satisfactory, since it ensures "at all times an immediate discharge of electrical energy without danger." It necessarily follows from this that however well earthed B is, it is not safe if y is less than the value of the expression $t(k + x)/(I - t)$, in which we have two factors (x and y) which are readily obtained by test, one (I) which will, we hope, be known in each case, and two (t and k) which are unknown. The author is, however, of the opinion that a safe value for t may reasonably be assumed, and he suggests 20 mA.

The value of k varies enormously, but since we are assuming that it includes the resistance of the two contacts and as, in practice, even fair contact at both ends is extremely improbable, the assumption of a fairly high value is justifiable. It must also be remembered that the value for k will include the resistance of the fault itself which, in practice, will not be inconsiderable on account of the insulating properties of paint, rust, dust, dirt, etc. The author therefore suggests 5 000 ohms. In this connection it is interesting to note that, in the comments so far received, the value for t has generally been accepted and that for k has been severely handled. At the same time it has been suggested that the proposal would be simplified if, instead of limiting the current, the drop across K were limited to 100 volts. Ohm's law being what it is, this, the most frequent and certainly the most valuable comment, suggests a measure of reason in the

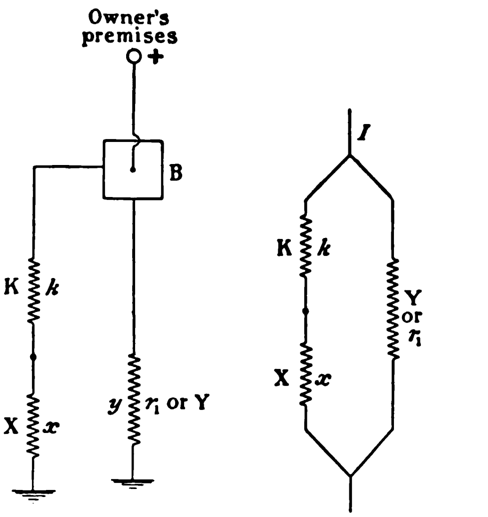

FIG. 2.

assumption of a value of 5 000 ohms as the resistance of the human body under poor conditions of contact.

The suggestion to limit the drop across K, i.e. between the earthed member and any point within touchable distance of it, is an improvement on existing procedure, but it necessitates assumptions no less uncertain than those of the values t and k. It will, presumably, be generally accepted that current is the principal factor in shock and that the fixing of a safe value for t offers little scope for controversy. If, therefore, the current is fixed, the permissible drop across the earthed member and any point within touchable distance of that member must vary directly with the resistance of the contact-making body; i.e. drop and resistance are equally variable.

Ignoring the contact resistance, can we definitely state upon what the variation depends? Probably the major portion of the resistance of the human body is in the skin and, if this is established, it would not be unreasonable to assume that moisture is the chief factor in the variation. This is capable of test and as moisture *in* the skin depends very largely upon atmospheric conditions—temperature and humidity—a range of reliable safe values for k might be fixed to cover all practical applications. But this is merely *en passant*.

Our expression now becomes

$$y < \frac{0\cdot02(5\,000 + x)}{I - 0\cdot02}$$

or

$$y < \frac{5\,000 + x}{50I - 1}$$

and, for all practical purposes,

$$y < \frac{5\,000 + x}{50I} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

Now let us consider the case of a d.c. motor the maximum fault current of which is 14 amperes (i.e. $I = 14$). Let us assume the resistance of the motor frame to earth to be 4 ohms—a figure generally accepted as satisfactory for such a machine. Substituting in (7) we get

$$4 < \frac{5\,000 + x}{700}$$

$$x > -\,2\,200$$

But x cannot be less than zero and hence this value indicates absolute safety; for even if in (7) we substitute $x = 0$ we get $y < 7\cdot14$ ohms. In this case, therefore, safety is assured even if the touching body makes perfect contact with earth.

Now let us take the case of a d.c. motor the maximum fault current of which is 250 amperes and the resistance of the frame to earth is 1 ohm. Substituting in (7) we get

$$1 < \frac{5\,000 + x}{12\,500}$$

or

$$x > 7\,500 \text{ ohms.}$$

A combination of a heavy earth on this motor and the proximity of a water pipe, or even moist earth, suggests tragic possibilities. (In the author's district, local authorities rarely permit the use of water pipes for earthing purposes.)

These examples will suffice to show that mere testing between earth and the earthing system is inadequate, and that tests should also be taken between earth and points within touchable distance of the earthed member. A visual inspection will usually indicate which points should be tested, and if one lead of the testing set is connected to a metal rod or a 28 lb. weight and the latter is poked about here and there, the test becomes very simple and, practically speaking, takes up no more time than the single earth test.

The problem may be elaborated by the introduction of additional circuits, but investigation will show that these do not affect the question at issue, viz. the limiting of current through the shock circuit, and that all such circuits may be considered to form part of one of the two branch circuits under consideration. And, as there is only one path through K, the conditions remain the same.

The conclusion arrived at as a result of consideration of the question from this aspect is that adequate shock protection is ensured only when

$$y < \frac{t(k + x)}{I - t}$$

And this, the author suggests, is one of the conditions to be satisfied in all cases of earthing of metal objects other than conductors. Hence an owner may eliminate shock risk by improving the insulation of bodies lying within touchable distance of the earthed members, and so reduce the necessity for elaborate and expensive earthing. It should be distinctly understood, however, that this is the shock aspect only, and that its application in practice is limited by considerations of fault localization and the importance of not insulating a fault beyond that point at which it has been pre-arranged that it should cause the opening of the circuit. (In a.c. distribution reactance will, of course, enter into the calculations.)

The function of an earthing system being to eliminate risk from shock and fire, satisfactory earthing may be considered to be a form of insurance to the owner—an aspect of the case deserving of consideration by the insurance companies. But whilst an owner should be prepared to pay a reasonable sum for a satisfactory earth, it is desirable that the cost of earthing generally should not be increased. Further, application of a definition should not add to the cost or to the complication of testing and should strictly avoid interruption of supply for the purpose of taking a test.

A matter of very great importance in the testing of earths is the selection of a test earth. Water pipes are usually considered to provide excellent test points, but the reverse is frequently the case. The author recently had occasion to test the earthing of an industrial motor and its control apparatus. The owner had protested against an order to improve the earthing. A test was taken across the earth and a convenient water pipe and the result was undoubtedly high. A second water pipe was found some 30 ft. away and a second test was taken, but with the same result, which was again obtained on testing between the two water pipes—both on the same service with less than a dozen yards between them. A nearby well was then put into commission as a test point. The result was:

To earthing system	low resistance
To water pipes	high resistance

Moral: Do not judge a water service by its visible components.

THE LIFE-TESTING OF SMALL THERMIONIC VALVES.

By M. THOMPSON, M.A., Associate Member, R. H. DUDDERIDGE and L. G. A. SIMS, M.Sc., Student.

[Communication from the Staff of the Research Laboratories of the General Electric Co., Wembley.]

(*Paper first received* 20*th February, and in final form* 10*th April*, 1926.)

SUMMARY.

The paper discusses the basis of a life specification for thermionic valves, similar to those in force for electric lamps, and indicates the assistance which a life-test equipment and data afford in preparing such specifications. The general characteristics of thermionic valves are then described, in relation to the problems involved in designing such an installation. Solutions of these problems are then discussed more fully, and a large installation for testing the life of valves is described. Typical examples of the results obtained are given.

(1) INTRODUCTION.

This paper is a fulfilment of a forecast in a previous paper,* that methods adopted in the life-testing of valves would subsequently be described. The present object is, therefore, to describe in some detail the valve-life testing organization with which the authors are associated.†

Certain advantages which are given by a life-test organization, such as the ability to control the production quality and to acquire knowledge of valve behaviour after many hundreds of hours' running, will be clear and need not be emphasized. In the same way, the assistance which a life-test installation affords in the design of new valve types will hardly need elaboration, particularly as the electric lamp industry has received material assistance in the past from similar installations. But the problem of running life-tests on thermionic valves is more complicated than the equivalent problem for lamps, due partly to the low operating voltages, and partly to the greater number of electrodes which are an essential feature of their construction. But despite dissimilarities from the case of the electric lamp, there is much that has been accomplished in the life-testing of lamps which can, with advantage, be applied to the testing of valves.

The valve industry will probably play as extensive a part in the present civilization, and one probably as valuable, as that played by the lamp industry. The time has already come when progress in development should be regulated by wise standards of performance fixed after a careful consideration of accumulated experimental data. This function has been performed for the lamp industry by the British Engineering Standards Association. At present valve types are multiplied almost at random, conforming to no universal standards of performance or manufacture, and the result is that, in this country alone, a bewildering number of types exists. The net result is of problematically small technical advantage to the user, and entails a sacrifice of the efficiency of manufacture, and uniformity of product, obtainable by standardization. It would seem inevitable that a British Standard Specification for valves should be considered, in the not far distant future, corresponding to the lamp specifications. Such specification would be most valuable if based on data which have accumulated during the life-testing of valves under carefully controlled conditions. It is hoped, therefore, that the present paper may stimulate interest in the preparation of such a specification, and also indicate methods by which reliable data may be obtained.

It should be made clear that, at present, only receiving types of valve are regularly life-tested in comparatively large numbers by the plant described in this paper, and any future extensions to cover the life-testing of the larger transmitting types are not discussed here.

In addition to the testing of valves with special experimental filaments, the life-test equipment has been used for tests on valves with bright tungsten filaments, with dull-emitting thoriated filaments, and with what are commonly known as coated, or "oxide" coated, filaments. The examples and remarks on methods of test given in the paper refer, however, only to the two former classes, as the considerable variations in total emission common to all "coated" filaments during life necessitate some alterations in the methods of checking the valve performance.

(2) GENERAL CONSIDERATIONS AFFECTING LIFE-TESTING OF VALVES.

The quantities which are of sufficient importance in receiving valves to warrant measurement during life are :—

(*a*) The filament current at rated voltage.
(*b*) The degree of vacuum.
(*c*) The total emission * from the filament at rated filament voltage.
(*d*) The voltage amplification factor.
(*e*) The internal impedance, as it is generally termed. By this is meant the ratio $\delta E/\delta I$, where $E =$ the anode voltage referred to the negative end of the filament, and $I =$ the anode current under specified conditions.

These are the factors which determine the performance of the valve when in use. In general, the

* "Thermionic Valves with Dull-Emitting Filaments," *Journal I.E.E.*, 1924, vol. 62, p. 689.

† This installation is established at the Research Laboratories at Wembley for testing the product of the M.O. Valve Co. Our acknowledgements are due to the Directors of the M.O. Valve Co.

* Or some other measurement which is very sensitive to changes in the total emission (see page 970).

life will be satisfactory so long as (*a*), (*b*) and (*c*) remain close to their specified values, since, in this case, (*d*) and (*e*) rarely alter. It is clear that the investigation of life performance will be sound, only if such accuracy and constancy is maintained in the test conditions throughout life that failures under heading (*a*), (*b*) or (*c*) are due solely to conditions within the valves themselves.

(*a*) *Filament current.*—Measurements of filament current at rated voltage provide a check on two important factors :—

(i) The manufacturing accuracy of the filament dimensions (length and diameter).

(ii) The rate of evaporation, during the life-test, of the filament material. This applies mainly to bright tungsten filaments, and also to a smaller extent to oxide-coated filaments.

With regard to (i), it is pointed out, later on, that it is advisable to obtain a more reliable check on the accuracy of manufacture by carrying out "rating tests" on much larger batches of valves, which are returned to stock and not subjected to life-tests.

It should be borne in mind that the life of the valve filament is very seriously affected by a small change of filament voltage (and therefore temperature) during the life-test. In the case of valves of the bright-emitter class, early failure will follow upon an increase of filament voltage, by actual burn-out of the filament, consequent upon rapid evaporation of the metal.

With dull-emitter valves the emission may cease early, due to the more rapid evaporation of thorium at the higher temperature, if the filament voltage is above its maximum rated value.

Clearly, therefore, constancy of filament heating supply is a vital factor in the life performance of valves, and it is important that the life-test conditions should be maintained constant during the whole life of the valves, so that any change of filament emission or filament resistance which may occur shall not be due to the test conditions. Only in such circumstances can the test-results be taken as reliable and comparable one with another. From life-tests on vacuum-type incandescent lamps it is known that a law for bright tungsten filaments may be approximately stated in the following form :—

$$L = A\left(\frac{1}{V^{15 \cdot 5}}\right)$$

where L = filament life in hours ;
V = voltage across the filament ; and
A = a constant.

This may be taken as applying reasonably closely to the case of the bright-emitter valve filament, so much so as to give a result of the correct order.

Thus for a given filament at two different voltages V_1 and V_2

$$\frac{L_1}{L_2} = \left[\frac{V_2}{V_1}\right]^{15 \cdot 5}$$

From this approximate relationship it is seen that a 1 per cent change of voltage, in the region of the normal voltage, will produce, in bright tungsten filaments, a change in life performance of the order of 16 per cent.

The case of the dull-emitter valve is different from that of the bright emitter in that the former is not, except by accident, liable to failure through burn-out of its filament, but rather through decrease in its dull-emitting properties alone. A similar law to that for bright tungsten filaments applies to dull-emitter (thoriated) filaments, and although the exponent of V has not yet been quite so accurately determined, its value is of the same order as for tungsten. Small changes in voltage, therefore, affect valve life profoundly.

Of the other factors which are measured during the life of a valve, that falling under (*b*)—the degree of vacuum—is next in order of importance.

(*b*) *Degree of vacuum.*—The modern valve is manufactured with a residual gas pressure not exceeding 10^{-4} mm of mercury, and any increase in this pressure is liable to affect adversely the valve life, particularly of dull-emitter types.

Assuming that the exhaust has been satisfactory in manufacture, the final degree of vacuum will be generally reached, by the aid of the magnesium "getter," in conjunction with the well-known electrical clean-up effect, within the first 100 hours of life, and the pressure will generally remain thereafter of the order of 10^{-6} mm. The only cause which may increase this pressure is the liberation of occluded gas from the electrodes or from the bulb, and such an occurrence will be due to some faulty detail in the manufacturing procedure, or to an accidentally applied overload causing overheating of the electrodes. In receiving valves the permissible range of anode voltage is much wider than that of filament voltage, since the power dissipated at the anode is so small that even proportionately large variations in its value make little difference to the temperature of the anode or of the bulb.

While discussing the degree of vacuum from the point of view of life-test, it may be advantageous to amplify the data previously published by us on the subject.* In the earlier days of dull-emitter valve manufacture, a gas pressure not exceeding 10^{-5} mm was considered to be imperative if the duration of the thorium emission was to be satisfactory. But pressures as high as 10^{-2} mm were permissible, provided that the residual gas was solely hydrogen, though the more rigorous limit of 10^{-5} mm was retained because it could not be guaranteed that only hydrogen would be present. The use of magnesium as an aid to exhaust, and further manufacturing experience, have since modified that limit. The action of the magnesium is to clean up the gases which militate against thorium emission, and to leave behind chiefly hydrogen, which alone is harmless. Thus it may now be stated that, with magnesium "getter," an approximate upper limit of 10^{-4} mm is entirely satisfactory. The usual method of arriving at the approximate gas pressure is to measure the reverse grid current due to ionization. There is then an empirical relation of the form

$$\frac{i}{I} = Kp$$

* Loc. cit.

where i and I = grid and anode current respectively, p = gas pressure in mm of mercury, and K = a constant depending upon the nature of the residual gas, the anode and grid voltages, and the geometry of the electrodes.

For the D.E.R. type valve, with an anode potential of 50 volts and a grid potential of -2 volts, and with hydrogen as the main residual gas, $K = 2$ approximately. For a pressure of 10^{-4} mm, and taking $I = 0{\cdot}5$ mA, we may solve for i, obtaining the value $0{\cdot}1\ \mu$A. This is therefore the limit of reverse grid current permitted on this type of valve, and vacuum tests are carried out, on those lines, enabling rapid determinations to be made with sufficient accuracy.

(*c*) *Total electron emission.*—A brief consideration of the relations between filament temperature and (*a*) voltage on the one hand and (*b*) emission on the other, will serve to show that the value of the emission changes very rapidly with voltage. From Richardson's equation $i = AT^{\frac{1}{2}}e^{-b/T}$ it is apparent that the emission is practically a logarithmic function of the temperature; it is also known that for a long tungsten filament at about 2 200° K. the voltage is approximately proportional to T^3. One would expect, therefore, that with changing filament temperature the emission will change much more rapidly than the voltage. Measurements on actual valve filaments show that a 1 per cent increase in voltage increases the emission by about 10 per cent for bright tungsten and by about 6 per cent for dull-emitting thoriated tungsten.

This point is important mainly in the measurement of valve characteristics during life test. The instruments employed must be of high accuracy, and the operator accustomed to taking close readings, if results obtained from successive valves are to be reliably comparable. Instruments which only just fall inside the British Standard Specification for sub-standard instruments are hardly good enough. In measuring the total emission it is usual to connect the anode and grid in parallel, and to measure the combined current at rated filament voltage and with a suitable anode-grid potential. The potential employed may be about 50 volts in the case of most receiving-valve types.

(*d*) *The voltage amplification factor.*—This is a constant for any one valve within reasonably wide limits on either side of the normal operating region, as it is dependent upon the geometry of the electrodes. The following empirical equation, due to H. J. Van der Bijl,* gives very good results and illustrates well the factors upon which this characteristic mainly depends :—

$$m = Cprn^2 + 1$$

where m = voltage amplification factor,
p = distance between plate and grid,
r = radius of grid wires,
n = number of grid wires per unit length,
C = a constant having the value 80 for the parallel-plane type of electrodes.

The accuracy of manufacture, therefore, determines the constancy of this characteristic between various valves of a type, but care has to be exercised in measuring it. By definition $m = \delta E/\delta e$, where δE = that change of anode voltage which would be equivalent in its effect on the plate current to a change δe in grid voltage.

It is usual, in order to facilitate the testing of large numbers of valves, to arrive at this ratio by taking two other ratios and dividing, thus :—

$$m = \left[\frac{\delta I}{\delta e} \div \frac{\delta I}{\delta E}\right] = \frac{\delta E}{\delta e}$$

where δI is the change in anode current occasioned by changes δe and δE in the grid and anode voltages respectively. Unless great care is exercised in making the measurements, the experimental errors may become comparable with those due to variations in manufacture.

The alternative method of plotting anode and grid voltages for a constant anode current is no doubt more accurate, but requires considerably more time. The ratio $\delta I/\delta E$ has to be measured, in any case, in order to determine the anode resistance, so that only $\delta I/\delta e$ is required, which merely involves two readings.

(*e*) *Internal impedance.*—The final characteristic to be considered is that known as the internal "impedance" or "internal resistance" of the valve. It should be noted that, in general, the term "impedance" is not strictly accurate, since it should include the inter-electrode capacity reactance, and the term "anode resistance" is perhaps preferable. In ordinary test procedure this inter-electrode capacity is neglected. Denoting this characteristic by R it may be defined as the ratio $\delta E/\delta I$. In routine work it is convenient to record δI for a constant change δE. The value of R obtained is less subject to serious error than was the case in measuring the voltage amplification factor m, but it should be noted that R is a function not only of the geometry of the valve, but also of the emission, and care must be taken to see that the filament voltage, which determines the latter, is correct. This characteristic is, therefore, one which may be adversely affected during the valve's life by incorrect life-test conditions, mainly incorrect filament voltage, leading to an impaired emission.

Rating Tests.

It will be seen that the procedure of life-test amounts simply to a series of tests of the rated characteristics of the valves during their life. As in the case of lamps, the number of valves manufactured is so great compared with the number which can possibly be tested, that it is usual to take rating tests on comparatively large batches of valves selected at random from stock, in addition to the limited number subjected to life-test. These large batches are then returned to stock. This procedure has been carried out in the case of incandescent-lamp testing in the past, and is now extended to valve testing. It is very valuable in enabling a closer check to be kept upon the general conformance of the product with its advertised rating, even though it gives no information about subsequent adherence to that rating. It may be of general interest to give a more detailed account of these tests, together with actual examples of the sort of spread of characteristics which is obtained in large-scale manufacture. The

* H. J. Van der Bijl: "The Thermionic Vacuum Tube," 1st edn., ch. 7, pp. 231 and 232.

batches of valves are obtained by haphazard selection of boxes of 50 from the despatch department of the manufacturer. The marked boxes are then sent to the laboratory, where the rating tests are carried out, without any preliminary treatment. To take one type, as an example of the routine, the measurements carried out are as follows (the rated filament voltage being 5 to 6) :—

(*a*) Filament current is measured at $E_f = 5 \cdot 4$, where E_f is the filament voltage.
(*b*) Total emission (I_e) is measured at $E_f = 5 \cdot 4$, and $E = e = 50$ volts, where E is the anode voltage and e the grid voltage.
(*c*) The quality of vacuum is determined by measuring the reverse grid current (backlash) at $E_f = 5 \cdot 4$, $E = 120$, and $e = -2$.
(*d*) Grid current (i.e. electron current) is measured at $E_f = 5 \cdot 4$, $e = +5 \cdot 4$, and $E = 120$.
(*e*) $\delta I/\delta e$ is determined by measuring I at $E_f = 5 \cdot 4$, $E = 100$, and $e = -4$ and 0.
(*f*) $\delta I/\delta E$ is determined by measuring I at $E_f = 5 \cdot 4$, $e = -2$, and $E = 100$ and 120.
(*g*) m, the voltage amplification factor, is obtained by dividing (*e*) by (*f*).
(*h*) R_a, the anode resistance, is the reciprocal of (*f*).

Target diagrams of which Fig. 1 (*a*) and 1 (*b*) are examples for two types of valves are then obtained by plotting m against R. In Figs. 1 (*a*) and 1 (*b*) are outlined also the limits for $\pm$ 20 per cent variation in m and R_a. Other types of valves are treated in a similar way, some or all of the voltages being different, depending upon the purposes for which the valve is most generally used. The main principle in every case is to make the measurements in the usual operating regions of the characteristics.

With most dull-emitter types, upper and lower limits are given for the voltage rating of the filament, which is designed to give :—

(*a*) Sufficient emission for satisfactory operation at the lower limit.
(*b*) A reasonable life at the upper limit.

This tradition in design is, of course, based upon the behaviour of the lead accumulator during discharge. The net result is that, provided the appropriate number of lead cells is employed, it is almost impossible for the user to shorten the valve life seriously by over-running the filament. This 10 per cent voltage range is of course only possible at the sacrifice of a certain amount of overall efficiency, and it is possible that the range may suffer reduction in the future, for the sake of greater filament efficiency.

When carrying out the rating tests, it is our practice to do so at the lower limit of the filament voltage range. Even then, with large amplifier valves, the total electron emission from the filament may be so great that, in measuring it, there may be dissipated as heat in the grid and anode an amount of power which is much greater than these electrodes have to withstand in normal operation. Indeed, with many types of oxide-coated-cathode valves it is useless to attempt a measurement of large amounts of total emission, because over-heating of electrodes causes liberation of gas which, when ionized, adds to the space current, and, by bombardment, causes additional heating of the cathode coating, thereby destroying any value which the emission measurement might have.

Considerations such as these have so far prevented us from rating valve filaments according to their electron emission, which quantity is, of course, strictly analogous in filament design to the candle-power rating of lamp filaments.

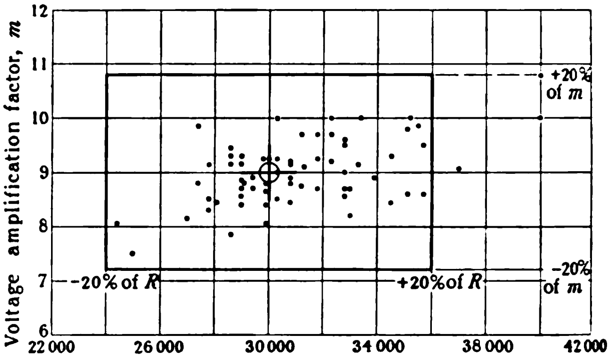

FIG. 1 (*a*).

In selecting lamps for life-test it is the practice to subject a large number to a candle-power rating test, and, from this large number, to select for life-test a comparatively small number, the candle-power ratings of which lie within the narrow central zone of the total spread shown by the large number. The average life of this small number which is life-tested, is, of course, much more truly representative of the average life of the factory product than would be the average life of a similar number of lamps selected at random, without the aid of a rating test.

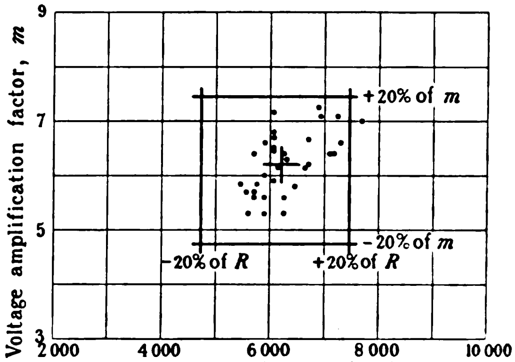

FIG. 1 (*b*).

Whenever the time comes to draw up a Standard Specification for valve life, the question of the method of selection of a batch for test will no doubt be of considerable importance, and it is unfortunate that the method of choosing for test a few valves, the filaments of which are operated at a temperature which is a mean for a larger number of filaments, is not directly applicable.

There is, of course, the oscillograph method of measur-

ing total emission, but this would probably prove to be too elaborate for incorporation in any proposed specification. Another possible method of fixing a total emission rating might be made dependent on emission measurements at a filament voltage considerably lower than the rated value; but the method would require an accurate knowledge of the voltage/emission relationship for all types of cathode, and might, therefore, be cumbersome and difficult to establish. In specifying the method of selection of valves for life-test there appears, then, to be no likely alternative to the choice of the completely haphazard method.

To return to the rating specifications themselves, altogether apart from life-test problems, there is with

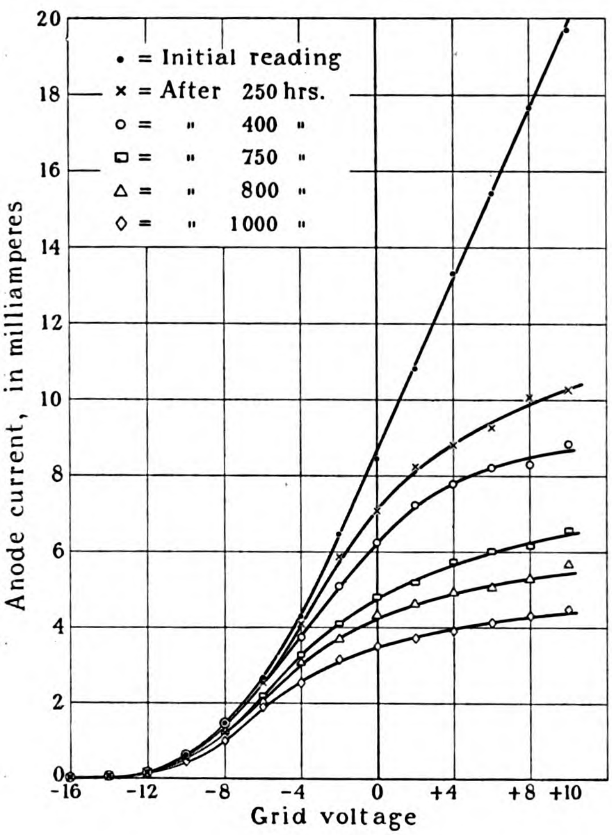

FIG. 1 (c).

them no real necessity to specify values of total emission. Total-emission measurements in receiving valves are, after all, principally made in order to ensure that there is amply sufficient to satisfy the anode characteristic, or; in other words, to ensure that this characteristic does not begin to bend over in the operating region. An alternative method of ensuring this would be to specify, for example, that

$$\left[\frac{\delta I}{\delta e}\right]_{e=+4}^{e=0} \not< \left[\frac{\delta I}{\delta e}\right]_{e=0}^{e=-4}$$

with rated filament voltage, and at the upper anode voltage rating. For purposes of illustration, an example of what happens to the anode characteristic as a result of rapidly decreasing emission is given in Fig. 1 (*c*).

SUGGESTIONS FOR A STANDARD LIFE SPECIFICATION.

The chief causes which terminate the life of a valve are :—

(*a*) filament failure,
(*b*) electrodes (or leads thereto) making contact with each other,
(*c*) loss of vacuum,
(*d*) loss of emission, with resulting deterioration in characteristics.

(*a*), (*b*) and (*c*) are all either self-determined or easily defined, so that (*d*) is the only factor for which it would be at all difficult to specify standards of life performance. In view of the difficulties in emission measurement, already discussed, a specification of emission life would probably be much more satisfactorily based upon measurements of anode characteristic. There are many possible modifications of this measurement which could be made at intervals during the life-test, such as :—

(*a*) the plotting of a short section of the complete curve,
(*b*) an internal resistance [$\delta E/\delta I$] measurement,
(*c*) some single point, which is very sensitive to emission change, such as the anode current (I_0) at the maximum rated anode voltage, with zero or slightly positive grid voltage, and rated filament voltage.

The life specification could then include a certain maximum permissible decrease (20 per cent or so) in I_0, or an increase in R_a of the same order, analogous to the permissible decrease in candle-power embodied in lamp specifications.

Some such specification of stability for I_0 or R_a would, if fulfilled, quite well ensure stability of emission, and, after all, the user of a receiving valve, whilst not directly interested in the stability of I_e, is keenly concerned with the stability of R_a.

(3) CONSIDERATIONS INVOLVED IN THE DESIGN OF A LIFE-TESTING INSTALLATION.

These points will be discussed under the following heads :—

(*a*) The types of supply for filament, grid and anode, and their permissible degree of fluctuation and methods of regulation.
(*b*) Details of the installation at Wembley.
(*c*) The accommodation required in order that representative numbers of valves of all types manufactured may be tested.
(*d*) The installation for measuring valve characteristics.
(*e*) The system of filing and plotting the results so that the maximum information may be obtained from the tests.

(*a*) TYPES OF SUPPLY.

Filament-heating supply.—The principal difficulty in designing a valve life-test installation lies in arranging a suitable supply for the filaments. It is always difficult to obtain voltages constant to 1 per cent, having regard to such changes of load as occur due to the

failure of a filament in one valve of a batch, or to switching in or out of valves. The difficulty is enhanced with the wide range of voltages which must be provided.

A simple calculation shows that it is quite impracticable to adjust the voltages of a batch by feeding from busbars through a common rheostat. Thus, the number of valves all burning at, say, 6 volts off a 12-volt supply through a common rheostat must exceed 200 if failure of two of them, which may occur when the installation is unattended, is not to alter the voltage on the remainder by 1 per cent, whilst removal of valves for test would necessitate constant adjustment of the voltage.

One obvious solution which presents itself is to use a separate rheostat for each valve, coupled with a supply transformer (if such be installed) of large capacity. For a small installation of 100 or so valves this method might be adopted. It suffers, however, from serious drawbacks:—

(*a*) Provision must be made for testing the voltage on each valve separately. Apart from the necessary switching gear, sockets, or tapping switches, this involves unnecessary labour when a number of valves are being tested on the same voltage, as is often the case.

(*b*) Trouble is likely to arise due to varying contact resistances on the rheostats, and to voltage-drop due to current taken by the low-reading a.c. voltmeter.

(*c*) Rheostats of sufficient range and current capacity take a good deal of space.

Nevertheless, for a small installation, particularly if allowance must be made for many different voltages, this solution is probably the best. It can be used with either a d.c. or a.c. supply, the latter having the great advantage that step-down transformers can be used with tappings to give low voltages, so that the whole installation can be fed from the customary high voltages. Whatever supply is used, however, it is clear that special steps must be taken to maintain it constant to within 1 per cent, a constancy which is, of course, not attained with any ordinary commercial supply.

The alternative method, which has been adopted with satisfactory results in the installation to be described, is the supply of small batches of valves from 415-volt busbars, kept constant within $\pm \frac{1}{2}$ per cent by an automatic voltage regulator, through induction regulators and step-down transformers. Such an installation is capable of expansion to cover many hundreds of valves, and requires no attention beyond the daily routine check of voltage on each batch of valves. With a suitably designed transformer and induction regulator the effect of failure of some of the valves is negligible.

The induction regulators, being on the supply side, may be of standard type. The number of valves to be fed by one transformer, and the number of transformers controlled by one regulator, depend on the size of batches and degree of flexibility required. Details of a particular installation are given below.

In deciding on such an installation, it was, of course, necessary to be satisfied that the results obtained by testing with alternating current would give the desired information, having in mind the fact that valves are normally burnt on direct current. That this is very probably so has been shown by a large number of tests carried out on batches of similar valves by both methods. We also have evidence from the life-testing of lamps, where it has been shown that no essential difference exists. Care should be taken, however, in the case of valves normally requiring a very large emission current compared with their filament current, such as some types of transmitting valve. In such a case, however, the whole method of test would be different and the installation described is not intended to deal with them. In any case, it is to be remembered that what is chiefly required is a comparison between different types of valve, or between different batches of the same type, rather than an absolute figure to a high degree of accuracy.

Although, as has been stated above, our object in conducting life-tests has so far been directed towards obtaining reliable figures for comparison, rather than data directly applicable to the conditions under which the valves are used by the public, it must be admitted that such data may one day be required. We do not anticipate that any great difference will be found between valve life on a.c. filament-heating, as against life on d.c. heating, but we cannot make a definite statement until further special and extensive d.c. tests have been run. General information, such as is forthcoming from large users of valves burnt on direct current, points to the correctness of our opinion, and it should be added that the practice of burning all valves on life-test at the upper limit of their filament voltage-rating will be undoubtedly more severe on them than are the d.c. operating voltages generally used.

The greatest differences between d.c. and a.c. testing will, of course, be obtained in valves in which the mean anode current bears the greatest ratio to the filament current. A very approximate estimate for a valve the thoriated filament of which requires a current of 120 mA at 6 volts, and which in normal use gives a mean anode current of 5 mA, indicates that under d.c. conditions, as a result of progressive loss of emission at the hotter negative end, the useful length of filament will be about 90 per cent of its initial value after completing 70 per cent of the life which is obtained when similar valves are tested at the same filament voltage, but with alternating current. In order to ensure, with this particular type of valve, that during d.c. operation no part of the filament shall be hotter than the hottest central portion would be under the 6 volts (a.c.) conditions, then the d.c. voltage would require to be as low as about 5·8 volts.

These figures deliberately overestimate the magnitude of the effect, for they neglect the appreciable amount of anode current emitted by the end of the filament which is within reach of the cooling action of the supporting wire, and they are also based upon conservative figures for the relation between life and temperature.

Anode and grid supplies.—These are still to be considered. In the case of the former, the use of direct current is desirable if the normal operation of the valve is to be imitated, and, since, unlike the filament voltage, there is no very close limit within which the anode voltage must remain, it is both con-

venient and satisfactory to obtain the anode voltage from a potential-divider. It is also satisfactory in practice to employ only one potential-divider, provided with four sliders, for four sections of valves.

The provision of the anode current from a separate d.c. generator, suitably driven and equipped, is preferable to the use of storage batteries, on account of the size of accumulator which would be entailed.

Finally, there remains the question of supply to the grids of valves under test. It is clearly important, if practical conditions are to be imitated, that valves of the low-frequency amplifier type should be life-tested with a definite grid bias. This involves the use of direct current, but the problem differs in several particulars from that of the anode supply. In the first place, the question is purely one of applying a potential to the grids, the current being inappreciable. The highest value of potential required is comparatively low and, in the case of smaller valves, not more than 1 or 2 volts. A supply is needed, therefore, which will remain constant in potential over long periods of time, and which is not required to provide power. It would clearly be uneconomical to employ rotating machinery for the production of such a supply. The use of dry cells is unsatisfactory on account of deterioration, whilst the lead-plate accumulator battery is not suitable where long periods of inaction are necessary, as in this case. A satisfactory supply is to be found in the use of nickel-iron storage cells, which offer the following advantages :—

(a) High permissible charging rate.
(b) Low voltage per cell (1·25 volts normal), thus allowing suitable voltages to be obtained without the use of potential-dividers.
(c) Low self-discharge.

These cells can be allowed to stand for much longer periods when in a charged condition, without recharge, than can the lead accumulator, and, moreover, a slow trickling discharge does not appear to cause deterioration to the same extent as in the more usual type of battery.

Thus, provision for the grid supply is satisfactorily made by a battery of these small nickel-iron cells, and this may feed the entire installation, each section of valves having a selector switch by which any one of a series of predetermined voltages may be tapped from the battery.

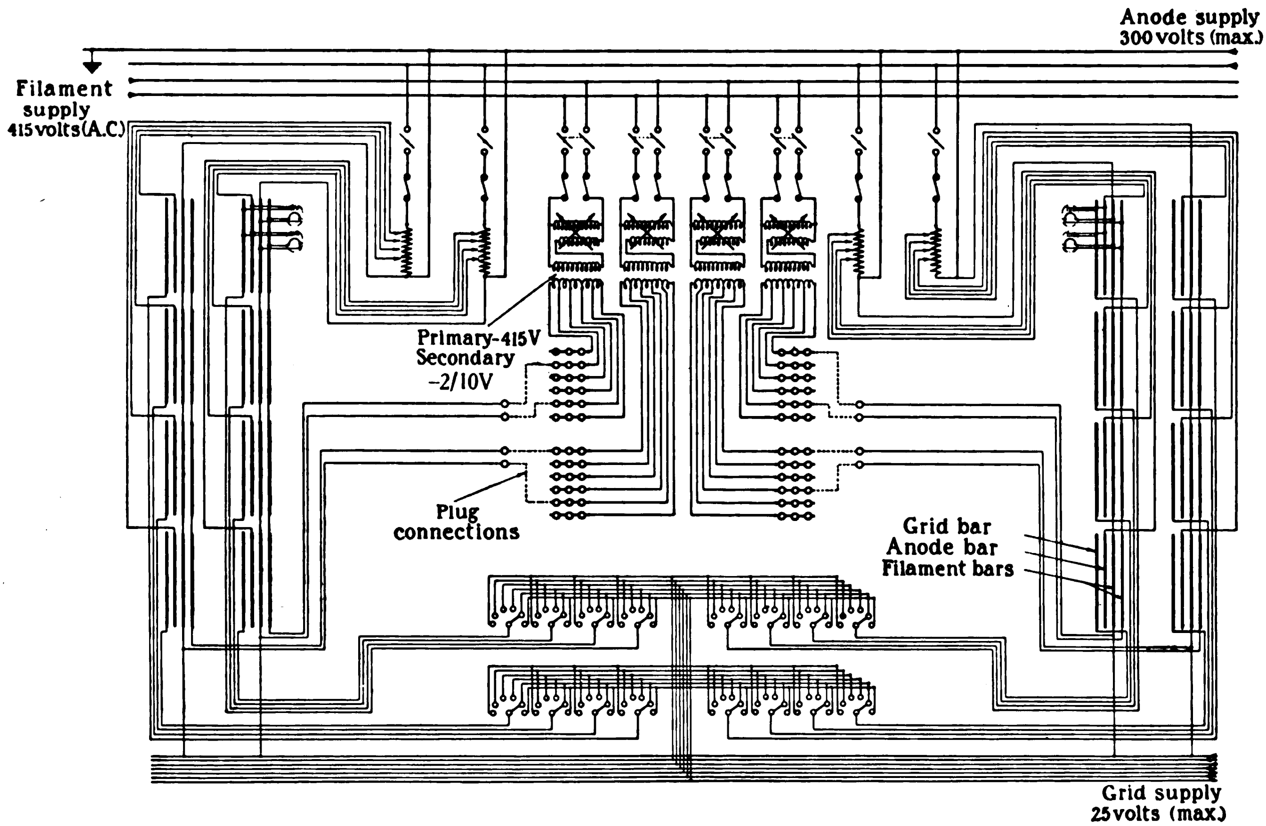

Fig. 2.

(b) Details of the Installation at Wembley.

For filament and anode-current supply a special motor-generator set is installed. This set, which was designed for lamp life-test work, consists of a 90-h.p. 415-volt three-phase motor directly coupled to a 50-kW 415-volt single-phase alternator, and, on the same shaft, two 2·5 kW 150-volt d.c. generators, the latter electrically connected to provide a 150–0–150-volt three-wire supply.

Fig. 2 shows a complete diagram of connections, and Fig. 3 the actual arrangement.

The 415-volt alternator is regulated by means of an automatic voltage regulator, which maintains the voltage constant to within $\pm \frac{1}{2}$ per cent. The valve anodes are fed from the 150–0–150 d.c. system. The framework holding the racks and local control-gear is of angle iron, mounted parallel to, and about 3 ft. from, the wall, the racks themselves being fixed to, and projecting from, this framework, thus forming alcoves, each of which is about 3 ft. wide. The control panels for each alcove are supported on the angle iron between the racks, and the transformers and other heavy gear are installed behind the panels.

Since all the racks are similar, it is only necessary to describe one alcove (a typical view of which is shown in Fig. 3). The whole of an alcove, with its attendant gear, only occupies a floor-space of approximately 4 ft. × 3 ft. Each consists of half of two projecting racks, the control panels being between them, and the heavy gear mounted behind.

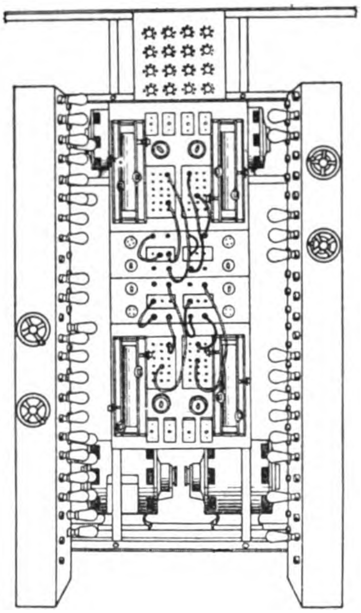

FIG. 3.

Each alcove has a capacity of 96 valves, arranged in four vertical sections of 24, two sections being mounted on each side of the alcove. Separate filament control is arranged for each section, which, in addition, is divided into four sets of six valves with separate anode and grid control. In other words, each alcove of 96 valves has accommodation for 16 sets of six valves with variable grid and anode voltages, these sets being arranged in groups of four, each bank of 24 valves so formed having separate filament-voltage adjustment. A reference to the diagram of connections will make this arrangement clear.

The control panels are of slate, and have mounted upon them the circuit switches and fuses for the filament and anode feeds, the anode potential-dividers, the filament supply socket bars, and the filament rack sockets. The actual valve-holder racks are of wood, with bakelite fronts, on the face of which are mounted the valve-holders, the supply busbars being carried at the back. To ensure good contact between the valve pins and the sockets, the latter are made self-aligning, so that any slight difference in the centres of the pins is taken up by the sockets.

For the filaments, the 415-volt supply is brought to the primaries of $\frac{1}{2}$-kVA transformers, having tappings on the secondaries at 2, 3, 4, 7 and 10 volts. In the primary circuit of each transformer is connected an induction regulator, capable of boosting and bucking $33\frac{1}{3}$ per cent of the normal voltage, and the transformer secondary tappings are so arranged that this variation on the transformer primary will give a continuous range of voltage from 1·33 up to 13·5 volts on the secondary.

Each secondary tapping is taken to a socket bar mounted on the control panels, and further sockets are connected to the filament bars of the racks. There are thus no moving contacts in circuit with the filaments—a very important feature. When setting up valves, a plug connection is made by flexible leads between suitable socket bars and the filament sockets. The plug-and-socket joints are well-made tapers, and excellent electrical contact is ensured, provided that care is taken initially in fitting the tapers.

Too much stress cannot be laid upon this question of contact voltage-drop. In the system described here, any contact may be called upon to carry a normal full load of 50 amperes, and for this reason it is the best practice, in view of the low voltage, and the close regulation required, to solder cables to the transformer secondaries rather than to make bolted connections thereto. Extra-heavy cables should be employed, and, in the design of the transformers, the copper should be increased so that the iron losses predominate, in order that the voltage regulation may be improved.

The question of flexibility is very important. We have found that subdivision of the filament supplies, so that each batch of 24 valves is independent as regards filament voltage, is barely sufficient. The designer should aim at subdivision into independent batches of 12 valves, and should also arrange that a portion, at least, of each 12 is so equipped that a series rheostat could, in special cases, be readily introduced into each filament circuit. Such a system would allow the testing of small batches of valves at unusual voltages, without disorganizing the routine work or causing numerous other sockets on the same voltage to stand idle, and the auxiliary system of single rheostats would not give rise to regulation trouble in the event of valves burning out.

Returning to the description of the plant, the anode supply is solidly connected through a potential-divider of 1 400 ohms resistance to the anode bars.

For grid supply there is mounted above each alcove a panel containing 16 small 6-point selector switches, one switch for each set of 6 valves. The switch points are connected to tappings on the grid battery, the range covering 25 volts, and the switch arms are taken direct to the grid bars.

(c) AMOUNT AND NATURE OF ACCOMMODATION REQUIRED.

The amount of accommodation, in the case of the plant under discussion, has been based upon figures

which have become recognized as standard in the life-testing of incandescent lamps. A compromise has to be effected between the testing of large numbers and the cost of such testing—both the initial cost of plant and the running costs. As with types of lamps in which the production is very large, running in some cases to hundreds of thousands per week, so with valves does the number tested have to be a very small percentage of the total production. In our case, the number of valves tested per week is of the order of 1 per 1 000 produced. Now it must be remembered that if, for example, 1 valve per week is taken, accommodation has to be provided for 6 such valves, since, on the basis of 1 000 hours' life-test, approximately 6 weeks are required to complete the test on each valve. Testing provision has therefore to be made for 6 times the number of valves collected from production per week.

installation under review, provision is made for experimental and modified valves equal to that for stock production valves, for the research work necessary in producing a successful new type of valve will involve the testing of many trial valves over periods of months.

These are the chief considerations which influence the accommodation required in a plant adequate for its purposes. In the installation discussed in this paper, a satisfactory compromise has been made by providing for approximately 600 valves to be burning at one time.

(*d*) The Installation for Measuring Valve Characteristics.

To deal with the characteristic testing of 600 life-test valves, at least two permanently equipped test-tables are needed. Direct current, with series-resistance

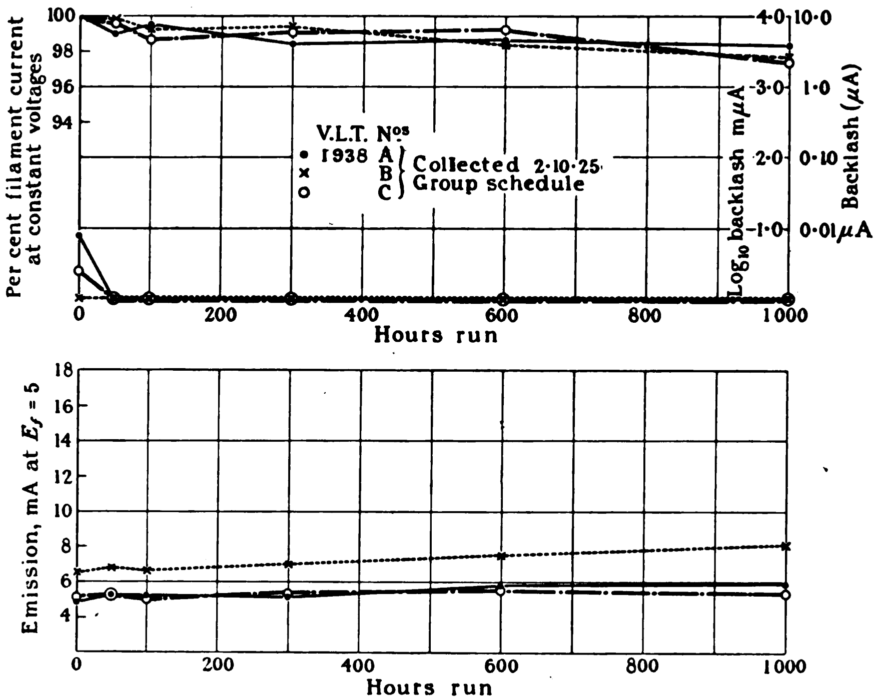

Fig. 4.

In the case of valves which are made only in comparatively small numbers, such as special types for short-wave work, or the larger types of power valves, the number tested will naturally have to be greater than 1 per 1 000 per week, as, in general, it is the best practice to collect valves for test at the shortest possible intervals, and certainly not less frequently than once per week. Where more than 1 valve per type per week is collected, the times of collection should be spaced evenly throughout the week. The significance of this factor is shown in the case of types produced in small numbers, for in such cases 1 valve per week should still be collected, and hence the collection figure may rise to 1 in 100 for certain types, or even higher, and every valve collected per week means that accommodation for 6 valves has to be provided. In the

control for the filament supply, and potential-divider control for anode and grid supplies, is satisfactory. High-grade multi-range instruments are required for measuring, and the calibration of filament voltmeters is necessary at frequent intervals. Reflecting galvanometers with variable shunts, and preferably sensitive to 1/1000th of a microampere, are necessary for rapid estimations of vacuum. The design of such tables should allow for the quick provision of abnormally large filament, anode, or grid voltages for special tests, or for insertion of extra resistance in any circuit. Provision should be made in the wiring to allow for testing of abnormal valve types (such, for example, as the 4-electrode type), by bringing leads out, in parallel with the usual valve-socket leads, to terminals situated, preferably, above the table-level. The latter device

enables uncapped valves to be tested with the same rapidity as capped valves. All meters should be well illuminated and mounted close together, preferably inclined at an angle to the vertical in order to facilitate quick reading without parallax errors.

(*e*) THE SYSTEM OF CURVE-PLOTTING AND FILING OF RESULTS.

As this Section may perhaps be of less general interest than other matter in the paper, it is relegated to an Appendix, where full details are given.

(4) EXAMPLES OF THE OPERATION OF A LIFE-TESTING ORGANIZATION.

So far as the general results of life-tests are concerned, the behaviour of bright tungsten filament valves is closely comparable with that of tungsten so until the valves were taken off test after 1 000 hours' running. The lower curves indicate a general rise of emission, at constant filament voltage, during life, indicating that the filament temperature increases gradually at points where evaporation of the metal has occurred, raising the total value of emission from the filament.

Fig. 5 shows typical results from good dull-emitter valves of uniform construction, run at the top limit of their designed voltage. The plotting of filament current is of little value with dull-emitting types, since the low temperature at which they run produces no observable thinning of the filament. It will be again noted that the vacuum became practically "dead hard" early in life, due to the electrical clean-up effect. The test-results shown were taken with a filament voltage of 5·4, but the life-test was run at 6·0 volts,

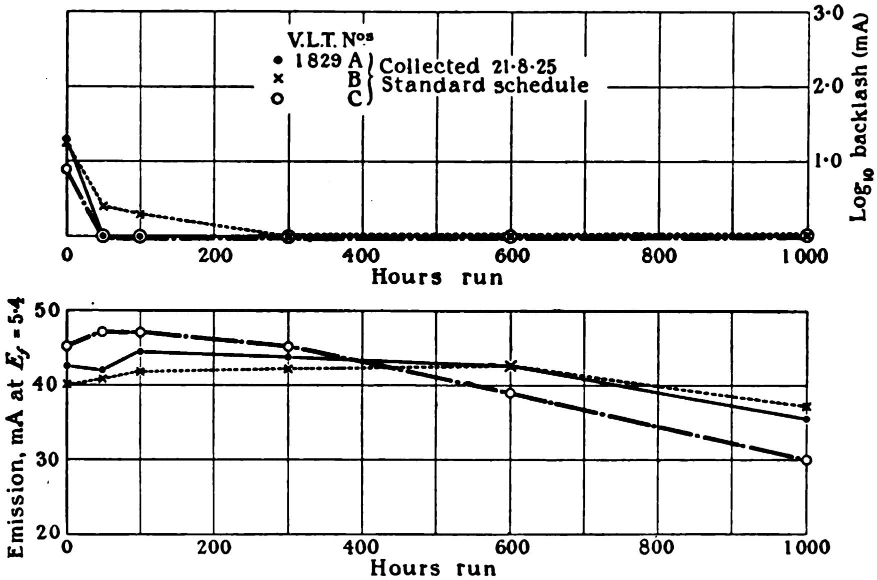

FIG. 5.

vacuum lamps, on which data have been published. Furthermore, the behaviour of the thoriated dull-emitter during life has already been discussed by Thompson and Bartlett.* In these circumstances a brief reference to the main life characteristics of both types will suffice.

Fig. 4 shows a typical set of curves upon a good batch of three bright tungsten-filament valves. Considering the top curves, it will be noted that the filament current at constant voltage decreases during 1 000 hours' life by about 3 per cent of its original value. This is due to evaporation of tungsten, at the high operating temperature, resulting in decreasing filament diameter and increasing resistance. Eventually the combined action of filament tension and local overheating due to this cause results in failure through fracture. (The bright emitter generally fails in that manner.) The middle curves show that the vacuum, though sufficiently good initially, was much better after 50 hours of life had expired, and that it remained

* Loc. cit.

which is the maximum rated voltage for the valve shown, and needlessly high for ordinary use. It is a good general principle in valve-life testing to run the actual test at the maximum rated filament voltage, and to take the characteristic measurements at, or about, the lower rated filament voltage. Valves which are satisfactory under such test conditions would be satisfactory to the user. It will be seen that there is a slight decline of emission during life, but all the valves still had, after 1 000 hours, 50 per cent more emission than would be required for satisfactory operation.

APPENDIX.

THE SYSTEM OF CURVE PLOTTING AND FILING OF RESULTS.

It is impossible to lay down hard-and-fast rules, but certain general principles may be indicated.

First, a system should be initiated whereby every valve of the 600 which may be burning should be capable of

rapid identification, and full particulars of its design data, etc., easily available. This involves a series of stock sheets such as that of which the top is illustrated in Fig. 6, giving the position and number of any valve, and preferably a series of small cards such as are illustrated by Fig. 8, the cards being held in a clip provided at each valve socket. By this combination of cards and sheets, it is assured that the valve concerned shall fulfilling the functions just described, ensures also, if the small rack card is continuously left in its clip until the valve either completes its allotted life period or fails, that the socket belonging to that valve must be regarded as occupied, even if the valve is removed for purposes of measurement. Confusion is thus avoided when several operators are at work, and one may be wishing to place valves on life-test while another has

have its characteristic measurements taken at the correct periods during its life. To each batch of valves, of every type, a serial number is allotted, and, in that batch, the valves are able to be identified by carrying a distinctive letter. Thus, a batch of valves might, for example, have the serial number 2078, and a given valve of that batch might be 2078A. This classification numbering is etched on every valve, and is also marked on the small card (Fig. 8) clipped beside the valve during the whole of its life. This system, whilst entirely valves removed for the measurement of characteristics. This point is of greater practical importance than might appear at first sight.

Measurements are made upon the valves in general at 0, 50, 100, 300, 600 and 1 000 hours during life, though at more frequent intervals in certain cases. The results are recorded in such a way as—

(*a*) To illustrate, in a graphical manner, the behaviour of the valves and thus to enable the manufacturer to modify his methods of production where

necessary, with the minimum of delay. To accomplish this, cards are prepared for each batch of valves (see Fig. 7), so designed that complete information is given of all the ordinary characteristics. In addition, two blank columns on the right-hand side of these cards enable measurements on additional properties, such as

soon as a batch of valves is put on life test. An exactly similar procedure is adopted with the slip illustrated in Fig. 10, which is made out when any single valve of a batch fails on life-test.

To make the system in use at Wembley clear, the case of a batch of two valves of stock production will be considered, in which one valve is entirely satisfactory, and one fails after some hundreds of hours' running.

These valves, in common with all stock valves tested, are selected at random by a representative of the testing laboratory, and are chosen during the last stage of manufacture. On arrival at the Laboratories they are checked against the collection schedule for that type of valve, are then each given a distinctive number, which is etched on the bulb, and their full details entered in the valve file (Fig. 6). Their life-test card is then filled in (Fig. 7) with the test-condition figures and date, and the initial characteristic readings are taken upon them, after which they are placed on the life-test racks, their rack cards (Fig. 8) being clipped beside them. At the same time the works are advised by a slip (Fig. 9) that the test has begun. On the proper dates, as shown in the valve file, they are taken from the racks and their characteristics are again measured and entered on the life-test card. Let us suppose that valve 2078A fails. The works are advised on the slip shown in Fig. 10. During life the main results accumulating on the life-test are plotted on a transparent graph sheet (Fig. 11), and, at the conclusion of the life-test, blue prints of the graphs so recorded are despatched to the works. The life-test cards are filed at the Laboratories to contribute data subsequently to statistical records.

Communicated Remarks.

Mr. R. C. Clinker: The data given by the authors will prove serviceable when the time arrives for valves to be standardized. The advantage accruing to the manufacturer as a result of life-tests is indisputable, and the maintenance of a constant check on life is a necessity. As regards the design of life-testing equipment, I note that the authors have definitely adopted alternating current for filament heating, as they are mainly interested in comparative figures rather than in the life when run under normal working conditions on a d.c. filament supply. I am inclined to think, however, that they have rather overstated the difficulty of keeping a constant voltage on the filaments. For 6-volt valves it seems unnecessary to drop more than 2 volts in the common rheostat (instead of 6), and a filament failure then affects the voltage on the remainder to a much smaller extent. It is certainly desirable to avoid a multiplicity of rheostats with their possible varying contacts. The testing intervals given on page 977 seem to be somewhat long. Are these the only intervals recorded for ordinary cases? Regarding the emission measurement, although it is true that observations of R_a or I_a are wanted in practice, yet these suffer from the disadvantage that a valve or batch of valves which may change their emissions rapidly in the early stages will not show this change unless, or until, it affects the anode current at $E_g = 0$. This test, therefore, would give a poor indication as to how a valve is behaving early in its career, although giving a definite indication of the end of useful life. A brief description of one of the life-testing equipments installed in the B.T.H. Co.'s laboratory at Rugby may be of interest. All valves are run on a d.c. filament supply, as it is desired to reproduce as nearly as possible the conditions obtaining in practice. Current is obtained from accumulators which are duplicated so that one battery can be charged when the other is running. The filaments of the valves are connected in parallel in batches of 12, and in series with a common filament rheostat, the voltage of the battery being not more than 2 volts greater than the rated filament voltage. A large-capacity battery is used, and the discharge current is kept much below the normal, so that the voltage variation over considerable time-intervals is small. These small variations can be corrected and check measurements made at convenient and specified intervals. Using this method, it is possible to keep the filament voltages constant to within 1 per cent or less, except in the special case in which a filament fails by open-circuit. This is of rare occurrence in dull-emitters and, in any case, is caught within a few hours. Each batch of 12 valves is provided with separate anode resistances and can be connected by means of a plug board to a convenient tap on the anode battery, which is a potential battery of relatively large capacity. The grid bias for each batch of valves is obtained from large-capacity primary batteries connected to a suitable plug board, so that any desired voltage can be obtained. The racks for the 12 valves are laid out in such a manner that a filament rheostat can be inserted, if desired, in order to meet special conditions. The layout of one unit of this equipment, suitable for testing batches of valves with a filament rating of 6 volts, for example, consists of a central slate control panel with the necessary rheostats, instruments, switches, etc. Four racks, designed to carry 12 valves each, are mounted on each side of this control panel. The wiring to the valve racks and instruments is easily accessible for purposes of calibration and checking voltages actually on the valve pins. The latter, however, is usually only necessary on special tests where separate filament rheostats are used with each valve.

Mr. T. E. Goldup: The life-testing of thermionic valves is a subject of extreme importance to the valve manufacturer in so far as it is an indication of the quality of bulk production, and in order to obtain reliable and consistent data with regard to the life of valves, an organized scheme of life-testing, where the conditions under which life-testing is conducted are those of constant filament potential and reasonably constant anode potential, is absolutely essential. In the dull-emitting type of receiving valves, failure during life is almost invariably due to the falling-off in the total emission, therefore the observation of this particular

quantity during life-test is of outstanding interest and, provided it remains above a certain predetermined level, one can assume that the characteristics of the valve will remain reasonably constant. In Section (2) of the paper, and also in the latter part of Section (1), the authors refer to the varying emission in oxide-coated filaments during life-test, and the unreliability of total-emission readings. While this is no doubt true in the case of the old types of filaments which were heavily coated with lime or barium, where the coating of the filament is at a considerably lower temperature than the core, it is certainly not true of that type of coated filament made by methods evolved during recent years. The target diagram of Fig. A shows the results during life-tests of such filaments, and it will be clearly seen that the variations between one valve and another, of the filament voltage and current for a given total emission, is remarkably small. It will also be observed that the magnitude of the variation actually decreases as the life-test progresses. The difficulties mentioned by the authors in connection with the measurement of total emission of oxide-coated cathode valves do not appear to constitute a problem that warrants the taking of static characteristics during life instead of the simple observation of total emission. If the exhaust during manufacture is thoroughly complete (which would mean the effective freeing from gas of the grid as well as the anode), the slight heating of the grid occurring during the total emission measurement should have very little effect on the reading. In a valve, for example, where the total emission is, say, 30 mA at a given filament voltage, the maximum power the grid could possibly dissipate with 50 volts on the anode and grid in parallel would be 1·5 watts during the emission test. Experience indicates that a good deal more power than this is required to heat the grid to such an extent that liberation of gas occurs, provided, of course, that the grid has previously been thoroughly freed of gas. It is worthy of note, however, that under normal conditions of filament voltage it has been found possible to run the oxide-coated cathode valves under total-emission conditions for several hours without any appreciable variation in the total emission. It can therefore be said that for at least one type of oxide-coated cathode the total-emission test can be applied during life test without unduly harming the valve, and such readings can be relied upon for the purpose of determining the performance of the valve in practice. The variations in R and m in Fig. 1 (a and b) indicate that much closer limits could be worked to than $\pm$ 20 per cent. In modern valve manufacture the bulk production is surprisingly consistent, especially so far as the m value is concerned. Fig. B shows a target diagram of a batch of oxide-coated cathode valves; it will be seen that the maximum variation in m is $\pm$ 7·5 per cent of the mean, and in R it is approximately $\pm$ 14 per cent. The question of the selection of valves for life-test is one for the individual manufacturers to decide for themselves, and they will naturally so arrange the selection that an effective life-test check is made at frequent intervals on their products, it being taken for granted, of course, that the valves chosen for life-test conform to some predetermined schedule. The question of whether life-testing should be done under a.c. or d.c. filament conditions is one which is largely determined by the type of valve to be life-tested. In the life-testing department of the Mullard Radio Valve Co. we have preferred to life-test under d.c. conditions, and it would perhaps be convenient to give here some details with regard to the installation. The supply for the filament is obtained from two specially designed low-voltage generators connected to the shaft of an a.c. motor-alternator. The latter is run from a 200-volt 50-cycle single-phase supply (there being no three-phase supply available) and ample cooling of both motor and generator is arranged for so that no over-heating occurs under normal conditions of continuous load. The wiring of the installation is shown diagrammatically in Fig. C. Across each low-voltage

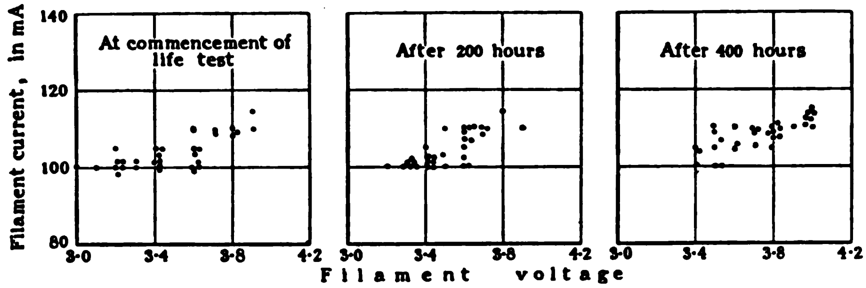

FIG. A.—Target diagrams showing filament current and voltage of P.M. valves for 20 mA total emission at various stages of life.

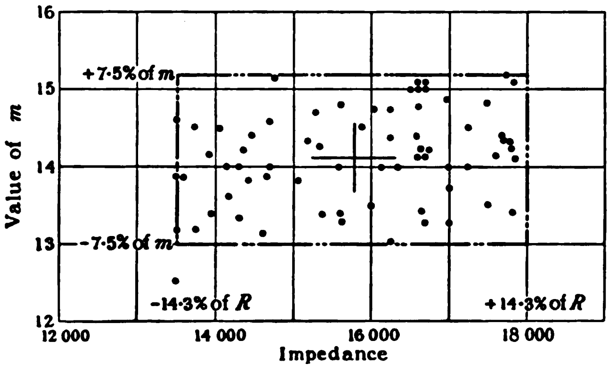

FIG. B.—Characteristic spread of P.M. 3 valves.

generator a low-resistance potentiometer is connected, thus enabling various potentials to be supplied by the one machine, and also ensuring a constant load on the generator irrespective of that due to the valves under test. The compounding of the generators is such that at full load and no load the terminal voltage remains practically constant, and, with the potentiometer constituting a permanent load on each generator, the insertion or removal of the valves makes no appreciable difference to the potential. Suitable voltmeters are permanently connected across the filament busbars. Fig. D indicates the general arrangement of a section

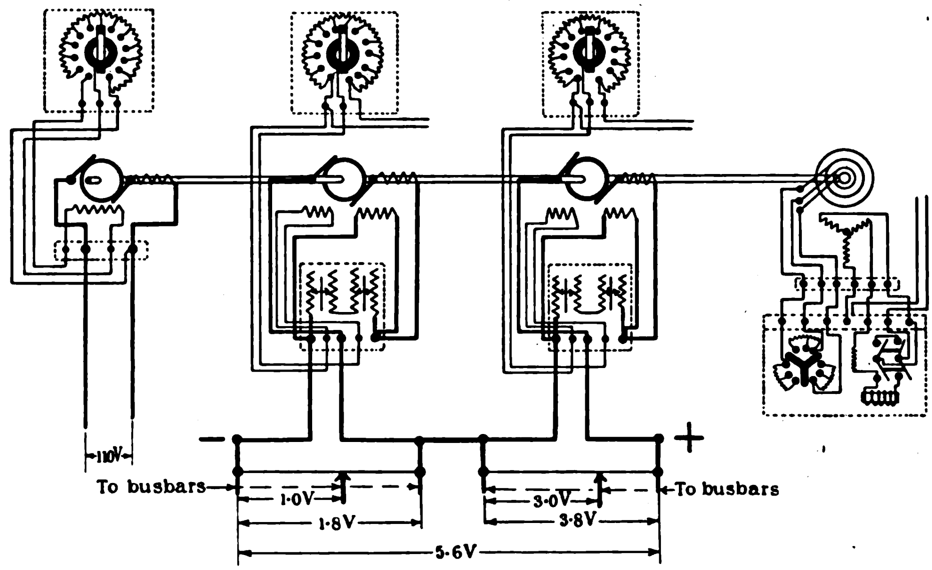

Fig. C.—Wiring diagram of life-test motor-generator.

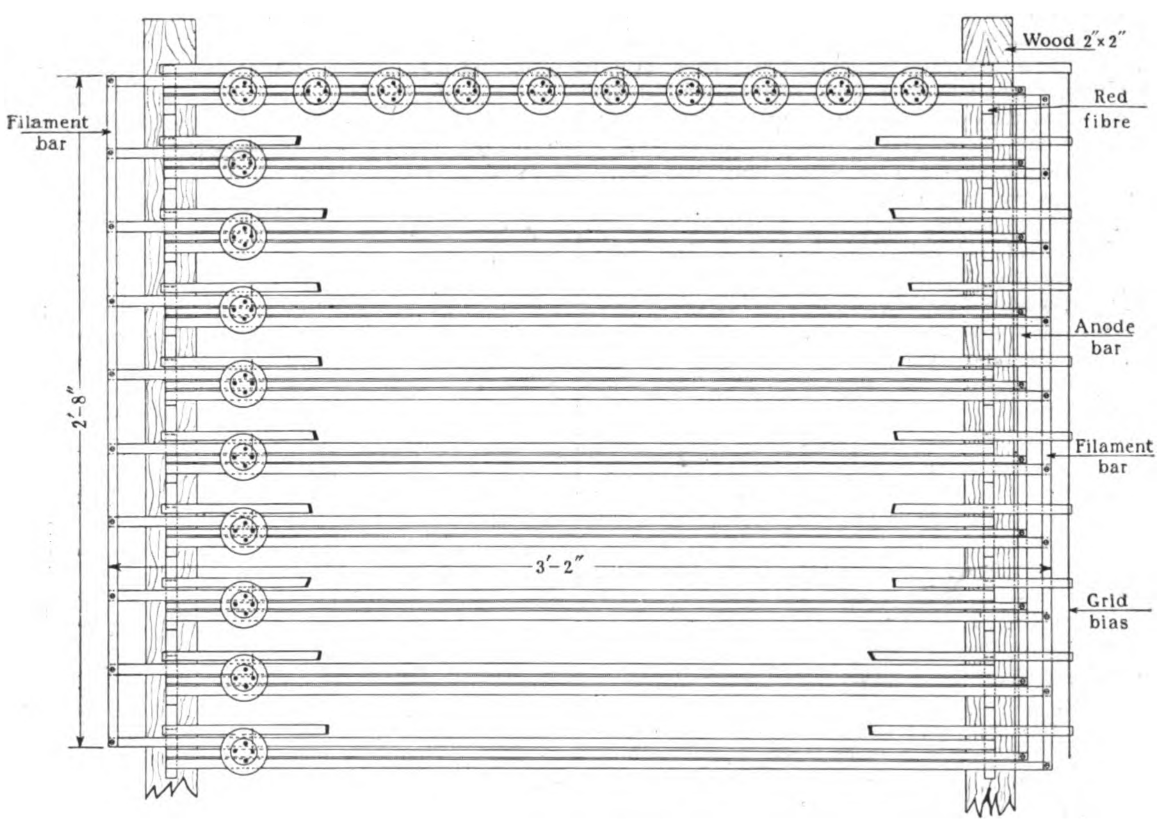

Fig. D.—Life-test screen.

of the installation which is capable of accommodating 100 valves. The anode and filament connections of the valve sockets are sweated to the horizontal busbars, and these in turn are connected to the potentiometers with copper strip $\frac{3}{8}$ in. wide and 0·1 in. thick. The anode potential for the installation is supplied by a d.c. machine which is connected to the same shaft as the low-voltage generators. A potential-divider is used for obtaining various anode voltages in different sections of the installation.

Mr. N. F. S. Hecht : For several years I have been engaged on life-testing valves, but as only one or two valves were tested at one time no problem of power supply has arisen. On the other hand the investigations with which I have been concerned have been directed mostly in the direction of forced life-tests on bright-emitter filaments in transmitting valves. In the case of low-power valves having a filament life of 50 hours or less no serious delay is caused by running the filament at its normal voltage, but in the case of larger valves having a filament life of 200 hours and above, considerable delay would occur in the acceptance of batches of valves delivered by the manufacturers if a normal burn-out had to be reached before the acceptance papers could be signed. Investigations were therefore carried out to determine the law connecting life and filament current or filament voltage and to ascertain the degree of reliability of such a law and its applicability to all sizes of bright-emitter filaments. In these investigations it was preferred to refer life to filament current instead of filament voltage as it was found that very appreciable variations occur between different makes and different types of valves owing to the voltage-drop in the connecting wires between the valve pins or lead-ends and the actual filament. This variability is avoided by taking measurements of filament current. The law connecting filament current and filament life was found to be $L = AI^{-18 \cdot 5}$, where L = life, A = constant depending on the dimensions of the filament, and I = filament current. For similar valves taken from different batches this law is subject to fluctuations in the index, the lowest value ever recorded being 17 and the highest 20·5. This variation, however, does not seem to have any connection with the dimensions of the filament and is very small for valves of the same batch. Knowledge of this law therefore made it possible to carry out life-tests at a filament current higher than normal, the current ratio being varied for different types of valves. This enabled life-tests to be completed in a day or two instead of weeks. I ought to state, however, that valves are not rejected on the result of this test; it is merely an expedient to expedite acceptance. Before this test can be accepted as standard and binding between manufacturer and user it would require confirmation and publication by some accepted authority such as the B.E.S.A. I have referred to this aspect of life-tests on account of the authors' statement at the foot of page 968. Here the law is given as $L = A\left(\frac{1}{V^{15 \cdot 5}}\right)$. It seems to me that the index is extraordinarily high; in my experience bright-emitters have never shown a higher value than 12 and it has been as low as 10, the average being about 10·7. I believe that Mr. Buckley, of the National Physical Laboratory, has obtained figures slightly higher than these but still considerably below the value given in the paper. It is interesting to hear that the law for dull-emitter filaments is similar to that for bright-emitters, and I hope the authors will be able to make a further statement on that point in due course. In conclusion I should like to state my appreciation of the authors' efforts to show the need for standardization of valves and valve testing. There is no doubt that the present multiplicity of types is no less confusing than the multiplicity of designation; I think it would be a great convenience if some definite and universal scheme were recommended by some such body as the B.E.S.A. and accepted by all manufacturers. Some of the existing methods employed to describe different types of valves are excellent but unfortunately they are employed by one or two manufacturers only.

Dr. B. Hodgson : Most people will agree that the principal factors to be measured are the filament current at a certain voltage, the vacuum and the total emission. Life-test factors depend upon the state or proficiency of the art of valve-making and it is assumed, in our opinion correctly, that failure due to lack of rigidity of valve parts or to poor quality of glass, etc., are only a small fraction of the total of finished valves, and attention is concentrated upon the most sensitive part of the valve, the filament. We have, however, two distinct uses for life-tests. The first is to discover the actual average life of a particular type of valve and ascertain how the individual valves of this particular type differ among themselves and deviate from the standard design. This test has for its object a check upon the factory acceptance tests of the valves, and yields information as to which particular branch of the manufacture needs improvement. The second use is to test the efficiency of different methods of manufacture or of different materials, apart from the variations of individual valves of a particular type. This is the test of one batch of valves against another, whilst the first use is a test of an individual valve against another of the same type. Now the filament suffers injury from three causes:—(1) Evaporation, (2) disintegration due to bombardment, and (3) physical or molecular changes. All these act together and it is difficult to distinguish or apportion the damage among these three. The filament current and voltage and total-emission tests are a check upon the filament dimensions; the disintegration is maintained below a certain amount by fixing a minimum backlash test; but no test exists for detecting changes in the constitution of the filament itself. (It might be mentioned here that most valve filaments are under *some* tension to prevent sagging and so making contact with the grid. The filament spring must be very carefully adjusted so as to put no undue tension upon the filament.) All these factors are influenced greatly by the temperature of the filament, and the loss due to evaporation, disintegration, etc., was greatly reduced by the introduction in receiving valves of the thoriated tungsten filament instead of the pure tungsten filament. Oxide-coated filaments have a further advantage over thoriated tungsten filaments in that the temperature is lower and the life consequently longer. Another

important result has been to observe that oxide-coated tungsten filaments suffer no appreciable deterioration in ductility: after a 1 000-hour run they can be bent and knotted without the slightest danger of fracture. There might be some difference in opinion as to the method of selection of valves for life-test. Valves may be selected haphazard from stock, but this might lead to erroneous conclusions because it is obviously impossible to life-test more than a very small fraction of the product. If target diagrams are used to sort out suitable valves it appears to us desirable to form the diagram with one of the variables, either filament current or filament voltage, or perhaps total emission. Both the quantities m and R_a used in the paper are dependent chiefly upon the geometry of the valve and, further, are not independent of each other. In general one can say that a high value of m and a high value of R_a will fall together and it would be expected that the points would lie along a slanting line. This is so in both the diagrams illustrated, and those valves represented by the centre of the target are those which have the expected and average geometry, and they may or may not represent the average life of the stock, according to whether the filaments in this batch are average or not.

Mr. H. G. Hughes: I should like to ask if the statement in Section 2 (*a*) concerning the application of the formula for lamp filaments to bright valve filaments has been tested and confirmed by the authors. Few of us have the opportunity of making a thorough investigation into such a problem, because naturally a very large number of valves must be consumed in the work and a very efficient equipment such as is described in the paper is essential; but the information would be most valuable to those concerned with valve design. It would be useful to know the range of voltage over which the formula holds good, and how it is affected, if at all, by the size of the bulb and the presence or absence of "getter."

Mr. L. C. Pocock: Although the authors have not dealt with valves having oxide-coated filaments, the growing popularity of this class of valve may justify the following remarks. The "considerable variation of total emission common to all coated filaments" referred to by the authors can be traced to two distinct causes: (*a*) Evolution of gas from electrodes during the first few hours of running; these changes may be very violent but can be prevented by proper exhausting. (*b*) Slow physical changes and evaporation of coating during life; these changes can be controlled by proper preparation of the filament, and they are then important only at the end of the filament life. The difficulty of making total emission measurements may be avoided in routine testing by measuring instead the increase of plate impedance for a given small decrease of filament current. When the total emissions must be accurately known the Davisson power emission chart may be used.* The authors do not mention a.c. bridge methods for valve testing. Bridge methods for measuring amplification factor, impedance and mutual conductance are well known, and experience shows them to be accurate and convenient.

* H. J. Van der Bijl: "The Thermionic Vacuum Tube," 1st edn., p. 82.

Colonel T. F. Purves: The methods described by the authors of dealing with the life-testing of valves on a large scale appear to be very similar in essentials to those at present carried out in the Post Office, except that alternating current is adopted for filament heating. In the Post Office tests the valves are run continuously under practically their working conditions; the correct anode potential is used and the grid is primed to its normal operating value. On page 970, in the routine measurements detailed in (*e*) and (*f*), it is noticed that the reading for (*e*) is taken with an anode potential of 100 volts, whereas the ratio $\delta I/\delta E$ in (*f*) is taken at 100 and 120 volts. Would it not be preferable to take this reading at 90 and 110 volts, as it is from these readings (*e*) and (*f*) that the amplification factor m is derived? It is noticed that the life-test curves given by the authors all stop at 1 000 hours. Presumably this is not the full life of the valves, and it would be interesting to know what life has been obtained from various types of filaments and valves. Can it be said what effect the continual switching on and off of the filament will have on the life of a valve? Have the authors considered the "slopemeter" test for obtaining the valve constants? In certain valves tested by the Post Office, the most marked change with length of service is not observed in their performance with normal voltage on the filament but in the more marked decrease in the amplification due to a given fall in voltage across the filament, as compared with that observed at the commencement of their life. This characteristic is of importance in practice, where periodical variations in battery voltages occur. Are tests of this characteristic made in the course of life-tests?

Dr. E. H. Rayner: The information given in the paper is of great value to anyone who has to do with the life-testing of valves. The descriptions both of the general arrangements and power equipment and also of typical results will be most helpful. I think it may be found that the relation between life and voltage as determined from experience with tungsten vacuum lamps may need some modification when applied to a valve filament a couple of centimetres long or even shorter. The effect of end-cooling may produce some modification, causing a temperature distribution different from that of the comparatively long filament of the vacuum lamp. Further information on this point, which is one of some importance as regards the steadiness of filament voltage which is necessary, would be helpful.

Mr. J. H. Reyner: One of the most interesting points raised is that of the standardization of valves. The multiplicity of valves existing in this country, all subject to different nomenclature, is one of the most bewildering and least desirable aspects of the radio industry. The general requirements are by now reasonably standardized, so that such a step would be quite possible. We require first a high-impedance valve suitable for the two purposes of high-frequency amplification and impedance coupling. A valve having an impedance of about 30 000 ohms is reasonably suitable for both purposes, although many high-frequency valves are made at present with higher impedances than this. Secondly, a low-frequency small power valve is required having an impedance of 6 000 to 7 000 ohms. Finally,

for general use, a general-purpose valve having an impedance of the order of 20 000 ohms would be desirable. These suggested three classifications are only tentative, and naturally some discussion would be necessary before any decision could be arrived at. For instance, dry-cell and accumulator types would be desirable in each class. The present state of radio technique, however, is such that quite satisfactory results can be obtained with the three types mentioned, apart from certain valves to fulfil special requirements. A point on which I am not quite in agreement with the authors is that of the method of testing the valves themselves. It appears that the valve is run, during its life-test, with the correct rated voltage on the valve. This is not a duplicate of practical conditions. What happens here is that the valve is run from an accumulator with a filament rheostat in series, and there is an increasing tendency towards the use of fixed resistances, which safeguard the valves and prevent overrunning. In such circumstances if the current taken by the valve during its life varies, the actual voltage on the valve itself will also vary. With a constant applied voltage on the valve, the current tends to decrease as the valve ages. If there is a resistance in series with the valve the voltage on the valve itself will rise accordingly. There may be a corresponding increase of current which tends to compensate for this, but I should like to have the authors' views on this matter. In view of the dependence of nearly all the characteristics on the filament voltage this appears to be a point worth considering. The suggestions raised by the authors for rating tests to be taken on valves are again interesting. In particular the suggestion made on page 971, that in order to ensure amply sufficient anode characteristics the expression

$$\left[\frac{\delta I}{\delta e}\right]_{e=+4}^{e=0} \nless \left[\frac{\delta I}{\delta e}\right]_{e=0}^{e=-4}$$

should be satisfied, is an interesting way of overcoming the difficulty, The valve quoted, however, would be discarded on this basis after 250 hours or less, which does not appear to be a very long life.

Mr. H. A. Thomas : The authors have produced a reliable method of testing valves produced in large numbers. Conformity to a given specification is always the test of the excellence of a commercial article, and in the case of a valve the precision of manufacture is such that the standard now obtained may be considered good. Yet much improvement is still necessary before the published characteristics can be considered to represent with precision the behaviour of the commercial product. The limit of 20 per cent, apparently now imposed, leaves much room still for development. It would be interesting to know to what type of valve Fig. 1 (*c*) refers, since the change of characteristic shown is extremely rapid. Have the authors carried out any tests on the nature of filament failure ? Life-tests on lamps have shown that failures take place at a weak spot on the filament ; the resistance rapidly increases and the filament diameter at the weak spot rapidly decreases until fracture. Does this failure take place at the negative end of the filament which is carrying the maximum current ? It would be interesting to know whether the life of a vertically supported filament is greater than that of a horizontally supported one.

Messrs. M. Thompson, R. H. Dudderidge and **L. G. A. Sims** (*in reply*) : Any value which our paper may have had in its original form has been considerably enhanced by the interesting contributions since made by others who are also intimately associated with valve-testing, and we are particularly glad to find that so many are in obvious agreement upon the desirability of ventilating the subject.

With regard to the use of alternating current for filament heating, we still think that in comparatively large installations this is considerably more convenient than the storage battery supply of direct current, while it will no doubt be readily conceded that it is also much more flexible than the d.c. generator system described by Mr. Goldup. It should perhaps be pointed out that when our installation was designed, quite a large proportion of the valves to be tested were of the bright tungsten filament variety, in which the normal cause of failure was a burnt-out filament. The use of the life-test circuit described by Mr. Clinker, with its series resistance common to 12 filaments, would have seriously prejudiced the results, since, for example, the failure of two filaments out of 12 would have brought about approximately a 5 per cent increase in the voltage-drop across the remaining filaments, the rate of decay of which would consequently have been doubled, until such time as the voltage-drop was re-adjusted. This advantage would, of course, be greater with a smaller number of valves in the batch.

Even with dull-emitter valves, the testing of an experimental batch in which a trial was being made of methods of applying filament tension might have been seriously complicated by the same effect.

The second point which has called forth considerable criticism is our suggestion that a measurement of I_e is not essential in any specification of life. This suggestion was made with the object of indicating the possibility of drawing up one type of specification embodying simple measurements which would be applicable to all the types of valve which are at present manufactured, or likely to be manufactured in the future. In point of fact we actually do take measurements of I_e on all the receiving valves tested on behalf of the M.O. Valve Company, and we agree with Mr. Goldup that with certain types of oxide cathodes similar measurements can be usefully made, but at the same time there are types of oxide cathode valves on the market in which such a measurement would, in our view, be perfectly useless. In such cases we have employed some other function, such as R_a or mutual conductance, as a criterion of stability of characteristics. In exceptional cases we have occasionally plotted the full anode characteristic curve at intervals during life; the curves of Fig. 1 (*c*), for example, were obtained from a valve which was tested at its rated voltages but which, we should perhaps explain, was not of a type manufactured by the M.O. Valve Co.

We were rather surprised to read Dr. Hodgson's repetition of the fallacious argument concerning the life

and temperature of different types of cathodes. In order to make clear the fallacy, it is only necessary to point out that an over-run dull emitter, although cooler than an under-run bright emitter, will give a shorter useful life. Examples in figures are as follows: Bright tungsten at 2 200° K. has a longer useful life than dull-emitting thoriated tungsten at 2 100° K., while thoriated tungsten at 1 900° K. has a longer useful life than an oxide cathode at 1 700° K. It is, of course, the stability of the emitting surface which is of decisive importance.

The criticism made by Col. Purves of the anode voltage figures which we gave by way of illustration of routine measurements is, of course, perfectly sound, and the figures in question should have been 90 and 110, as he suggests. In reply to another query, although most of our regular tests cease at 1 000 hours, we have at various times run tests for much longer periods, and a few types are regularly tested for periods varying from 5 000 to 20 000 hours. The latter figure, which represents about 2½ years' continuous running, has been well exceeded by samples of a valve-type designed primarily for telephone repeater use. We have no figures connecting the life of valves with the frequency of switching on and off. With regard to Col. Purves's last point, his requirements are in agreement with the view which we expressed in the paper, that when a valve is required to give satisfaction throughout a range of filament voltages, the life test should be conducted at the top, while the periodic measurements of characteristics, emission, etc., should be made at the bottom of the range.

Several contributors to the discussion remark upon the need for an experimental determination of the relation between life and temperature of short tungsten filaments. The relation quoted in the paper is well-established for the long filaments used in lamps, and our experience confirms that the same formula is closely applicable to the 10- to 20-volt filaments used in transmitting valves. Our life-test results obtained from the lamps used in mines (2 volts) and on motor-cars (6 volts), and also from small valves (4–6 volts) are certainly in very fair agreement with the same formula although it certainly cannot be claimed that some small adjustment to the value of the exponent to V would not be necessary for these short filaments.

There is one interesting point in the design of a life-test circuit which has arisen since the paper was originally drafted, which is that of self-oscillation occurring among a bank of valves running in parallel. This is more liable to occur when the valve is of a type having a high value of mutual conductance and was indicated in our case by the milliammeter, which is kept permanently installed in the grid bias circuit. Although all connecting leads are kept as short as possible, there is apparently sufficient inductance in the circuit to enable such oscillations to be set up. In our case the difficulty was overcome by connecting small condensers between the filament and grid terminals at the back of the valve sockets.

THE BENEVOLENT FUND.

28TH ANNUAL GENERAL MEETING, 27 MAY, 1926.

Mr. R. A. Chattock, President, took the chair at 5.30 p.m.

The notice convening the meeting was taken as read.

The minutes of the 27th Annual General Meeting held on the 7th May, 1925, were also taken as read and were confirmed and signed.

The Report of the Committee of Management (see below) and the Statement of Accounts for the year 1925 (see page 670) were presented, and, on the motion of the Chairman, seconded by Mr. P. Rosling, were unanimously adopted.

The Chairman proposed, and Mr. Roger T. Smith seconded, that Mr. J. Attfield, F.C.A., be re-appointed Hon. Auditor. The motion was carried unanimously and the meeting then terminated.

REPORT OF THE COMMITTEE OF MANAGEMENT OF THE BENEVOLENT FUND FOR THE YEAR 1925.

CAPITAL.

The Capital Account stood on the 31st December, 1925, at £10 004 11s. 3d., which is invested.

RECEIPTS.

The Income for 1925 from dividends, interest, and annual subscriptions was as follows :—

	£	s.	d.
Dividends on investments ..	493	16	5
Interest	13	1	8
518 annual subscriptions	327	0	0
	£833	18	1

In addition to the foregoing, the Fund benefited during the year by the following amounts, many of which are non-recurring donations :—

	£	s.	d.
I.E.E. Entertainment Fund	100	0	0
Electrical Engineers' Ball Committee ..	70	0	0
Birmingham and Midland Electrical Engineers' Ball Committee	26	5	0
W. T. Henley's Telegraph Works, Ltd. ..	25	0	0
Western Centre (collected)	22	2	8
" Twenty-Five " Club	21	0	0
W. B. Woodhouse	10	10	0
General Electric Co., Ltd.	10	10	0
Incorporated Municipal Electrical Association	10	10	0
F. R. Marsh	10	10	0
J. D. Dallas	10	0	0
Sir Alexander B. W. Kennedy	10	0	0
Sir George Sutton, Bart.	10	0	0
and 1 093 donations of under £10	542	15	11
	£879	3	7

The accumulated balance of the Income and Expenditure Account amounted on the 31st December, 1925, to £2 380 9s. 6d., of which £1 998 14s. was invested and £150 was on deposit with the Institution bankers.

DONATION TO CAPITAL.

The thanks of the Committee are due to Mr. C. P. Sparks, C.B.E., Past-President, for a special donation of £35 given by him in 1925 for the purpose of bringing the Capital Account of the Fund to over £10 000.

DONORS AND SUBSCRIBERS.

Lists of the names of donors and subscribers during 1925 have been published in the *Journal*.

The Committee of Management desire to acknowledge their indebtedness to the donors and subscribers, and to intimate that, apart from donations, the Committee will be grateful for annual subscriptions of any amount.

GRANTS.

Applications for assistance were made by or on behalf of 30 persons during 1925, and the Committee, after due consideration, made grants in all of the cases. The total amount of the grants was £1 199 5s. 1d.

WILDE FUND.

The Capital Account stood on the 31st December, 1925, at £2 949 6s. 7d., all of which is invested and brings in an annual income of £106 11s. 10d.

The balance standing to the credit of the Income Account, from which, under the Trust Deed, full Members only can benefit, on the same date was £111 18s. 7d.

A grant of £107 was made from this Fund during the year.

PROCEEDINGS OF THE INSTITUTION.

743RD ORDINARY MEETING, 8 APRIL, 1926.

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 18th March, 1926, were taken as read and were confirmed and signed.

Messrs. E. T. Williams and R. Wightman were appointed scrutineers of the ballot for the election and transfer of members and, at the close of the meeting, the result of the ballot was declared as follows :—

ELECTIONS.

Graduates.

Andrew, John Cardell P., B.Sc.
Baillies, Douglas C.
Lord, Bernard Stevenson.
Reeman, Herbert Frederick.
Smith, Charles Henry.
Smith, William.

Students.

Baldwin, Michael C.
Barker, Percy Landen, B.Sc.
Baynton, Ronald Alfred.
Bean, Leonard Carlin.
Blake, Ernest Cuthbert.
Bland, Leonard George.
Boul, John Edward.
Bowles, Charles.
Brunker, Alfred John.
Buck, Charles Leslie F.
Buxton, Henry Fowler.
Caine, Kenneth Ernest.
Clark, Reginald Erskine.
Couch, Percy Reginald.
Cowan, James Allan.
Deacon, Frederick James.
Duncan, Nigel Leigh.
Edgar, John Alfred.
Edwards, Eric Walter.
Elton, John Goodenough.
Fisher, Alexander.
Gillam, Gerald Hugh.
Graham, Malcolm Taylor.
Gray, Robert.
Groom, Francis Henry.
Hamilton, Thomas William.
Hancock, Eric Holland.
Handley, Eric Thomas.
Harvey, Robert Burrell.
Haskell, David Nissim.
Heath, Frederick Ernest.
Holt, Alfred Ifor W.
James, David Urmston.
Jarvis, William.
Kishk, Mohammed Mahmoud.
Klesel, Kenneth John.
Langdon, George Ellis.
Lewin, John Robert.
Lister, Edward.
Lovelock, Herbert Ralph.
McEwan, Ronald Grant.
McRostie, John Baxter.
Mallinson, William David.
Mason, Frederick Oliver.
Mawson, Spurgeon.
Mercer, Jonathan.
Merrick, Ernest Clifford.
Mildner, Raymond Charles.
Millar, Harold James.

Students—continued.

Mills, Harry Douglas.
Moffat, Henry James.
Murphy, James Thomas D.
Nash, Harold Arthur.
Neave, James William C.
Pearce, John Broyd.
Pritchard, Ronald.
Richards, Claude Langdon.
Rooney, James Louis.
Sage, Harry Edward.
Scott, Douglas Murray.
Sher, Wsewolod.
Small, Charles John P.
Sparrow, Leslie Francis.
Stebbings, Reginald William C.
Swann, Sydney Bernerd.
Thompson, Harold Norman.
Venables, Albert Henry.
Wearmouth, Albert.
Wellard, William John F.
Westaway, Edgar James.
Westlake, Cyril Maude.
Whittaker, James Edward.
Wilkinson, Charles George E.
Wolff, Frank Edward.

TRANSFERS.

Associate Member to Member.

Melsom, Sydney William.

Student to Associate Member.

Lovely, William Stanley, B.Sc.

Student to Graduate.

Ashton, Arthur Leigh, B.Sc.
Cunliffe, Cyril Henley.
Freeborn, Frederic Victor, B.Sc.(Eng.).
Howe, Reginald Percy.
Shearer, George, B.Sc.(Eng.).
Shepherd, Joseph Hubert.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see page 503) was taken as read, and the thanks of the meeting were accorded to the donors.

The following papers : "The Application of Machinery at the Coal Face," by S. Mavor, Member, "The Design of Storage Battery Locomotives for use in Coal Mines," by L. Miller, Associate Member, and "Electricity in Mines : A Short Survey," by R. Nelson, Member, were read and discussed.

On the motion of the President a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 7.55 p.m.

53RD MEETING OF THE WIRELESS SECTION, 14 APRIL, 1926.

Major B. Binyon, O.B.E., M.A., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 3rd March, 1926, were taken as read and were confirmed and signed.

A paper by Mr. E. H. Shaughnessy, O.B.E., Member, entitled "The Rugby Radio Station of the British Post Office" (see page 683), was read and discussed.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.50 p.m.

INSTITUTION NOTES.

Students' Premiums.

The Council have awarded Students' Premiums, each of the value of £10, for the session 1925–26 as follows :—

Author.	*Title of Paper.*
W. F. C. Cooper	" Some Experimental Work on Relays."
F. J. Lane, M.Sc.	" A Rotary-Converter Automatic Substation."
C. T. Melling, M.Sc.	" The Design of Current Transformers."
H. Pryce-Jones	" Electric Winding Engines in Collieries."
E. Youel, B.Eng.	" The Thermionic Vacuum Tube."

Public Works, Roads and Transport Congress and Exhibition, November, 1927.

The Congress Organizing Committee have decided to offer the following prizes for papers submitted for discussion at the Congress to be held in November 1927 :—

1st Prize—Gold Medal and £50.
2nd Prize—Silver Medal and £25.
3rd Prize—Bronze Medal and £10.

The subject of each paper must be one which falls within the services covered by the Congress, that is to say :—Highways and bridges, water supply, sewerage and sewage disposal, cleansing, gas, electricity, housing and town-planning, tramways and light railways, agriculture (small holdings, land drainage, land reclamation and agricultural education), and local government organization.

The prizes will be awarded to the authors of those papers which, irrespective of the subjects dealt with, are considered by the adjudicators to contribute most materially to the advancement of local government in the services covered by the Congress.

Application for the rules of the competition should be made to the Hon. Secretary, Public Works, Roads and Transport Congress, 84 Eccleston-square, London, S.W. 1, from whom more detailed information as regards the subjects for papers may also be obtained.

Papers must be submitted not later than the 17th January, 1927. Papers may also be submitted for discussion at the Congress without being entered for competition. Such papers should be clearly marked " Not for competition."

Regulations for the Electrical Equipment of Ships.

The Council have revised the I.E.E. Regulations for the Electrical Equipment of Ships and have authorized the publication of a Second Edition. Copies may be obtained from the Secretary, or from Messrs. E. & F. N. Spon, Ltd., 57 Haymarket, S.W. 1., at the following prices :—

Bound in blue cloth : 3s. 6d. net (or 3s. 8d. post free).
Bound in black American cloth : 2s. 6d. net (or 2s. 8d. post free).

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 July–25 August, 1926.

	£	s.	d.
Bechar, S. (Kharagpur, India)		5	0
Bentley, J. C. (Manchester)		5	0

* Annual Subscriptions.

THE APPLICATIONS OF MACHINERY AT THE COAL FACE.

By SAM MAVOR, Member.

(*Paper first received 6th January, and in final form 24th February,* 1926; *read before* THE INSTITUTION *8th April,* 1926.)

SUMMARY.

The necessity for reduction in the cost and price of coal is considered, and the use of labour-saving machinery in the primary processes of winning coal is indicated as the most effective means by which the high labour cost can be substantially reduced.

The evolution and early history of coal-cutters are outlined, the later developments of these machines are indicated, and the leading characteristics of the bar, chain and disc coal-cutters are detailed.

The nature of the service required of coal-cutters is explained, and the conditions under which the service is rendered are defined.

Conveyors for underground use are described, and an outline is given of their place in the practice of intensive mining; first, in increasing the output per man at the coal-face, and, second, as an aid to the reduction of the cost of transport of the coal from site to the mechanical haulage.

An endeavour is made to indicate the respective spheres of electricity and compressed air for actuating coal-face machinery.

INTRODUCTION.

When it was suggested that I should prepare this paper it was proposed that it should deal with "The introduction of coal-cutting machinery of either the compressed air or the electrical type to avoid hand-hewing, and the most economical method of conveying the coal from the coal face to the main haulage roads either by conveyors or by other means." In the present condition of the coal industry this subject has more than technical and industrial importance. It is a matter of grave national concern; therefore there is no need to stress the opportuneness of such a paper. It is also appropriate that a paper on this subject should be included in the *Journal* of the Institution, because the great expansion of mechanical mining of coal not only in this country where coal-cutters were originated, but also abroad, has been due in large measure to the application of electricity to coal-face machinery. It may further be said that the electric coal-cutter has stimulated improvement in and use of compressed-air machines for the same service.

The mining industry of this country contains within itself the means of its own regeneration, and if relieved of legislative interference these means would become increasingly operative. It is impossible for anyone familiar with recent practice in mechanical coal-mining and with its economic results, to be otherwise than optimistic as to the future of the industry if the colliery owners and the miners are left to settle their own affairs. In mining, as in every other industry, the problem of cost reduction is that of increasing individual output, but in mining this problem has special significance because labour accounts for 75 per cent of the total cost of production, and because the higher this proportion the more effectively it can be attacked. Many palliatives of the existing situation may be suggested, but, apart from the number of working hours, the only way to effect substantial increase of output per man and consequent reduction of costs is the systematic application of labour-saving machinery. In other words, there are too many men in the mines; the number must be reduced, for the industry cannot afford to support them. The necessarily gradual nature of the process of adapting mining methods to the use of machinery will to a great extent avoid the imposing of individual hardship by reduction in the number of men employed. At many collieries modern coal-producing machinery is, even in these days of low prices, earning profits that without it would be non-existent. The condition of unsettlement and the sense of insecurity of recent years and of the present day, have seriously retarded progress in the equipment of mines with machinery of production, and have thus accentuated the difficulties of the present situation.

In England the proportion of machine-cut coal to the total output is, according to the latest Report of the Mines Department, 14 per cent, whereas in Scotland the proportion is 47 per cent. The geological conditions in Scotland are not more favourable to machine mining; the difference is due partly to economic pressure compelling a reduction in cost of production, but largely to the permissibility of electricity at the coal face in most of the Scottish mines. In Scotland 93·25 per cent of the coal-cutters in use are electric and 6·75 per cent are compressed-air machines. It is not generally realized that a very important factor in the rapid extension of machine mining in the United States is that the comparative freedom from gas in the mines renders electricity permissible, and it is noteworthy that in the most recent years the rate of increase in the proportion of machine-mined coal has been greater in Scotland than in the United States.

To the members of this Institution any technical means of reducing the cost of coal—the raw material of power production—must have lively interest, and to many of them it is a subject of vital concern. The Coal Commission, whose chief function was to ascertain how the cost of coal production could be reduced, had the immediate anomalous result of retarding the progress of the most effective means of reducing costs—the extended use of the machinery of coal production. The period of uncertainty and unsettlement that attended the crisis last autumn was continued by the

appointment and sitting of the Royal Commission and by the period of waiting for the Report. Under these conditions, the majority of colliery owners were disinclined to incur avoidable capital expenditure; much development involving all kinds of colliery equipment was therefore suspended, and, whilst the mines have urgent need for new machinery, the workshops that might have been making it were half empty, and operative engineers were added to the numbers on the dole.

Many papers have been presented to this and to other Institutions on the various problems of the generation and distribution of power at collieries and of its application to winding, ventilating, pumping, haulage and so on; all these papers have been concerned with what may be described as services. The surface equipment of many collieries is splendid, but underground, where the money is lost or made, the coal faces are crying out for machinery. This paper will deal with the application of power to the primary operations of winning the coal and conveying it from the immediate vicinity of the face—operations to which the whole surface and underground equipment and organization of the mine are secondary. The peculiar physical conditions under which these primary operations are conducted have an important bearing on the problems of applying power to coal-producing machinery.

In order to provide a background for what is to follow it is necessary to give a general but brief outline of the principal characteristics of the coal seams of this country and of the methods by which they are mined.

The Coal Seams and Methods of Mining Them.

The coal seams vary greatly in thickness, in depth from the surface, and in inclination from the horizontal, but it may be said that the output is obtained chiefly from seams between 2 ft. and 6 ft. in thickness, at depths between 300 yards and 800 yards, and at inclinations between zero and 15°. The geological associations of the coal seams also differ widely, and the seams may be clean, may contain bands of such material as fireclay or shale, or may be overlaid by friable material that falls with the coal.

Broadly it may be said that the methods of mining coal may be grouped under two systems: (1) The "pillar and stall" system, and (2) the "longwall" system: each of these has many variants, in some of which demarcation disappears.

In the "pillar and stall" system, which was the earlier, the coal is extracted in stalls, pillars of coal being left to support the roof, the width of stalls and the size of the pillars being determined by the superincumbent weight and the character of the roof. The first working is the forming of the stalls, and the second working is extraction of the pillars; where disturbance of the surface must be avoided, the coal pillars may be left to support the roof. Fig. 1 illustrates the system, which in this country has to a great extent been superseded by longwall mining.

The term "longwall" also is descriptive, for in this system (Fig. 2) the coal is exposed on a long face or wall that may be 50 yards long or 10 or more times that length. Advancing longwall is usual, i.e. as the coal is extracted the faces advance from the shaft towards the boundary. It will be seen that in this system the main and branch haulage roads, and the gate roads which give immediate access to the face, are formed and maintained in the areas from which all the coal has been extracted. In seams of a height that permits the trams to be taken along the face to be filled, gate roads that give access to the face are formed at distances of 20 to 40 yards apart; in thinner seams the gates are usually about 15 yards apart, and

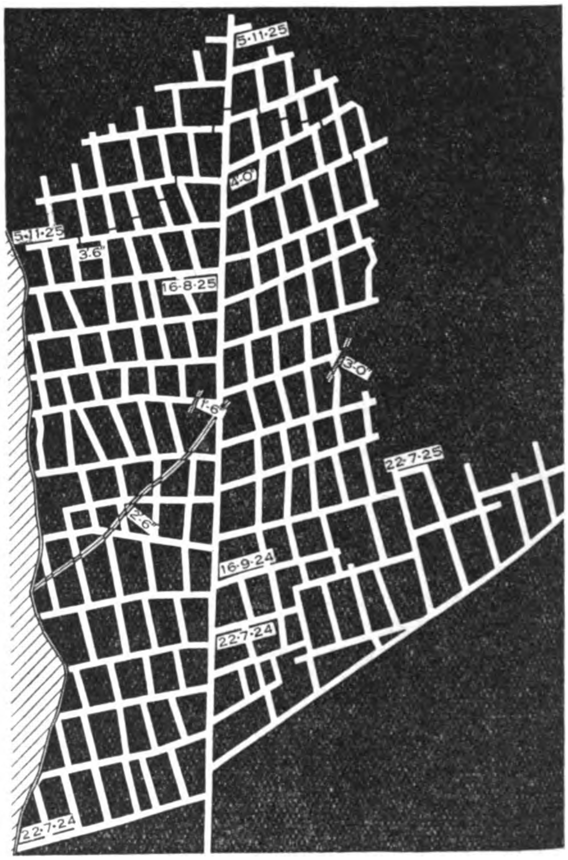

Fig. 1.—"Pillar and stall" system of mining.

the coal is cast by shovel to the gate-ends where the trams are filled.

In both systems the actual operation of mining the coal consists of cutting a slot in the coal usually at the floor-level; the coal, if strong, is then broken down by explosives or by wedges, or where it is friable it may collapse and is then shovelled to the trams.

It will be apparent that the application of machinery to the undercutting and conveying of coal from the working face in these two systems of working present quite different problems.

A coal-cutter for "pillar and stall" service is required to cut, to a depth of about 6 ft., a "place," in width between 9 ft. and 20 ft., and then to flit to the next place to cut again, and so on. A machine of the requisite power and strength is necessarily heavy, yet it must be extremely mobile and amenable to control.

Such machines are usually self-propelling and are flitted on the tram rails, but where the inclination of the seam is too great for safe flitting on wheels, the machines are mounted on sledges and fitted with gear for rope haulage. Collection of the coal by trams from a large number of " places " is a difficult problem; in thick seams the output from the individual headings may warrant the use of mechanical conveyors, but for the small output produced in the individual headings in thin seams, mechanical transport from the faces would not be economical.

For reasons quite unconnected with the use of coal-face machinery, longwall working has become general in this country, but this system happens to be favourable to the application of machinery both for undercutting and for mechanical conveying. As a very large proportion of the total output in this country is won by it, the longwall system and its mechanical equipment will now be dealt with.

The function of the coal-cutter is to undercut the face of coal. In one method of working, each machine has allotted to it such length of face as it can with certainty cut in one shift; on the next shift the cut coal is cleared, and on the third shift the roof in the gate roads is ripped to give height, the ripped material being used to build pack walls in the waste to support the roof. In the three shifts, i.e. in 24 hours, the complete cycle of operations is performed; on the next cutting shift the machine begins the same cycle of operations, cutting along the face from end to end in the opposite direction. This method is termed the " unit " system, and its working requires that the whole length of the face shall be cut on each cutting shift, and from the whole length of face the coal must be completely cleared on the filling shift. When rhythmical conduct of the operations is established, a definite daily output is obtained from each unit face. Failure of the machine to cut to the end of its face on any

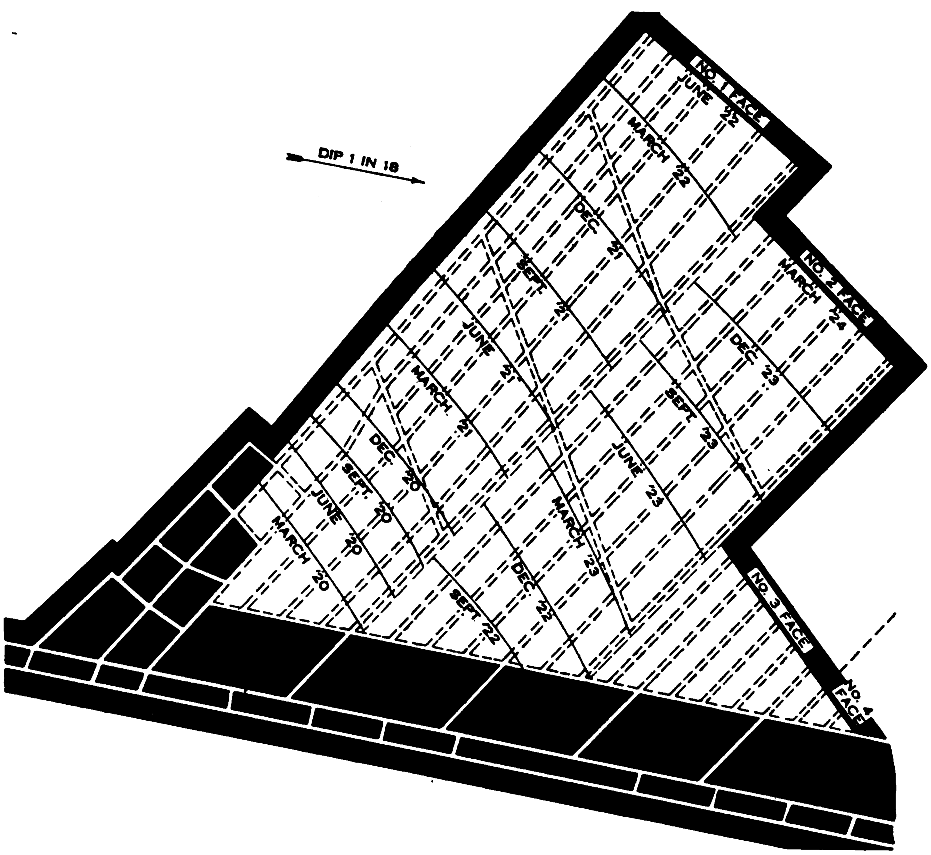

FIG. 2.—" Longwall " system of mining.

cutting shift would involve the loss of a day's output from the unit; no derangement of a machine, short of a complete breakdown, prevents its being driven to the end of the face.

The other method of applying longwall machinery is to open out an extended face a few hundred yards or many hundred yards in length; along the face two or more coal-cutters follow each other from one end of the face to the other, and each machine on reaching the end of the face is flitted on a trolley through the roadways to start again another cut along the face in the same direction. This method is general where the thickness of seam and the depth of cut produce more coal than can by the available means be cleared in

time to permit the machine to cut to and fro; cutting and filling may proceed simultaneously at different parts of the face. The machines can cut only when the coal immediately in front of them (cut by the preceding machine) has been cleared; the length of face available for each machine to cut is variable and so therefore is the work done by the machine and its crew. On one shift only a short distance may be available; on the next a long distance of cleared face may present opportunity for forcing the machine, and the crew paid by the ton. Those who may only have earned the minimum wage on the previous day are less concerned in driving the machine considerately than in increasing their earnings.

In the mining of coal seams by machines, the undercut is usually between 3 ft. and 6 ft. deep, according to the conditions, and is made in the plane of the seam. The slot or cut is not necessarily made in the coal; it may be made in the stratum immediately underlying the coal, or in the coal, or in a band of foreign material contained in the seam at any intermediate position between floor and roof, or above the seam, up to a height of between 4 ft. and 5 ft. from the floor. The purpose of the slot is to give relief, and so permit the breaking up of the seam by collapse of the coal, or by wedging or blasting it from the roof, or, in case of intermediate or overcut, by wedging or blasting it from the floor. The making of the slot by hand-picks is an irksome, laborious and, in thick seams, sometimes a dangerous task. The depth of cut made by hand rarely exceeds 3 ft., and to reach the back of even a 3-ft. cut the miner must hew clearance for his arms and shoulders and so a considerable amount of coal is broken up.

Evolution of the Mechanical Coal-Cutter.

Soon after the middle of the eighteenth century the problem of providing the pick man with mechanical aid began to engage attention. The earliest form of coal-cutter was the "iron man," so called because the aim was to simulate the operation of a manually wielded pick. The "iron man" was a contrivance which held a miner's pick, to which a reciprocating motion was imparted by a system of levers, power being applied through crank handles by two or more men. Many variants of the "iron man" were devised but, so long as the machine depended on muscle power, little progress was possible.

The first suggestion to discard the reciprocating pick in favour of continuously moving cutters was embodied in a patent of 1843 for a machine—the precursor of the disc coal-cutter—which was in effect a circular saw; but without adequate power to drive it such a machine could not succeed. It was not until after the middle of the nineteenth century, when compressed-air power became available for underground service, that development of the coal-cutter was possible. Compressed-air power was at first applied to energize the "iron man," the pick of which operated by percussion at a point, but it was soon recognized that the new power might be utilized to greater advantage than by restricting it to delivery of blows by an individual pick. The application of air power to the driving of a rotating disc with cutters fixed at its periphery was a revolutionary innovation, for it marked not only the change from reciprocating to rotary movement, and from a individual pick to a group of picks, but also marked a radical change in the principle of attack by the tool. The pick on the swinging arm of the "iron man" operated by the shattering effect of impact and penetration of its point; the picks on the rotating disc operate by sustained pressure along a line, removing the material by cutting or tearing it from the face attacked. The power available from the air motors could not be fully utilized by an individual pick on a swinging arm, but on the other hand the possibility of multiplying the number of cutters on the rotating disc, and of increasing the lineal speed of the cutters and their pressure upon the material attacked, could not be fully developed for lack of sufficient power in the crude air motors that were are at first employed.

The sixth decade of the last century was marked by important steps in the evolution of the compressed-air coal-cutter; and to the disc machine were added in 1853 the chain machine and, 10 years later, the bar machine; in both types the movement of the cutters was continuous. Yet the "iron man" made a brave struggle for survival, and persisted in a losing battle against its rivals, for, 10 years after the first application of air power to a disc machine, a patent was granted for a machine in which a compressed-air, steam, or water turbine operated a cam whereby, through a system of levers and springs, an arm carrying a pick was caused to strike the coal "with force at least equal to that which can be given out by the blow of a pick wielded by a man's arm." That the "iron man" held its ground for more than 20 years after power had been applied to the disc machine may be taken as evidence of the difficulties experienced by the early designers of coal-cutting machines.

Since the period referred to, the development of power, strength and cutting capacity in coal-cutters has been progressive, but the principles that are applied with such effect in present-day coal-cutters were embodied in embryo in the early disc, chain and bar machines which were all originated in this country.

Between the 'sixties and 'eighties of last century, those who devoted themselves to the problem of mechanical coal-cutting struggled against many adversities, not the least of which were due to inadequate power of the air motors, and to the unsatisfactory character of the power service. Many difficulties were due to failure to recognize the limitations of coal-cutters; tasks impossible to the machines of those days were attempted, and failure and disillusion were the result. Yet some enthusiasts were constant to their aim, and a few of them achieved results that rewarded their tenacity. The disc machine was the earliest to gain any measure of economic success, and its first effective rival was the chain machine.

A new era in the evolution of the coal-cutter was opened by the application in 1885 of electricity as the motive power. In 1863 a patent had been granted for a reciprocating pick machine to be operated, through a system of levers, by electromagnets; but even if such a contrivance had been practicable the means of

energizing it were not at that date available. The first coal-cutter to be driven by an electric motor was a bar machine invented by James Blackburn, a Yorkshire colliery manager. It is suggestive of the difficulties of the pioneers, and of the far from satisfactory results obtained from compressed air as a source of power for coal-cutters, that Blackburn in his original machine adopted the hazardous expedient of driving by a wire rope running along the face at high speed. This wire rope was driven by shaft and pulleys from a main haulage rope. The occasion for resorting to an electric motor was experience of the inconvenience and imminent danger that resulted when the wire rope at the coal face left its pulleys.

A Past-President of this Institution, Mr. Ll. B. Atkinson, was associated with the design and fitting of a 10-h.p. electric motor to this machine. The comparatively high speed of rotation of the cutter bar was a characteristic favourable to the electric drive; the results of the experiment were so promising that a machine was specially designed to be driven by an electric motor. It soon became apparent that the electric motor required protection from the dust and dirt in which a coal-cutter moves and works; moreover, the sparking brushes of the motors of those days were manifestly unsafe where gas might be present. Mr. Atkinson rose to the occasion by designing and building a completely enclosed electric motor, the first used for any purpose; this step was soon followed by complete enclosure of the gearing of the machine. The bar type was the first coal-cutter to be so enclosed.

As in the whole range of engineering the electric motor has had a beneficial influence on the design of every machine with which it has been associated—so with coal-cutters the application of the electric motor resulted in rapid advance in the development of these machines. The priceless advantage in the use of electricity, that the power can be easily and accurately measured, was quickly turned to account in coal-cutters and the power and strength of the machines were rapidly increased; the application of the electric motor to the disc coal-cutter, and later to the chain machine, followed its successful use in the bar machine. Complete enclosure of the gearing of both disc and chain machines followed the adoption of the enclosed electric motor.

Previous to the use of the electric motor the coal-cutter had been at a serious disadvantage because of the unsatisfactory power service provided by compressed air. In those days the efficiency of the compressed-air system was extremely low, and when the motors near the pit bottom and those near the main pipes were supplied with air, and after loss of pressure by pipe friction and leakage of air from joints and open drain cocks had done their worst, little pressure and volume were available at the coal-cutters, which were necessarily remote from the compressors. In consequence, many attempts to cut coal mechanically ended in failure and the machines were unjustly discredited.

As in so many other early applications of the electric motor, the power required to drive a coal-cutter was at first underestimated; this underestimate was the more serious to coal-cutters, especially to disc machines, at a time when the limitations of the machines in other respects were little understood.

The next notable advance was the application of the three-phase motor, and the credit for taking the first steps is due to Mr. Roslyn Holiday who, at Ackton Hall Collieries early in 1898, replaced the compressed-air motor of a disc coal-cutter by two 10-h.p. three-phase motors with wound rotors and slip-rings; later the slip-rings were removed and the rotor windings closed. In 1901 Mr. Holiday fitted three-phase motors, with wound rotors short-circuited, both to chain and to bar machines. The author believes that these were the first coal-cutters to be fitted with three-phase motors. Increasing recognition of the advantages of the three-phase system for colliery power service led to the installation of many three-phase plants, and coal-cutter makers responded to the consequent demand by incorporating three-phase motors in their machines. The first coal-cutters to be put on the market with squirrel-cage rotors were probably the three-phase bar-type machines produced early in 1903.

The compressed-air motors originally applied to the disc machine had single cylinders with reciprocating pistons. They were followed by twin cylinders side by side; this type was also applied to bar and chain machines and was in general use until the turbine was introduced. It still survives in some disc machines which continue to do good work where the undercut is not deep and the air supply is adequate.

Later Development of the Coal-Cutter.

The electric motor importantly influenced the design of the coal-cutters with which it was incorporated; the possibility it introduced of developing large power in small dimensions resulted in the design of the whole machine being made more compact. The axis of the crank shaft of the compressed-air motor was across the coal-cutter, whereas the rotor of the electric motor, which was too long to be arranged crosswise, had to be placed in the long axis of the machine; this and the high speed of the electric motor, compared with that of the compressed-air motor, required complete redesign of the coal-cutter, with the cutting member as already developed and the electric motor as the bases of the design. The necessity for compliance with the principal dimensional characteristics of the electric motor resulted in a degree of uniformity not hitherto existing in the leading features of the designs of coal-cutters of the various types and by different makers.

Modern coal-cutters thus conform generally to the stabilized types illustrated in Figs. 3, 4 and 5, on which the principal components, the gearcase to which is attached the cutting member, the motor and the haulage gear, are indicated by the letters "A," "B" and "C."

For convenience in manufacture the overall dimensions of the d.c. and a.c. motors were made alike and with identical facings, so that either type of motor could be assembled in a coal-cutter; this interchangeability is an advantage to the user who may have occasion to change the system of power supply. Standardization having been carried so far, it became obviously desirable that the compressed-air motor should be brought into conformity with the new general design of the coal-

cutter; this involved approximation of the compressed-air motor to the size and shape of the electric motors. The compressed-air motors designed for the purpose indicated were short-stroke, high-speed, single-acting motors of the 3- or 4-cylinder type actuating a crankshaft in the long axis of the coal-cutter. Motors of this type and form were made to be interchangeable with the electric motors in the coal-cutter structure.

These air motors gave good service, but, owing to the necessary lightness and delicacy of their fast moving parts, they were not well suited to the rough usage and strenuous service to which they were subjected.

Another important step in the evolution of the coal-cutter was marked by the advent of the so-called "air turbine" motor. This motor consists of a casing in which twin hollow cylinders are formed; within the cylinders are two rotors on the surfaces of which are cut double helical teeth, the teeth of the opposing rotors meshing with each other as helical gear wheels; cylinder heads closing the ends of the cylinders carry ball bearings which support the rotor shafts. Air under pressure is admitted at the bottom of the casing through a port which opens on the apex of the teeth and fills the spaces between the teeth that are opposite the port; the pressure of the air forces the teeth apart, so causing the rotors to turn; as the rotors turn, the spaces opposite the port are in succession filled with air under pressure, the apex of the space in one rotor recedes from the apex of the tooth on the other rotor that engaged with it, and so the space is enlarged and the imprisoned air, while expanding, continues to do work until released at the ends of the rotors where the spaces are opened in succession by disengagement of the teeth.

The power is developed by the cumulative effect of the pressures in the spaces acting against the teeth of the opposing rotors and forcing them apart. It is essential that the teeth of the two rotors shall engage so closely that their lines of contact shall make practically airtight joints. The motor is extremely simple and robust, but it depends for its economical use of air upon a high order of precision in manufacture and upon accuracy of its adjustments.

This type of "turbine" was the subject of a long-expired British patent which probably brought no profit to its inventor, because the machine tools and engineering methods of his day could not approach the requisite accuracy. So the invention remained dormant until the development of engineering practice enabled an American firm to produce a satisfactory motor. The suitability of this type of motor for incorporation in the coal-cutters that had been adapted to the electric motor was apparent.

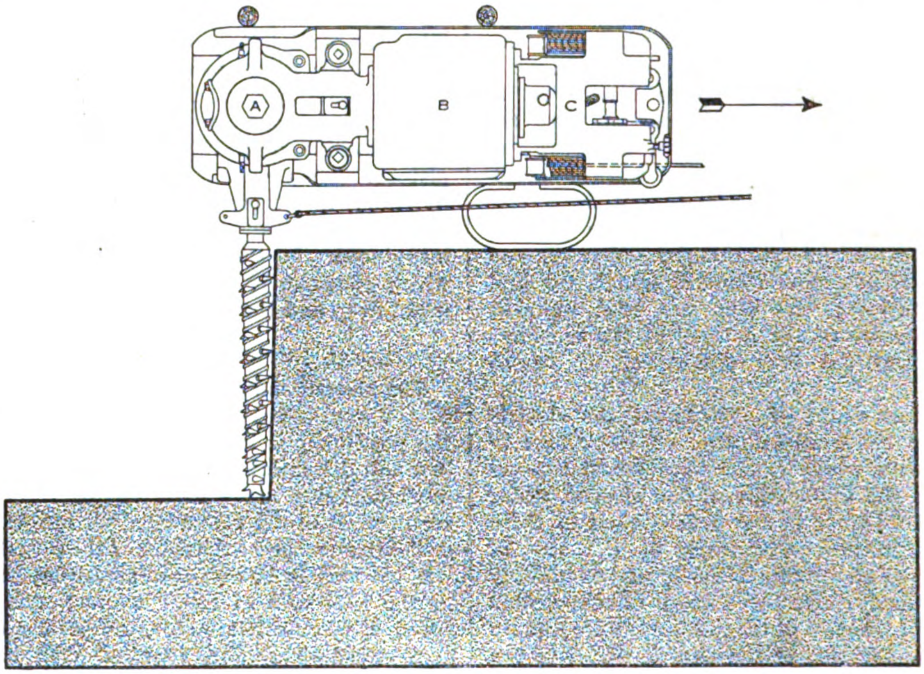

FIG. 3.—Bar type of coal-cutter.

In 1912 some American coal-cutters fitted with air turbines reached this country. They were at first regarded with scepticism; their economical use of air was doubted, and so was the suitability for coal-cutter service of machines which required delicacy of adjustment of their parts. The doubters were confounded, for air economy at least equal to that of the best reciprocating motors was demonstrated, and, in respect of reliability in service, experience proved their superiority. In the result the reciprocating motors were soon superseded by turbines in all modern British coal-cutters, and the simple rotary motion, which has ousted reciprocating motion in so many spheres, scored another triumph. Its advantages for coal-cutters are decisive.

The design of electric motors for coal-cutters is

subject to many limitations. D.C. motors which were first applied were favourable to the development of relatively high power in limited height because it is possible to use a rectangular and oblong cross-section, giving a flat and comparatively wide machine with its height as its least dimension, and extending laterally and longitudinally to dimensions that are less rigidly restricted. With a.c. motors, in which the magnetic and electrical elements are necessarily circular in form, the difficulty of the problem of meeting demand for equal power within the same limit of height as in the d.c. machine will be apparent.

In the case of industrial electric motors, the maximum output which can be obtained from a given size of motor shell is limited in the case of d.c. machines by the permissible temperature-rise at the end of a full-load run for a specified period, and by the maximum current with which the commutator can deal without sparking. For a.c. motors the temperature-rise is the controlling factor; the question of commutation does not arise. Secondary considerations must be taken into account in determining the size of shell to be used; it must be so chosen as to give an efficiency and, in the case of a.c. machines, a power factor not less than the recognized standard for the given output.

The conditions are entirely different in the case of

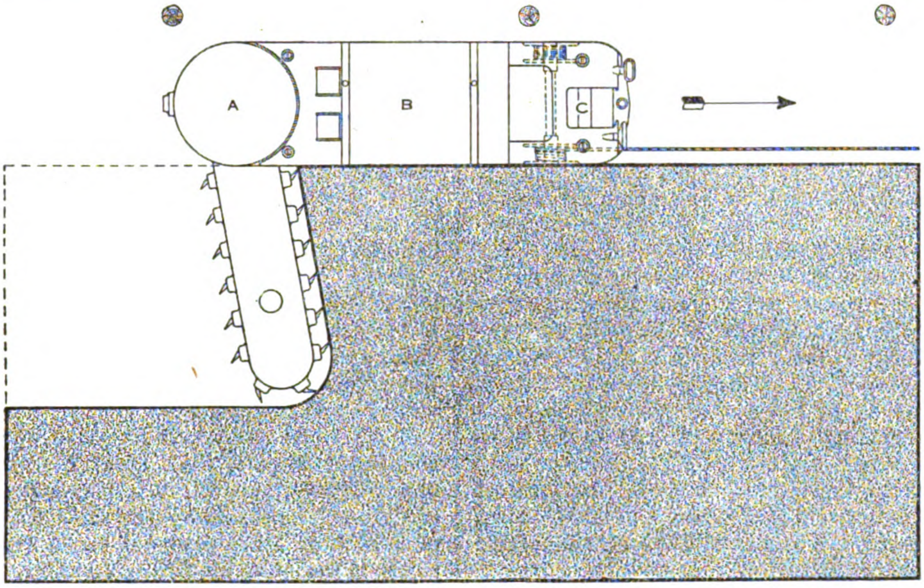

FIG. 4.—Chain type of coal-cutter.

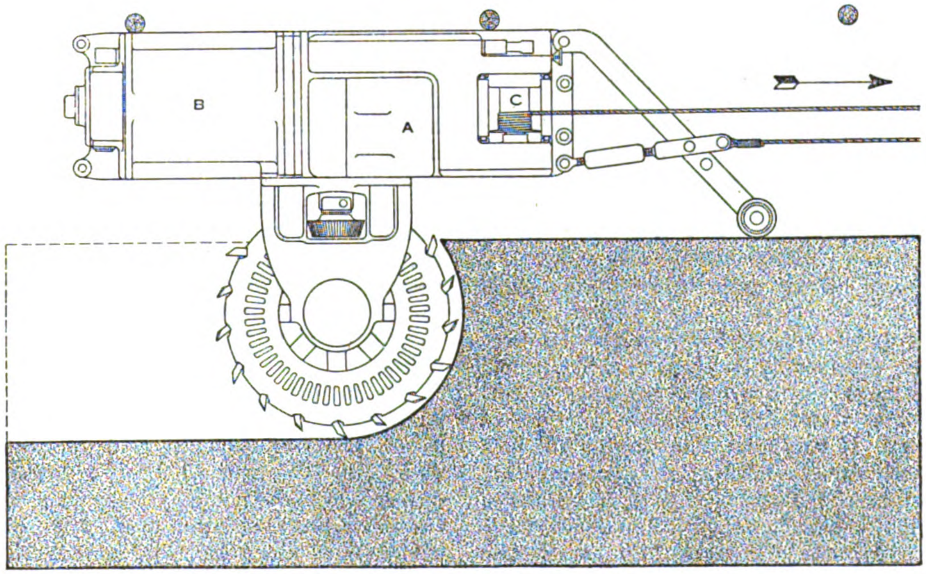

FIG. 5.—Disc type of coal-cutter.

motors to be used in coal-cutting machinery. There the dimensions of the motor are strictly limited by the conditions of service of the coal-cutter in which the motor is to be incorporated; the height especially is rigidly fixed, and this determines the maximum diameter of the armature or rotor. The problem is therefore presented to the electrical designer from a totally different aspect, and the ordinary canons of electric motor design cannot be applied. In the case of the normal industrial motor, with stated speed, output and voltage of the motor, the designer is required to determine the size from which he can obtain the best electrical properties; in the case of the coal-cutter motor, which is not a normal machine, he is confronted by precise limitations of space, the speed is determined by mechanical considerations, and he is required so to utilize the restricted space that the greatest possible horse-power is obtained. The work done by a coal-cutter is intermittent and may fluctuate violently from instant to instant, and the machine is liable to demand from its motor very large increases of power for brief periods, as when the cutters meet some obstacle, or when the overlying material collapses on the cutting member and jams or tends to jam it. The words "greatest possible horse-power" should therefore be interpreted to mean the greatest power that the motor will give without breaking down or ceasing to function, and should have no connection whatever with temperature-rise.

The limiting condition in the d.c. motor is commutation; when the load rises excessively, sparking occurs and may ultimately flash over from brush to brush. In the a.c. motor the limit is much more definite; it is the current at which the motor stalls. This current can be predicted from the design within fairly narrow limits.

The d.c. motor will accordingly be designed in the first place to have the best possible commutating properties. The a.c. motor will be designed to give the largest practicable stalling torque; other electrical properties will be ruthlessly sacrificed to this dominating requirement, and as a consequence the a.c. motor of a coal-cutter presents wider departure from normal design.

These essential points having had first consideration, it remains to the designer so to proportion the copper and iron in the motor as to get the smallest possible loss, the number of watts lost being the measure of the heat generated. If he succeeds in making the best possible use of the space available, and in providing for a maximum rate of dissipation of heat, he will have turned out the best coal-cutter motor, but he will have sacrificed many normal characteristics of electric motors and will have made many compromises between the desirable and the attainable. The temperature-rise of the motor at the end of any working shift will depend on the degree of skill exercised in driving the machine, on the depth of undercut, on the nature of the material being cut, on the condition of the cutter picks, and on the greater or less intermittency of the work.

Apart from the necessity for restricting the length of the machines, simplicity and robustness are so important in coal-cutter motors that in three-phase machines squirrel-cage rotors are generally used, although for disc machines, and in some cases for chain machines, wound rotors would have advantages. The stators of some machines are switched straight to the line, whilst others are wound for star-delta switching. Electricity supply at most collieries is on such a scale that no trouble is experienced from the high starting current required by individual coal-cutter motors. The circuit breakers on feeder cables to coal-cutters are set with a suitable time-lag—for example to trip in 10 to 15 seconds with the overload determined. The E.M.F. for which coal-cutters for service in this country are wound varies from 400 volts to 550 volts. The objections to lower pressure, especially for the larger machines, are (1) the weight, unwieldy character and increased liability to damage of the trailing cable that would be required, (2) the difficulty of allotting space to the larger switchgear, (3) the difficulties of winding, added to the existing limitations of winding space, and (4) the difficulties due to heavier sections of stator bars and the accommodation of windings suitable for different voltages and frequencies.

There is no recognized standard of power rating of coal-cutter motors, each maker's rating is individual and arbitrary, and, whilst it may serve for comparison of different machines by the same maker, the absence of a uniform basis prevents useful comparison of the rating of machines by different makers.

Characteristics of Bar, Chain and Disc Coal-Cutters.

For reasons that cannot be fully described here, the mean and the maximum powers required by the bar type (Fig. 3) are less than for the chain and disc types, the chain type (Fig. 4) is next in order, and the greatest mean and maximum powers are required by the disc machine (Fig. 5). The cutter bar of the bar machine is armed throughout its length with spirally arranged cutters; when it rotates, a reciprocating motion in its own axis and exceeding the axial distance between the cutter points is also imparted to it; the bar is thus surrounded by a zone bounded by the cylindrical or (with tapered bar) conical surface described by the points of the cutters in their combined circular and reciprocating motion.

The cutting member of the bar machine is by this characteristic enabled to follow irregularities of contour in the plane of advance, and to accommodate itself to irregularities of the floor of a seam or of a band of dirt in which the cut may be made; moreover, neither the resistance to rotation of the bar, nor the progress of the machine along the face, are affected by collapse of the coal or other material immediately behind the line of the cut. Owing to the large number of cutter picks of the bar machine, the comparatively small bite taken by each pick, and the immunity from liability to jamming of the cutting member, the power required by the bar machine varies less from the mean than in the other types.

The cutting member of the chain machine consists of a rigid jib round which a "race" is formed to guide the chain that carries the cutters. The cutter picks of the chain machine are fewer in number, and individually

they take a bigger bite than those of the bar machine. From the illustration it will be seen that the chain jib presents surfaces of considerable area in the space that has been undercut; if the cutters, for example, when they are improperly formed or adjusted or when they are worn, do not make adequate clearance, the jib may be jammed and the machine subjected to overstrain; or the same result may attend collapse of the material being undercut. It will also be seen that the width of the chain jib in the plane of the cut renders difficult any changes in contour of the cut to conform to an undulating floor. These characteristics of the chain machine are liable to impose on the motor considerable overload for periods of greater or less duration.

The cutting member of the disc machine presents a still larger area in the plane of the cut, and the attendant difficulties described in relation to the chain type are much accentuated; as the disc machine is less amenable to manœuvring than either of the other types, it must therefore overcome difficulties by frontal attack and must be endowed with great reserves of strength and power. The foregoing remarks on bar, chain and disc machines do not refer to the order of merit of the machines, each of which has its sphere, but only to characteristics that have special bearing on the power of the motors.

Coal-cutters are required to cut, not only in coals which in different seams vary widely in constituents and in physical structure, but also in strata adjacent to, or contained in the form of bands in, the coal seams; these strata are usually fire-clays, shales, etc., containing gritty matter in greater or less proportions and, not infrequently, layers or nodules of ironstone or metal pyrites. None of the known methods of measuring comparative hardness, when applied to materials of the kinds referred to, is of any value for the determination of comparative "cuttableness." With modern coal-cutters the "cuttableness" of any material depends on the endurance of the cutter picks, which are made of high-carbon steel hardened and tempered to suit the nature of the material to be cut. Where the material to be cut is highly resistant to penetration by the cutters, the pressure of the cutters against the material must be correspondingly increased; the point of the cutter, which moves at high velocity, may then become heated to a degree that softens it, with the result that the point is quickly worn off and the cutter no longer cuts.

It is clear that under such conditions a comparatively massive cutter, apart from its greater strength, has greater capacity for absorption of heat and will endure longer than a cutter of smaller mass. The massiveness of its cutters is one of the characteristics to which the disc machine owes its superiority in the hardest cuttable materials. The chain machine for a similar reason has in hard materials an advantage over the bar type.

The limits of the field of usefulness of coal-cutters cannot be defined with precision; they are elastic and have been widely extended by development of the capabilities of the machines. It may be said, however, that the respective types—bar, chain and disc—have comparative limitations imposed by the mining conditions. This subject cannot be treated at length here, but the following may be given as examples of mining conditions that impose limitations: Hardness of the material to be cut, presence of hard foreign bodies such as ironstone or pyrites at the holing position, friableness of the material under which the cut is made, the height from the floor at which the cut is required, undulations of a very hard floor, weakness of the roof of the seam, steepness of inclination of the seam, occurrence of faults or hitches in the seam, and so on. When it is considered that the cutting member of the disc machine—the disc—presents a large surface in the slot being cut and in the plane of advance of the machine; that the cutting member of the chain machine—the chain jib—presents a less surface, and that the bar machine presents only the bar, in effect a line, and that is entirely armed with cutters—the nature of some of the limitations of the respective machines may be understood.

A factor that limits the application of all machines, but in different degrees, is the hardness of the material to be cut, or rather the effect of the material on the cutter picks.

Conditions of Service of Coal-Cutters.

Coal-cutters are portable machines in a special sense, for the feed of the cutter picks is applied by advance of the whole machine along the face. While in operation the machines are in continuous movement, on rough floors which may be inclined from the horizontal between zero and 60° or more, in closely confined spaces, in more than semi-darkness, in floor water or under roof water, or in an attending cloud of dust, and driven by a rough-handed class of men whose familiar tools are pick and shovel. It will probably be agreed that in the whole range of services to which electric motors are applied none is more exacting than the driving of coal-cutters; and it will be clear that the design of these machines presents problems of more than ordinary difficulty. The pressing demands for maximum power, strength, rigidity and durability, all to be fulfilled within severely limited dimensions, and with flame-proof enclosure combined with ready access to the working parts, and over all the dominating essential of reliability, impose on the designer many compromises between desirable but mutually antagonistic characteristics. Features important in the views of the mechanical and the electrical engineer must make concessions or sacrifices to insistent demands by the mining engineer who does not always appreciate that fulfilment of his requirements in one direction implies his acceptance of limitations in another.

Many attempts have been made to produce coal-cutters; the small number of makers who have emerged successful—they can almost be counted on the fingers of one hand—is a measure of the difficulties of the problem. The successful machines have been evolved by the slow and costly—costly alike to the maker of the machine and to the colliery owner—process of trial and error, under actual service conditions. Coal-cutters of to-day are highly specialized machines; they are designed with less regard to the duties to be performed than to the abuse to which they will be subjected; selection and treatment of the materials of the component parts is based on experience of the

degree of durability of the respective parts in past service, and in selection full advantage is taken of recent advances in metallurgical science; the methods of precision and the machine-tool equipment employed in the production of coal-cutters are in line with the highest developments of modern engineering practice. The period of apprenticeship of the coal-cutter has expired; shortcomings and defects that formerly were condoned are no longer tolerated. The more the coal-cutter takes its place in the general scheme of mining, the more important becomes its reliability in service, for the greater is the responsibility placed on it. Where the mining conditions are favourable and systematic coal-cutting has been established, the machine takes the primary part in a cycle of operations organized to time table for production of 70 to 150 tons per shift, and in which 20 to 50 men (according to the seam conditions) may be engaged. The penalty of failure of the machine to fulfil its part is disorganization of the whole scheme, suspension of the correlated operations, loss of wages to the men, loss of output and serious increase of costs to the colliery.

In machines the working load of which depends so much on the personal factor in the driver, the electric motor has advantages and disadvantages. Coal-cutters with blunted cutter picks are often cruelly over-driven by careless or inexperienced men, and the willing electric motor responds by maintaining its speed and developing more and more power up to the limit of its capacity—power which is wasted in grinding away the picks and in wear and tear of the overstressed mechanical parts of the coal-cutter. With the compressed-air system applied to the driving of coal-cutters the b.h.p.-hours required to be delivered to the compressors is roughly between four and five times that required to be delivered to electric generators for an equal amount of useful work done by coal-cutters. This relatively low efficiency of compressed air is partly inherent in the system as applied to colliery service, and partly due to the conditions under which coal-cutters are used. Wherever considerations of safety do not preclude the use of electricity for coal-cutting, electricity should always be adopted. There are, however, a large number of collieries in this country where there is no alternative to compressed air and its indispensability condones its relative inefficiency. Generally, compressed-air power systems are much less efficient than they ought to be and might be, because engineers in charge have not yet acquired the habit of measurement that has so importantly contributed to efficiency in electrical engineering. At many collieries, alongside electric generating plant with switchboards loaded with measuring instruments, powerful air-compressors are at work with no other instrument than a simple pressure gauge. There are now a number of exceptions but, generally, compressed air is sent underground without being measured, and there is no check upon extravagance in its use or waste. Reliable air meters of the indicating, integrating and chart types are available, but at comparatively very few collieries are they used, and often not even a pressure gauge is to be found below ground. The neglect of measurement is the more serious, because in every compressed-air system in colliery service there is a pernicious tendency towards inefficiency, which can only be restrained by unremitting vigilance. The liability of the long ranges of piping to disturbance by movements of the strata and to rough treatment incidental to road repairs, is the source of much loss of volume by leakage, and the overloading of existing pipe ranges by adding motors, and the extensions of piping as the coal faces recede further and further from the pit bottom, are the frequent causes of extravagant loss of pressure. Leakage in the case of pressure air does not burn like steam, nor give shocks like electricity, and defects or derangements in the compressed-air pipe system may be economically very serious without compelling their repair. The development of defects may be so gradual and insidious as to escape detection, until the dwindling effectiveness of the air-driven machines and the consequent decline in coal output develops a crisis; repairs are then effected and the process of decline begins again.

Coal-face machinery, being the most remote from the compressors, is most affected by fall in the efficiency of the power supply. It may be said that the conditions under which coal-cutters are required to work impose upon compressed-air machines low efficiency in respect of air consumption. It is easy to design an air motor which will be economical in its use of air when worked under stated conditions of air pressure, rotor speed, and load. In coal-cutter service there are no standards of pressure, speed, or load; these conditions are all variable to wide limits, yet the machine is expected to go on with its work. The air pressure may vary or fluctuate during a shift between 70 and 30 lb. per sq. in., and the motor must be large enough to drive the machine at the low pressure. Fulfilment of this condition not only involves extravagant use of air at higher pressures, but also renders possible excessively high motor speeds and development of greatly increased power, and the whole machine must be capable of withstanding the consequences.

When the air pressure varies, the motor speed and the load are at the discretion of the machine-man, who has little regard for economy of air, and seldom much consideration for the machine as a piece of mechanism. The air consumption of a motor is more nearly proportional to the number of strokes of the pistons or revolutions of the rotor than to the useful work done, and if when the pressure is high the motor is allowed to race, it may swallow more air when running light than when fully loaded at normal speed. The air consumption per square yard undercut by a given machine depends on the rate of cutting; the faster the cutting speed the fewer revolutions will the rotor make while the machine cuts a square yard, and the less air will be used. The rate of cutting depends on many factors external to the machine—the conditions of the roof and floor of the seam affect the rate of progress, so do the hardness, toughness or brittleness of the material being cut, the form, condition and adjustment of the picks, and the personal factor in driving the machine.

It will be understood from the foregoing considerations that, apart from the inherently low efficiency of the compressed-air system, the conditions of use of coal-cutters depress the air efficiency of these machines below

that of, for example, pumps working at constant speed and load.

Fig. 6 compares the energy used by compressed air and electric coal-cutters tested under similar working conditions. The two curves are drawn to the same scale of energy, the compressed air and the electricity delivered to the machines being reduced to the equivalent horse-power-minutes. The curve of the electric machine may be taken as characteristic of all electric coal-cutters; that of the compressed-air machine in shape and in position on the scale is individual, but it roughly represents compressed-air machines in general. The curve of the compressed-air machine reveals how largely air consumption depends on skilful driving and how important it is by attention to cutter picks, etc., to enable the machine to travel as fast as practicable while working.

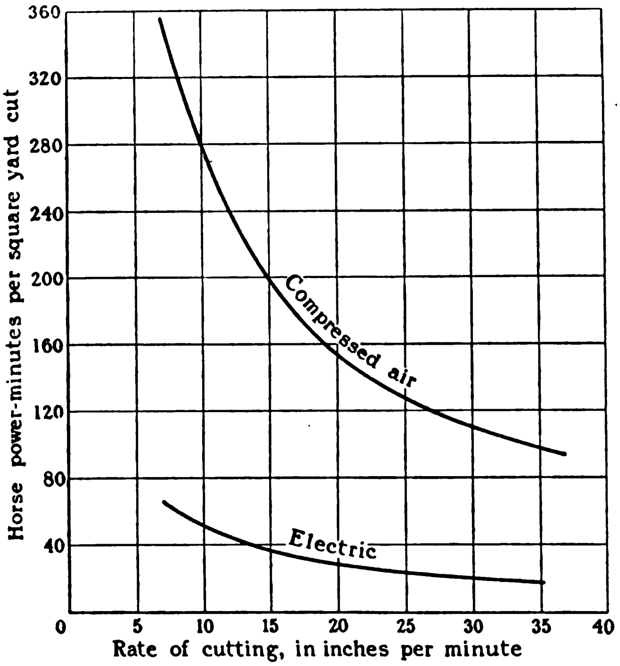

FIG. 6.—Energy used at various rates of cutting by compressed air and electric coal-cutters.

The b.h.p. rating of coal-cutters is arbitrary; the rated powers of the machines in most general use are between 20 b.h.p. and 50 b.h.p., but all have large overload capacity for short periods, and not infrequently they are required to develop it.

Under normal conditions the energy delivered to electric coal-cutters per square yard undercut varies from about 0·2 kWh in the most easily cut materials to about 1·0 kWh in the hardest cuttable materials. The average may be taken as 0·4 to 0·5 kWh. For the reasons already described, the equivalent in the case of compressed-air machines is much higher, especially in the case of harder materials.

MECHANICAL CONVEYING AT AND NEAR THE COAL FACE.

The application of power to the conveying of coal at and in the vicinity of the coal face may be described as technically and economically essential to intensive mining in which the productive effort is concentrated and large outputs are obtained from comparatively small areas. Coal-cutters increase largely the yield of coal per lineal yard of face per day, and, if full advantage is to be realized from the machines, the coal produced must be promptly removed from the faces. The workings of most existing collieries are laid out for hand-mining, and the arrangements of gate roads to the face, and of haulage roads (Fig. 2), are designed to deal with a comparatively small output from each working place. The introduction of coal-cutters to formerly hand-worked faces, by largely increasing the output to be loaded and drawn in a given area, puts excessive strain on the organization for distribution and collection of trams to and from the gate-ends. That the difficulties of dealing with the output from coal-cutters, without radical change in methods of loading the coal and delivering it to the mechanical haulage, are practically insuperable is becoming more widely recognized.

Many of the considerations that affect adoption of mechanical conveying cannot be referred to here, but two main functions of the system may be presented. First, conveyors laid along the coal face greatly accelerate the rate of clearance of coal from the face, and also increase substantially the output per man. Referring to Fig. 2, in thin seams the coal must be shovelled along the face, breaking it and often dirtying it in the process, to the gate-end where height is ripped to permit filling the coal into the trams. The coal is usually lifted by shovel and cast three times; the loading of 5 tons into a tram at the gate-end is thus approximately equivalent to shovelling 15 tons on to a face conveyor. In thick seams the trams are manhandled on rails laid along the face. Secondly, the collection of coal from face conveyors, by conveyors laid in gate roads (at intervals, for example, of 100 yards from each other), and its delivery to trunk conveyors from which the trams are loaded. The first of these functions affects face costs, and the second transport costs; the latter is often the more important. Consider, for example, that to get from a seam 3 ft. thick, 750 tons per filling shift, of coal undercut by machine on the previous shift, by the system illustrated in Fig. 2 it is necessary to supply to the face about 1 500 trams—20 to each of 75 gate-ends, and so to maintain the regularity of supply and withdrawal of the trams that the work of the men of the face shall not be delayed.

The system shown in Fig. 7, which illustrates a double unit with face conveyors to right and left delivering into a gate-end loader, or into a gate conveyor, reduces the number of tram loading-places from 75 to 4. If still fewer loading-places be desired the number can be reduced to 2, or even to 1, by a variant of the arrangement shown in Fig. 8; by this arrangement the face conveyors deliver into gate conveyors which from right and left convey to a trunk conveyor in the mothergate. The starting and control of such a group of compressed-air conveyors is simple, but it will be appreciated that the switching and cable arrangements for control at the discharging-end of the mothergate conveyor, of the individual motors on the electric power system, presents a somewhat special problem.

The plans referred to are typical of actual practice. Applied on the methods indicated, mechanical conveying contains the solution of the problem of avoiding the delays inherent in the system of loading individual trams at the face and manhandling them individually through gate roads to the mechanical haulage.

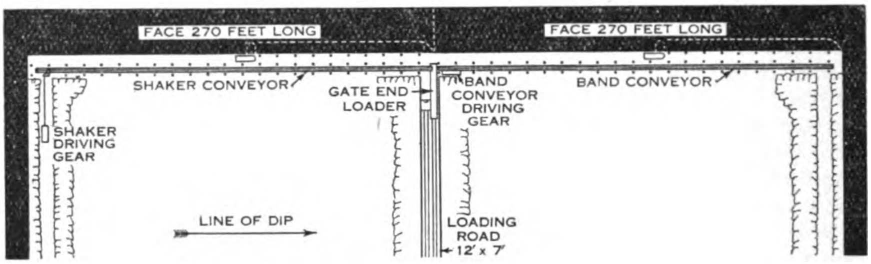

FIG. 7.—Double unit with face conveyors.

Individual face conveyors are usually of length between 75 and 150 yards; in gate roads greater lengths are not infrequent and trunk conveyors may extend to several hundred yards. The principle governing the use of conveyors for collecting is that the maximum daily output per yard of coal face shall be obtained, and that the lay-out of the faces and gates—subject to the mining conditions—shall be such that the desired output shall be delivered to the tram loading position by the minimum length of face and gate conveyors.

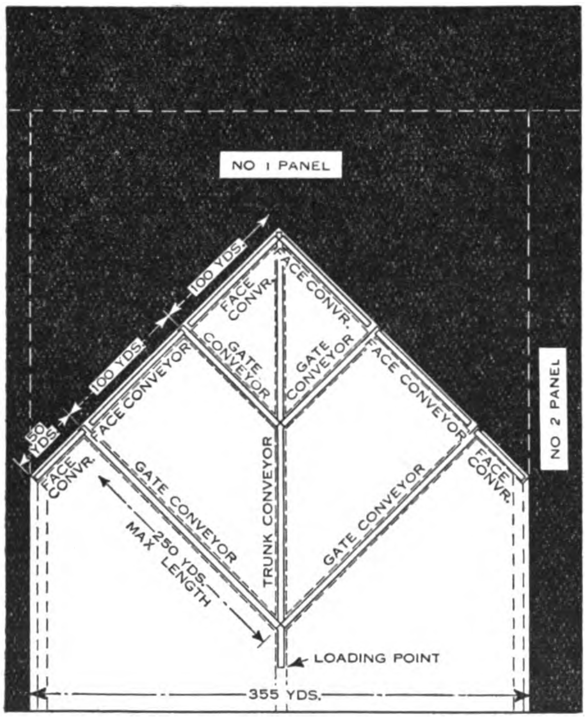

FIG. 8.—Gate conveying for collecting from a number of face conveyors to a single loading point.

The conveyors used for the purposes indicated are of three types, (*a*) the shaker or jigger, (*b*) the chain scraper, and (*c*) the band (a textile band usually faced with rubber). The scraper and the band types are unidirectional in operation and, apart from limitations of space, which are less stringent than in the case of coal-cutters, the application of electric motors to these machines does not present special difficulty to those experienced in the design of coal-cutter motors. The driving of the shaker conveyor, however, presents special problems. It is unnecessary here to refer in detail to the relative advantages of the three types; experience has allotted—without rigid demarcation—to each type its own sphere, and only where the mining conditions approach the border line between these spheres is there doubt as to choice of type. The sphere of one type or other may be extended by improvement in conveying capacity, or by mitigation or removal of disabilities.

Chain scraper and band conveyors are used where the gradient is against the load, and the band where the volume of coal to be conveyed is beyond the capacities of the scraper and shaker. In respect both of volume and of distance conveyed, the capacity of the chain scraper is comparatively limited; for trunk-conveying of volumes over 300 tons per shift for distances over about 200 yards the band type conveyor, the capacities of which in regard to volume and distance are limited only by economic considerations, will hold the field. Special conditions such as inclination, and special circumstances, may determine overlapping of the normal spheres of the respective types.

The shaker conveyor which was originated on the Continent is by far the most widely used of underground conveyors. Its special sphere is where there is a gradient in favour of the direction of delivery, but it is largely and successfully used on the horizontal and even against small gradients. It cannot be said that the possibilities of the shaker type of conveyor have yet been fully exploited, but restrictive elements inherent in the type will probably prevent any considerable extension of its already demonstrated capabilities in respect of conveying capacity on the level and against gravity respectively. The possibilities that remain are chiefly concerned with the characteristics of the appliance, whether actuated by electricity or compressed air, that imparts the reciprocating motion to the trough.

The shaker conveyor was first applied in steep seams. It was preceded by a line of stationary troughs on such inclinations that the coal cast into the troughs was

conveyed by gravity to the loading level. Where the troughs were used on gradients just insufficient to enable gravity to keep the coal moving downhill, a slight shaking movement of the trough was applied to aid gravity in overcoming the inertia, friction, and "stiction" of the coal and to make it move downhill. To facilitate shaking, the troughs were suspended by chains and the reciprocating movement of short conveyors was applied by hand; the length of troughing that could be operated manually was limited and the use of a compressed-air cylinder with reciprocating piston soon followed. Suspension of conveyors at the coal face is often inconvenient, and the next step was the mounting of the troughs on rollers carried by roller tracks placed on the floor. The application of electric motors followed at a later date.

With the compressed-air drive the usual arrangement is that the piston pulls the troughing backwards uphill; on a level seam the roller path on the floor gives the required rise, troughing and coal then fall by gravity, until at the end of the stroke the motion of the trough is arrested and the coal slides forward.

In the electrically-driven shaker gear a crank is interposed and by the use of a system of links the uniform angular motion of the crank results in non-harmonic motion of a rocking arm. On one stroke of the rocking arm to which the conveyor is connected, the acceleration is nearly uniform during a considerable part of the stroke, and on the other stroke the acceleration rapidly rises to a high value. This special motion of the rocking arm, communicated by a connecting rod to the troughing, is used in conjunction with the appropriate form of roller path to propel the coal along the conveyor troughing.

On considerable inclinations a short harmonic stroke, with the troughs on straight upper and lower paths, is sufficient, but for conveying on the level and against gravity a number of interesting and somewhat complex problems are involved in adapting the rate of reciprocation, the length of stroke, the rate of acceleration, and the form of the upper and lower roller paths, all in combination, to the conditions of service and to the kind of coal (large or small, dry or damp) to be conveyed. It will be recognized that for imparting to the troughing a reciproacting motion at a rate between 60 and 90 strokes per minute the simple compressed-air cylinder, despite its comparative extravagance of power, has certain advantages over the electric drive with its rotary motor, reducing gear and crank.

The very wide range of conditions under which conveyors are applied, and the frequent necessity for adapting the conveyors to changes of seam conditions and mining circumstances, present abundant opportunities for exercise of ingenuity. The development of conveyor design and the improved capabilities and versatility of these machines are largely due to the initiative and resource of colliery officials in surmounting the difficulties with which the vicissitudes of mining confront them. These developments are reflected in the diversity of forms of shaking gears and their accessories produced by makers experienced in this speciality.

Conveyors may be described as semi-portable machines; the position of face conveyors is stationary throughout the working shift, but the whole length of the conveyor, and usually its driving gear, are moved towards the face once in each 24 hours; in thick seams or in hand-got seams the forward move may be every second day. Gate conveyors in respect of their delivering end may remain in position for months, but are gradually extended at the receiving ends as the face conveyors follow the face in its advance.

In operation, conveyors are not subjected to the same kind of treatment as coal-cutters, but face conveyors especially are similarly liable to excessively rough usage—usage that would soon wreck any plant not designed with special regard to the nature of the service.

When it is considered that 100 yards of medium-size conveyor trough when filled weigh about 6 tons, and of large trough about 10 tons, that nearly double that length is sometimes connected, and that this weight, supported on rollers from more or less correctly placed roller paths, must be reciprocated at a rate of between 60 and 90 double strokes, of between 2 and 10 inches, per minute, on one stroke the whole load being raised against gravity, it will be understood that the duty required of the shaking gear and of the whole trough structure is severe. But when it is further considered that the line of face may not be straight and that the troughs may be sawing into many wood props, that the floor may have considerable undulations, that accumulated dirt from the seam may prevent free movement of the troughing, that the roller tracks may become displaced, that soft floor or roof may allow the props that secure the shaking gear to become loose and the gear to depart from alignment, that irregular supply of trams at the loading position may require frequent stopping of the conveyor and the restarting of it with overloaded troughs, and that the complete stripping of the coal from the face to allow the coal-cutter to work on the next shift means that the conveyor must go on working at all costs, it will be realized that face conveyors of the shaking type have no ordinary task, and that anything that can go wrong with them will go wrong. Yet nothing must go wrong, for reliability and freedom from derangement of the conveyor is the essence of the economic success of mechanical conveying. The larger the daily output of the conveyor, the more important it is that there shall be no interruption to the regularity of output, and the greater is the responsibility of the conveyor.

The stresses to which such machines and their motors are liable have no relation to the useful work to be done, and, as in coal-cutters, factors of safety cannot be calculated. The machines must simply be strong enough, and the designs of the machines that are strong enough have been evolved by experience of the actual conditions of service.

Other Applications of Power at the Coal Face.

The drilling of rock or other strata too hard for cutting by the edge of a rotating drill is a special problem. The material must be attacked by percussive blows and the tool must reciprocate. The difficulties of applying electric power to this service are well known;

the compressed-air drill holds the field. The enormous economic importance of the rock drill applied to metalliferous mining, to quarrying, to tunnelling and to many other services besides coal-mining, has led to a probably greater degree of concentration of attention on the compressed-air rock drill than has been devoted by inventors to any other individual mechanical appliance. The result is that electricity has here a very highly developed competitor the convenience and effectiveness of which condone its admitted extravagance of power. The attempts to gain a footing with devices comprising combinations of electric motor, with springs or with compressed air or hydraulic links or relays, have not yet achieved technical and economic success, and so the nearest approach of the electric motor to rock-drilling near the coal face is the driving of an in-bye air compressor for air supply to percussive drills.

The drilling of shot holes for blasting in the coal face, and in the roof or floor strata to make height in the roadways or to provide material for packwalls to support the roof, is an important service which electricity directly applied to the tool has not yet succeeded in rendering; opportunity still awaits the successful designer. For drilling the coal by electric power a rotary drill with twisted stem to convey the cuttings from the hole is required. Attempts have been made to fulfil the conditions with electric drills, but none has succeeded in surviving the test of enduring service and in finding general acceptance by mining men. In such drills the principal desiderata are lightness and portability, adequate power, and robustness to withstand rough usage. The drills produced have conceded too much to lightness and have had inadequate power and strength, or they have had adequate power and strength at the expense of portability, and so, although at some collieries electric drills are used, shot holes in coal when not drilled by compressed air are still generally drilled by hand. In many electrically-equipped mines the advantages of compressed-air drills are obtained by the use of a portable air compressor driven by electric motor; the combination is mounted on flanged wheels to run on the mine track, and the output is usually equal to the supply of air to two drills for making shot holes in the coal and in the adjacent harder strata.

Other machinery that may be used at and near the coal face, not directly for coal production but for secondary services, such as motor-driven auxiliary fans, pumps and haulages, is too familiar to require detailed reference here.

Closely allied to the application of electric power at the coal face is the problem of improved lighting. At most modern collieries the pit bottoms are now not merely lighted by electric lamps—they are illuminated —and illumination pays because it facilitates activity and promotes safety in the operations conducted. Where the coal is hand-worked and the miners are distributed along thousands of yards of face, there is no economic alternative to the individual miner's lamp. But with intensive mining as now increasingly practised, whereby large outputs are got from comparatively short faces, new possibilities open out of general lighting at the face without reference to the individual workers. In recent years the standard of lighting in all surface industries has been greatly improved and it is now recognized that good lighting pays. On conveyor faces the men are grouped in considerable numbers, and although the work is not of a kind that demands a high standard of lighting, the light from the ordinary hand lamps is inadequate. The miner with his individual lamp which requires frequent attention that distracts him from his work, is a more or less isolated centre of activity, whereas with general lighting in the region of concentrated and intensive operations the men are brought into more effective association and the co-ordinating supervision is facilitated. In no surface work requiring grouping of men similar to that on conveyor faces would operations be carried on in such comparative darkness, and surface standards of lighting might with advantage be applied to conveyor faces. Improved lighting promotes activity in the sphere of operations and raises the efficiency of labour and so increases output. At the coal face it is conducive to safety, and where the seam contains dirt bands less dirt is sent with the coal to the surface. There can be no doubt as to the desirability of improved lighting at conveyor faces; the only question is that of feasibility. In open-lamp pits with a.c. power cables at the face, there is no difficulty; a small transformer stepping down to 25 volts is used, and flexible conductors with lamp sockets fitted at intervals of about 12 ft. are supported by the props along the line of face; the lamps—of 25 c.p. with frosted globes—are protected by suitable fittings. The work of Prof. W. M. Thornton has gone far towards making available, in closed-lamp pits, the advantages of coal-face illumination that have been demonstrated where the use of existing equipment is permissible.

Conclusion.

It must be accepted that electricity will continue to be excluded from the coal face in many collieries, but the number of these may be reduced by fuller knowledge by mining men of the characteristics of mining electrical appliances and of the conditions essential to securing and maintaining the highest degree of safety in their use, and by fuller knowledge by electrical men of the conditions of service of coal-face machinery and other in-bye electrical apparatus and of the rough nature of the treatment to which it is unavoidably subjected.

Practice of the intensive methods of mining, rendered possible by coal-face machinery, has a bearing on the permissibility of the in-bye use of electricity. The reduced pit room, the less surface of exposed gas-bearing coal, the diminished number, increased area, and improved maintenance of the air ways, and reduction of air leakages between intakes and returns, are all favourable to more effective ventilation, and therefore to safety in the use of electricity. On the other hand, the more rapid advance of the workings may in some gaseous seams liberate so much gas as to exclude electrical appliances at the face. This also applies to seams liable to the occurrence of sudden outbursts of gas, and to places in the working of normal seams where accumulation of gas may be difficult to avoid.

Where such ventilation can be provided that explo-

sive mixtures of gas and air are prevented, it is clear that electricity may be used with impunity. The measure of the risk that may attend the use of electricity is the degree to which the ventilation falls short, or may fall short, of the standard indicated above; in some seams that standard may be unattainable, in others attainable with difficulty. As already remarked, the mine manager, on whom the responsibility rests, has in every case the sole right to decide whether electricity shall or shall not be used. Generally, intensive mining by promoting effective and economical ventilation should, to the extent it does so, also promote the adoption of electrically-driven coal-face machinery.

The flame-proof enclosure of electrical apparatus is not designed for normal conditions of working, for the Regulations require that the men shall be withdrawn if the proportion of gas in the air reaches a figure which is much below the lower limit of danger of ignition. The purpose of flame-proof enclosure is to safeguard against any accidental or unexpected rise in the proportion of gas in the air, such as might be ignited by open sparks. A defect in design or maintenance that might destroy the flame-proof properties of an electric machine or appliance need not, and probably would not, affect normal working under normal conditions, and this renders the more necessary the periodic careful examination and maintenance of flame-proof apparatus. Assuming that apparatus is flame-proof when installed, the safeguard depends on maintenance of that state.

Everyone familiar with underground conditions knows the difficulty of securing adequate maintenance of underground electrical apparatus. It takes time to train the personnel, but experience is educating mining men in the necessity for due attention to this subject, and improvement is progressive. At large collieries with competent electrical staffs, adequate in number, very good standards of maintenance exist; only at such collieries is it wise to send underground delicate automatic devices which are only a snare if their condition and adjustments are not properly maintained.

Coal-mining has greatly profited by the versatility of the electrical engineer, and by the high standard of quality, both electrical and mechanical, of his products. In the main, the sphere of electricity underground will continue to be in the secondary services—ventilating, pumping, hauling and winding. In application to the primary processes of mining at and near the coal face, the use of electricity is restricted; although increasing confidence in electricity may lead to some relaxation, it is certain that compressed air, displaced by electricity from important services at and near the shaft and in intake airways, will be very much more difficult to dislodge from the region of the coal face.

There are wide differences between mining operations and the work carried on in factories and workshops; many of the underground conditions and the forces to be dealt with are beyond control of the mining engineer, and they govern his plans of operation. Yet the special difficulties and vicissitudes to which mining is subject are mostly amenable to a considerable degree of control by methods appropriate to the conditions. Intensive mining facilitates control of the physical conditions, and further, it facilitates control and increases the productive effect of labour. Intensive mining on the unit system implies a considerable amount of standardization of method, a daily cycle of operations at each unit of coal face is established, and several clearly defined operations are repeated in the same sequence day after day by men whose labour is specialized, and the work becomes comparable with some repetitive processes in workshops. These conditions render practicable the application to mining organization and operations, of the principles that in recent years have so greatly increased the productivity of labour in other industries—notably in engineering.

The services of the mechanical and electrical engineer to the mining industry have been manifold, but abundant opportunity remains and the measure of it is the high cost of coal production. The output per underground worker is too low, therefore too many men are in the industry—that is why wages are low and costs are high. By mechanical and electrical aids to production the output per man can be increased, wages and the status of the miner can be raised, and the cost and price of coal can be reduced.

[The discussion on this paper will be found on page 1015.]

THE DESIGN OF STORAGE-BATTERY LOCOMOTIVES FOR USE IN COAL MINES.

By L. MILLER, Associate Member.

(*Paper first received* 1*st January, and in final form* 12*th February,* 1926; *read before* THE INSTITUTION 8*th April,* 1926.)

SUMMARY.

This paper deals with the general considerations which affect the design of a battery locomotive for use in mines. The usefulness of such a piece of apparatus in a mine is briefly discussed and the general conditions to be met are described.

Detail points in the design are dealt with on broad lines, and the results are given of certain tests designed to compare the coefficient of adhesion obtained with specially prepared wheels and standard wheels on rails prepared to represent conditions met with in practice.

The various methods of obtaining flame-proof enclosure of the electrical apparatus are described.

Finally a rough idea of the cost of running a battery locomotive is given.

In order to design a battery locomotive which will be successful in operation it is necessary to study the conditions under which it will perform its work. It is therefore proposed, before dealing with the detail points in design, briefly to run over the general considerations bearing upon the question of the use of locomotives in mines.

GENERAL CONDITIONS.

The average cost of power in a mine works out at 1s. per ton of coal produced. It is clear, therefore, that any slight saving in power which might be achieved by the use of locomotives cannot have very much effect on the cost of the coal at the pit mouth. Any gain in output which may result from the more efficient gathering and conveying of the coal to the surface may, however, have quite a considerable effect on the price.

In considering the use of locomotives to replace rope-haulage systems, there is no doubt a very good case to be made out from the point of view of power-saving and efficient and speedy handling of the loaded trains, provided that the haulage roads are level. If gradients and faults exist, then the locomotive cannot compete with rope haulage from the point of view of speed, and, in fact, if the gradients are much worse than 1 in 20 the use of a locomotive may be quite impracticable.

For gathering work the locomotive cannot compete with a conveyor system from the point of view of speed. Conveyor systems can be used economically only in thick seams, and owing to the cost of the installation a case cannot be made out for thin or comparatively thin seams. In such cases the pit pony is used for gathering and marshalling the loaded tubs on the main haulage road and for keeping a supply of empty tubs at the coal face. This is a case where the battery locomotive can be used to replace the pit pony, with satisfactory results from the point of view of speed and cost and also from the purely humanitarian point of view.

The locomotive can also be efficiently employed for marshalling purposes at the junction of haulage roads.

DESIGN OF THE BATTERY LOCOMOTIVE FOR GATHERING PURPOSES.

From the foregoing it would seem that a case can be made out only for the use of the battery locomotive on thin seams. In such cases the gate roads will be very restricted in dimensions, and if the locomotive is to proceed by the gate road to the coal face it must be of such dimensions as to conform with the size of the gate road and to allow sufficient clearance to prevent fouling at curves.

The rails on these gate roads are usually put down in a very rough-and-ready manner, and the locomotive must be such that in the event of a derailment it can easily be placed on the rails again. The design, however, should be such that it is very difficult to derail the locomotive.

In addition, the design of the locomotive must be such that it can be taken down in the cage either in pieces or as a whole, run over the main haulage roads to the gate roads, and be able to clear all the obstructions which exist on the main haulage road.

In order to achieve these objects the following limitations are placed on the design :—

(1) The height, width and length of the locomotive are limited. These must conform with the dimensions which can be accommodated in the gate roads or the cage.

(2) The weight is limited to that which can be safely handled in the cage or in the case of a derailment.

(3) Ample clearance must be allowed underneath the locomotive to clear obstructions on the main haulage road, such as tub greasers, pulleys and other devices used for controlling the tubs.

(4) The locomotive must also be capable of giving sufficient adhesion to pull at least a load of 5 tons on a grade of 1 in 20 and have a speed on the level of about $3\frac{1}{2}$ miles per hour when pulling the same load.

(5) The wheel base of the locomotive must be such that the locomotive is capable of going round a curve of about 12 feet radius. The overhang when negotiating the curves must be such as not to foul the sides of the gate road.

(6) The whole of the electrical equipment must, of course, be flame-proof and of a type which it is safe to operate near the coal face. It must, in addition, be capable of being worked in the open air with rain falling and of being operated through a considerable depth of water without permanently affecting in any way the sanding gear or the electrical equipment.
(7) It must be possible to change the battery quickly.

In 1923 a Committee was formed, at the instigation of Mr. Markham, with the object of preparing a Specification covering the design of a battery locomotive for gathering service. Mr. Markham offered a prize of £1 000 for the best battery locomotive which would conform with certain tests. This Specification was prepared after very careful deliberation by the Committee and it outlines very successfully the general requirements of the battery locomotive as far as the above points are concerned. It is not proposed to duplicate the details contained in this Specification, but the information is available to anyone who is sufficiently interested in the matter.

Cost.—Obviously, where the locomotive is to compete with the pit pony, and its use can only be economically justified on narrow seams, the cost of the locomotive is of paramount importance. The locomotive must therefore be of the very simplest construction and the cost should be kept down to the lowest possible figure.

Standardization is, of course, the most satisfactory way of keeping down the cost, having got the simplest design, and it is only possible to reach the minimum cost on a locomotive which is being turned out in reasonable quantities and which does not vary in design.

Rail gauges and radius of turns.—The chief difficulty affecting standardization is the gauge question. The Markham Committee very wisely chose a 2-ft. gauge. It will be seen from the data contained in the recent B.E.S.A. Report on Colliery Light Rails,* which gives the results of an investigation on this subject, that out of a total of 468 collieries 132 are using the 2-ft. gauge. This Report also makes it clear that there are 56 different gauges in use.

With regard to the question of the minimum radius of the turns used, the Report also states that the average minimum radius of turn for secondary haulage work was found to be equal to from 3·5 to 4 times the gauge. This gives a figure slightly less than that in the Specification issued by the Committee.

Battery capacity.—The battery capacity given by the Committee was 12 kWh at the 1-hour rate, and not less than 18 kWh at the 5-hour rate of discharge. The working voltage was stated to be not more than 80. This, of course, fixes the maximum number of cells at 40, if 2-volt cells are used. In designing a battery, however, the largest possible individual cells that can be accommodated in the space available should be used. Obviously a battery composed of a few large cells would require less space than one made up of many small cells, because of the smaller proportion of tray and container to working material.

* C.A. (C.R.) 9295.

In addition, the cost and weight will be less for equal output. The cells will be stronger, there will be fewer to maintain and these will be more easily repaired.

These factors will all tend to keep the voltage below 80, rather than above it.

It is not proposed in this paper to go into the merits of the various cells which are now on the market, beyond just stating that although the nickel-iron cell is undoubtedly the most robust it has a very serious disadvantage in its high internal resistance, and this is especially inimical to its use where heavy gradients are in existence. Whatever battery is used, however, it must be capable of being short-circuited without injury and of being run down rapidly without serious detriment to its subsequent working. Arrangements should be made to see that the electrolyte cannot be spilled, and the cells should be of sufficient depth to ensure that there is no possibility of this occurring.

The life of a lead battery is about 3 years, and that of a nickel-iron battery is about double this, provided that reasonable care is taken of them and that they are kept clean, charged regularly and not left for long periods without charge.

Charging the batteries.—The question of charging has, of course, to be considered in connection with these batteries, but it does not in any way affect the voltage question. A motor-generator set will have to be supplied and the generator can be designed to give any suitable voltage. Automatic charging devices can be used with advantage, and they do away with any trouble due to overcharging. The frequency of the charge will depend upon the conditions. Usually it will be advisable to change the battery every shift, one battery being charged while the other is in service. Care should be taken to see that the water lost by evaporation during the charge is replaced, otherwise the life of the battery is impaired.

The nickel-iron battery will not sustain much damage due to carelessness in charging at too high a rate, but many of the lead batteries require careful treatment in this respect, and care must be taken with either type to see that the temperature does not rise above certain limits (110° F.) laid down by the manufacturers. A little reasonable care and a study of the instruction books issued by the manufacturers will do away with any charging difficulties.

Number of motors.—The choice lies between mounting a single motor which drives one axle, the second axle being connected by means of a connecting rod, or by a Cardan shaft and worm drive, and using two motors, one on each axle, connected through suitable gearing. The two-motor scheme has the advantage that by connecting the motor armatures and fields in series-parallel it is possible to do away entirely with resistances. This is, of course, impossible in the case of the single-motor drive, where resistances have to be used to reduce the speed. On straight runs any advantage due to this will not appear, but in marshalling the tubs and manœuvring, which will have to be done at a restricted speed, the advantage of the two-motor scheme will be apparent. This has been found to be the case in America, where the actual power consumption in

service has been found to be very much in favour of the two-motor arrangement.

Design of the motors.—The motors will, as far as the electrical design is concerned, be of the usual series-wound traction type. They will be totally enclosed and will consequently be subject to condensation due to the variable temperature under which they will operate. The insulation should therefore be of a type that will not suffer when subjected to such conditions.

It is very difficult to work out a schedule for a gathering locomotive, which is entirely different from a haulage service where the schedule can be determined and the R.M.S. current-rating of the motor worked out. The formula

$$\text{Horse-power} = \frac{583 \times \text{Weight in tons} \times \text{Miles per hour}}{\text{Efficiency of gears} \times 375}$$

gives a clue to the short-time rating of the motors. This gives a figure of 1·64 h.p. per ton per mile per hour. In obtaining this figure a coefficient of adhesion of 25 per cent is employed, plus 1 per cent for the locomotive friction. The efficiency of the gears is taken at 95 per cent. The 1-hour rating of the motors on locomotives employed for gathering service can usually be taken at roughly half this figure where the grades do not exceed 5 per cent and are not long.

Weight of the locomotive.—In order to provide the necessary adhesion the weight of the locomotive must be proportional to the grade on which the load has to be hauled. Usually an up-grade can be accomplished on the overload capacity of the motor, but the time required to surmount the grade should not exceed such overload capacity.

The usual formula for determining the weight is :—

$$\text{Wt. of locomotive in tons} = \frac{T(R_F + R_G + R_A)}{0{\cdot}25 \times 2\,240 - (R_G + R_A)}$$

where T = total weight in tons of trailing loads ;
R_F = frictional resistance of tubs, in lb. per ton ;
R_A = acceleration resistance, usually taken at 20 lb. per ton, giving an acceleration of roughly 0·2 mile per hour per sec. ; thus

$$\text{Force} = \text{Mass} \times \text{Acceleration} = \frac{0{\cdot}2 \times 5\,280 \times 2\,240}{3\,600 \times 32} = 20{\cdot}5 \text{ lb.}$$

R_G = grade resistance in lb. per ton ; this is 22·4 lb. per ton for every 1 per cent of grade.

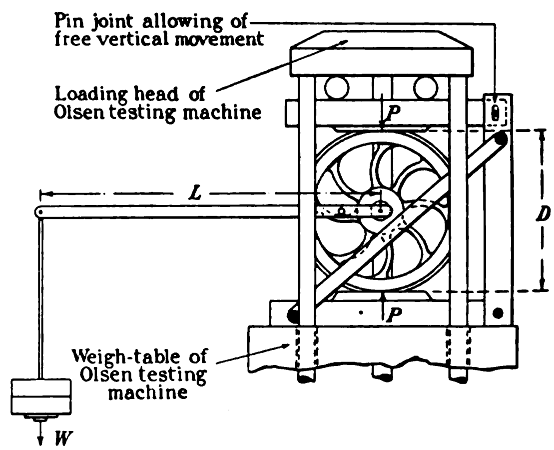
The figure of 0·25 for the coefficient of adhesion can as a rule be considerably improved at starting, and 0·3 is frequently used.

Coefficient of adhesion.—There are a great many things which affect the adhesion factor, and the author recently had some tests carried out on an 18-in. diam. steel wheel which show the effect of several variables on the coefficient of adhesion.

In an attempt to improve the adhesion the effect of inserting "Ferodo" into the wheel was tried. The wheel with "Ferodo" insertion was never used in practice, as the advantage was not considered to be sufficiently great and the life of the "Ferodo" insertion was regarded as doubtful. These figures are shown in the report of tests given in the Appendix. This experiment probably gives no new information and the results are included in order to show graphically how the conditions affect the coefficient of adhesion.

Attention is called to the effect of increasing the lines of contact from ½ in. to 1¼ in., which shows a marked improvement in the coefficient. This illustrates the importance, from the point of view of adhesion, of using flat-topped rails. The high figure obtained with sand with the ½ in. line of contact is due to some difference in the conditions not detectable by observation. This is indicated by the deep scoring which occurred when the wheel finally slipped. Increasing the diameter of the wheel also tends to increase the coefficient of adhesion.

It is quite clear from these tests that the sanding apparatus on the locomotive is of great importance in obtaining good adhesion, and the sanding gear should



Apparatus for determination of static friction of mining-type locomotive wheels.

be so designed that it cannot be put out of action when going through water.

Design of the controller.—The controller should be of very strong and robust design. The trend of development in controller design for heavy service is towards the contactor type. There are several reasons for this, the principal ones being :—

(1) This type of controller has been found in practice to stand up to severe conditions and maltreatment much better than the drum type.

(2) The renewal of the contacts becomes a very simple matter. The electrician can renew the whole of the contacts in a controller in a few minutes, using only a screwdriver. This cannot be accomplished with a drum controller, where the drum must invariably be extracted from the controller in order to fit new rings.

It is extremely inadvisable to rely on fuses for overload protection. Careless operation may result in the blowing of a fuse, and until the electrician has replaced it the locomotive will be inoperative.

The best arrangement is some form of interlocked circuit breaker which can be replaced only when the controller is in the "off" position. The controller

should be arranged with the so-called "dead man's" handle which, in the event of the operator releasing it, immediately cuts off current to the motors.

Braking.—Brakes should be supplied acting on all four wheels, and the design should be such that the pressure is equalized in each brake shoe. The shoes should be lined with "Ferodo" or similar friction lining to prevent any possibility of dangerous sparking.

The importance of sand as an aid to improving the adhesion, and consequently the braking effort, has already been emphasized.

It should be possible to apply the brakes by means of the foot as well as by hand, thus, in the case of emergency, leaving the operator with both hands free.

Type of drive.—There are at least three possible methods of gearing the motor to the driving axle:—

(1) Double-reduction chain drive using some form of silent chain for the first reduction, and an ordinary roller chain for the low-speed drive. The high-speed drive should be enclosed and, preferably, the low-speed drive as well.
(2) Double- or single-reduction spur-gear drive. This also should be of the enclosed type.
(3) Enclosed worm drive.

In America the tendency is to adopt either spur or worm gearing, and the chain drive is not regarded as sufficiently robust for the service. This is what would be expected for American conditions, where a great many large trolley locomotives are in service engaged on straight haulage work and operating at speeds up to 10 miles per hour at their rated draw-bar pull. For the small powers and low speeds required for gathering service the author believes that a properly designed chain drive will give satisfactory service. It is cheap and easily renewed at low cost, and can be accommodated in a small space without sacrificing the necessary clearance required to avoid the obstructions in the haulage roads.

Ball or roller bearings.—The saving in power due to the use of roller bearings in the tubs and locomotive axles will amount to 40 per cent of the power required to overcome friction.

The use of ball bearings on the motor will result in a reduction in the length between bearings and will assist in obtaining a satisfactory flame-proof design.

The actual saving in power consumption, taking into account braking, flange and air friction, grades and curves, will probably amount to as much as 20 per cent. This saving will enable a smaller battery capacity to be utilized for the same amount of work. The extra capital cost entailed in fitting roller bearings to the tubs and locomotive axles should soon be wiped off.

Roller bearings are, however, not likely to be received with any enthusiasm by the colliery personnel.

Winches.—It has been suggested that where the gate roads are such as to have a heavy grade against the loaded tubs, or where they are of such dimensions as to make it difficult for the locomotive to proceed to the coal face, a winch driven from the propelling motor would be an advantage. This would enable the full rated power of the motors to be utilized without considering the question of adhesion, and the loaded tubs could be hauled up a grade on which the locomotive could not operate. In fact the locomotive would, in addition to its marshalling duties, act as a portable haulage. By arranging a sheave on the roof timbers it could be utilized when erecting or dismantling pumps, coal-cutters, erecting or withdrawing props, etc.

There are, however, difficulties in the way of designing a gathering locomotive with a winch attachment. These are chiefly concerned with the limitation in dimensions, and the design of a satisfactory clutch member to declutch from the wheels and clutch on to the winch when required. These difficulties, so far as the author is aware, have not been quite satisfactorily overcome.

Flame-proof enclosure of the electrical gear.—The enclosure of all electrical apparatus used on the locomotive must conform with the definition laid down in British Standard Specification No. 229 and must be capable of withstanding the tests laid down in that Specification. The definition is as follows:—

> "A flame-proof enclosure (including explosion-proof) for electrical apparatus is one which will withstand without injury any explosion that may occur in practice within it under the conditions of operation within the rating of the apparatus enclosed by it (and recognized overloads if any associated therewith) and will prevent the transmission of flame such as will ignite any inflammable mixture which may be present in the surrounding atmosphere."

The problem of providing suitable protection therefore resolves itself into providing a means which will give sufficient relief to prevent the pressure increasing to a dangerous value, having regard to the strength of the enclosure, and at the same time will prevent flame reaching the outside atmosphere at such a temperature as to ignite it.

The "Safety in Mines Research Board" have issued a report on "Flameproof Electrical Apparatus for Use in Coal Mines" by Messrs. Statham and Wheeler which deals thoroughly with the question of "Flange protection." This is described by them as follows:—

> "Flange Protection.—Release of the pressure produced by an internal explosion is provided at flanged joints, the spacing between the flanges and their width being so proportioned that flame cannot reach the outer atmosphere."

This document deals very fully with the question of flange protection and demonstrates without any doubt whatever that this simple method of protection is most effective.

Although Messrs. Statham and Wheeler have not dealt with the alternative methods of protection, the matter has been dealt with by the American Bureau of Mines and several Continental investigators.

The alternative methods in question are:—

(*a*) Gauze or perforated plate protection and various combinations of the two.
(*b*) Gauze protection with the addition of a spring-controlled relief valve.
(*c*) Tubular or labyrinth protection providing a long, tortuous path for the passage of flame.

(*d*) Plate protection consisting of a large number of thin plates with distance-pieces between them, the flame being passed between the plates.

It is significant that 15 years ago manufacturers were experimenting with devices of this kind, but nowadays none of these are being used by the people concerned in these experiments. They have practically all adopted flange protection.

There are many reasons for this; for instance, gauze is not sufficiently mechanical to stand up to everyday wear and tear, especially in a mine, and even if protected by a valve there is grave danger of the valve being damaged so that it cannot operate. It must be remembered that devices of this kind are fortunately not often in operation and, in fact, may never be called upon to operate, and it is the danger of carelessness due to long immunity which has to be guarded against.

Apart from the question of mechanical damage or incorrect assembly, there is the proved fact that gauze or labyrinth protection very often gives too free a passage for the escape of pressure, with the result that the pressure in the enclosure actually falls below that of the outside atmosphere. This difference in pressure results in a fresh explosive mixture being immediately drawn into the enclosure. This may cause another explosion to take place, and this may go on until ignition actually occurs. Protecting the gauze by a valve might be expected to do away with this difficulty. It is, however, a very difficult thing to devise a valve which would be reliable under the conditions of operation.

Labyrinth or tube protection may suffer from the same defect as gauze. There is no doubt, however, that successful protection can be designed on these lines so long as care is taken to ensure that the path is not too wide, is properly protected, and cannot be wrongly assembled.

Plate protection is also perfectly safe, providing the plates can in turn be protected. The arrangement, however, can easily be assembled incorrectly and is so fragile that it has generally been left out of consideration.

The protective device should have the following features :—

(1) It should be capable of absorbing a large amount of heat.

(2) It should afford as much relief to the pressure as is consistent with the prevention of the flame igniting the inflammable mixture outsider the enclosure.

(3) It should be of a very robust nature and so constructed that it cannot be assembled incorrectly.

It is the author's opinion that flange protection most fully meets this specification, and the designer has complete information on this subject in Messrs. Statham and Wheeler's report previously mentioned.

The battery box must also be made strong enough to withstand a fall of roof or similar accident without crumpling, and should prevent damage to the cells or a short-circuit in the event of such an occurrence. Hydrogen may be evolved when the battery is being charged, so that the ventilation provided for the battery box should be ample to allow this gas to escape and not imprison it so that it is present when the locomotive is in service. If the battery box is subdivided in order to reduce the weight of an individual part or to obtain additional strength, then the connections between compartments must be made through flame-proof bushings and care must be taken to prevent intercommunication between compartments which may cause, in the event of an explosion in one, a rise of pressure in the next.

The plug and socket or jumper which is attched to the battery box must be so designed that it can be locked in place and cannot be pulled out except by an authorized person. The design should be such that, in the event of a short-circuit in the plug, flame cannot be communicated to the atmosphere. The controller

cover and all doors easily accessible should be locked so as to prevent unauthorized persons tampering with them. The terminal boxes of all the apparatus used must, of course, be made flame-tight, and where the cables are taken off they must be provided with suitably designed flame-tight bushes.

Cost of running.—No data are available, so far as the author is aware, as to the running costs of locomotives as compared with ponies on gathering service in this country.

In America the conditions are so different that data from this source do not seem to be applicable. The *Coal Age* of the 16th February, 1922, an American publication, contains some interesting data, which, although the figures are not applicable to the conditions in England, nevertheless show the trend of opinion in America and the results achieved by the use of battery locomotives.

A gathering locomotive will cost £400 to £500 per annum to run, and it will be necessary to replace at least three ponies to cover this expense. It is claimed in one of the cases mentioned in the above issue of The *Coal Age* that one locomotive replaced six mules. Where the conditions are such in this country that it is possible for the locomotive to replace six pit ponies the case, in the opinion of the author, is very strongly in favour of the battery locomotive, from the point of view of running cost and speed of handling the coal. The conditions vary to such an extent in every mine that it is impossible to lay down any hard-and-fast rule.

REPORT OF TESTS ON THE 18-IN. DIAMETER MINING LOCOMOTIVE WHEELS TO ASCERTAIN THE COEFFICIENT OF ADHESION.

General.—The tests were made on two wheels :—

A plain cast-steel wheel.

A cast-steel wheel with "Ferodo" insertion. The "Ferodo" was inserted in a spiral groove cut in the face of the wheel.

The coefficient of adhesion was obtained with both wheels in a perfectly clean and smooth condition and the rails in the following conditions:—(1) Extremely rusty; (2) reasonably clean, as would be expected in normal service; (3) perfectly smooth and bright.

In addition to these tests, the effect of a very heavy grease on the rails was ascertained by using paraffin wax. Paraffin wax was used in this case in preference to axle grease as being less likely to break down under heavy loads, and to represent more closely the conditions which might arise with a mixture of axle grease and fine coal dust.

(1) *Rails in extremely rusty condition.*—As this was regarded as a condition not likely to be, or at any rate very infrequently, met with under normal working conditions, only one set of figures was obtained, and these were with the rail in a perfectly dry condition.

(2) *Rails in reasonably clean condition.*—With the rail in this state, figures were obtained for the coefficient of adhesion with the rail treated in the following manner:—(*a*) Perfectly dry; (*b*) sprayed with water; (*c*) sprayed with water and oil; (*d*) dry and sandy.

ELECTRICITY IN MINES: A SHORT SURVEY.

By R. NELSON, Member.

(*Paper received* 1*st January, and read before* THE INSTITUTION 8*th April*, 1926.)

SUMMARY.

The paper provides a general review of the present position of electricity in mines, with particular reference to coal mines. Dealing with the safety aspect, it is claimed that the special requirements of colliery work have been amply met by manufacturers of electrical apparatus. It is further claimed that Great Britain has established a lead over other countries in respect of the design of mining electric plant. The question of public versus private supply is discussed, and the author states that, in his opinion, supply from an outside source is overwhelmingly the correct policy wherever two rival estimates show an equal, or nearly equal, financial result.

Some general statistics are given and the conclusion is ultimately drawn that one-half the motive power of the mines of Great Britain still remains non-electric.

Finally, some important directions in which the use of electricity in mines is likely to increase are mentioned.

The Annual Report with statistical appendices issued by the Secretary for Mines forms a very good indication of the extent and importance of the mining industry. The statistics show, by the number of persons employed and the value of the output, that in Great Britain coal mining is of much greater importance than metal mining.

This survey will be mainly concerned with the use of electricity in coal mines.

The general position of electrical engineering in relation to mining is worth a few moments' consideration. Mining was already an old industry with fixed traditions and well-established practices long before electricity made its appearance. In order to obtain due consideration, electrical engineers had therefore to overcome the natural tendency to follow old and well-tried methods, as against the adoption of a new, untried, and even "mysterious" agent. It is chiefly for this reason that although the special adaptability of electricity for use in connection with mining was mentioned in a paper before the Institution of Mechanical Engineers as early as the year 1852, it was not until 1883 that the first electric motor was set to work below ground in a British mine. This was at the Trafalgar Colliery, Drybrook, Gloucestershire, and the person responsible was the late Sir Francis Brain. Electrical and mining engineers had, however, still to do a good deal by way of educating each other, and themselves, before they evolved practical and satisfactory solutions of all the problems presented by the distribution and use of electricity under mining conditions. There is now more than 1½ million horse-power of electric motors in use in and about the mines of Great Britain, whilst it is doubtful whether there was as much as 10 000 horse-power in 1900. This indicates a greatly accelerated rate of growth during recent years, but, as will be seen later, the total is, in itself, a moderate one, having regard to the field for the further use of electricity that still exists on the surface and below-ground in mines.

The increased rate of growth just mentioned dates from the introduction of the three-phase induction motor and has been due partly to its convenience and reliability, and partly to increased confidence in the safety of electricity. In spite of the great improvements which have been made in distribution apparatus, and the high efficiency and low first-cost of modern electric motors, there is, however, still some inertia to be overcome in the coal-mining industry (which has always, and quite rightly, examined every new process with deliberation) before full advantage can result to that industry from the present situation. Whatever demerits electricity may possess, it can at least be claimed for it that it is practically and economically far and away the best medium at present known for distributing power over long distances below ground. It is proposed now to glance at the present position of electricity in mines and afterwards to outline the directions in which we may expect to see the uses of electricity further developed.

It will be convenient to deal first with one general aspect of the matter, namely, the use of electricity in mines from a safety standpoint. On this subject it is possible to quote some very important evidence by two well-known mining engineers. Prof. Douglas Hay and Mr. I. C. F. Statham recently gave an interesting account of some investigations carried out by them in the Mining Department of the University of Sheffield into the design of flame-proof casings for electrical apparatus.* All kinds of apparatus were submitted for test—motors, controllers, switches, coal-cutters, gate-end boxes, and cable joint-boxes—and in the end Prof. Hay and Mr. Statham reported as follows:—

> "It is satisfactory to be able to record that very few failures occurred under test; in fact, with one exception, such failures as there were took place under abnormal conditions imposed to determine the limits of safety, so that failure was anticipated."

Prof. Hay and Mr. Statham sum up their view of the risk to be apprehended from the use of well-chosen electrical mining apparatus in these words:—

> "With the continued improvement in the standard of design and maintenance of electrical plant, it is obvious that in the future the risk of danger arising from the use of electricity will be almost negligible.

* DOUGLAS HAY and I. C. F. STATHAM: "Flame-proof Design of Casings for Electrical Apparatus: An account of Investigations carried out in the Mining Department of the University of Sheffield," *Transactions of the Institution of Mining Engineers*, 1923-24, vol. 67, p. 23.

Side by side with this advance there is also the steady improvement in the standard of ventilation in mines and a progressive diminution in risk from the presence of coal dust. It must be believed that the risk of failure of apparatus coinciding with the presence of dangerous conditions due to firedamp and coal dust will be remote, and this fact must tend towards an increasing use of electricity underground."

The author agrees with them. The electrical manufacturers of Great Britain have amply proved their willingness and ability to meet the special requirements of coal mining, so that, given the correct choice of apparatus and due care and attention to its maintenance, a high degree of safety is now readily within reach. The present satisfactory position was, however, not reached without effort. Gloomy fears and predictions of disaster were frequent between 10 and 15 years ago, when "electricity in coal mines" passed through a critical period. To meet this situation a sustained and eventually successful effort was made by British electrical manufacturers to establish electricity in the confidence of the mining community. One good result has followed. The author's own experience is that British-made mining electrical apparatus is at the present moment substantially better than German-made apparatus. In fact, in this connection it may reasonably be claimed that we have established a lead over *all* other countries.

It would be possible at this point to leave the safety aspect, but the author wishes to add that the correct solution of safety problems in mining owes a great deal to the skill and perseverance of Prof. W. M. Thornton, who gave a detailed account of his work, extending over a period of 15 years, in a recent paper before the Institution.*

The first general question which arises in connection with the use of electricity in mines is the source from which the current is to be derived. Supply from an outside source, whether from a public supply or from a neighbouring privately-owned generating plant, has not, everywhere, commended itself to colliery owners. This is one of the points about which there still remains a very common difference of opinion between electrical and mining engineers. In their Memorandum of Evidence before the recent Royal Commission on the Coal Industry, it is given as the considered view of the Council of the Institution of Mining Engineers that "unless power companies can supply current at prices very largely below those now in operation the major proportion of the collieries are correct in continuing to produce their own power, either from exhaust steam or by waste heat from other sources or by generating plant using low cost fuel."† It will be observed that the statement is not made in respect of a few examples of large colliery establishments. If it were, something might be said for it. It is made in respect of the "major proportion of the collieries," and implies support of the policy of continuing to use private generating plant for colliery purposes, even where supplies of reasonable efficiency are available from outside sources, unless, indeed, such supplies can be obtained "at prices very largely below those now in operation." The question raised is one the solution of which requires no special mining or electrical knowledge, and it is therefore one about which difference of opinion must be based either upon difference of outlook, or upon failure to appreciate on one side or the other, or on both sides, the full merits of the case from the opposite point of view. It is probable that each of these factors has contributed in most cases where differences of opinion have arisen.

A mining engineer justifying the existence of a private generating plant such as is seen "at the major proportion of the collieries," has usually the argument of a plant-in-being to support his view, coupled with the utilization of fuel a sale for which cannot always, or readily, be found. In some cases waste heat from one source or another may be available. On the other hand, to set against these substantial arguments he has very rarely a complete appreciation of the fact that his power plant, as such, regarded from the point of view of efficiency, is a very indifferent performer indeed. Further, unless he is an exceptional man, his method of keeping power costs may well leave something to be desired in respect of accuracy and completeness, and it is only where accurate records are available that a true comparison of costs can be made. As the result of investigation at a colliery it often transpires that the prevailing idea of the cost per unit of current has its justification more firmly founded on tradition than on measurement. The official figure upon which argument is conducted is often based upon an engine or turbine test under full load, remote in point of time, with a definite steam pressure, dry steam, tight valves, and a sustained vacuum; conditions which the engine or turbine may never have the good fortune to encounter again in the long course of its useful career. It is, at any rate, unusual for a careful record to be kept of the output of the generators on the one hand, or of the amount of fuel burnt in the boiler furnaces and the cost of upkeep and repairs on the other, to say nothing of provision for depreciation, and it is only where such records are kept, and due provision is made, that it is possible for any approach to a close comparison of costs to be made.

An electrical engineer, an emissary of the power company, subjecting a plant such as is above described to friendly scrutiny, concludes at once that from the point of view of efficient power generation he is contemplating an anachronism. He has been taught to believe that the important requirements of a source of power for any industry are reliability, flexibility, and efficiency, and it is most likely that he will regard all three of these first principles as grossly outraged by the plant before him. He further reflects that power-plant equipment is inherently expensive, and he is amazed that it should be considered economically possible to continue to sink capital, bearing interest and depreciation charges of not less than 15 per cent per annum, in power equipment, when there exists the alternative of carrying the whole (or a large proportion) of the cost of power as a working expense, without involving the expenditure of any large capital sum. How flourishing must be the condition of an industry

* W. M. THORNTON: "Researches on the Safe Use of Electricity in Coal Mines," *Journal I.E.E.*, 1924, vol. 62, p. 481.

† *Transactions of the Institution of Mining Engineers*, 1925-26, vol. 70, p. 119.

to which power is a prime necessity and which can afford to pay so little attention to its efficient generation! But the electrical engineer may in his turn harbour some hallucinations. He sometimes fails to appreciate that a saving of even 50 per cent in the cost of power may mean no more than an improvement of 5 or 6 per cent in the pit-head cost of the coal won. He may also overlook the fact that it is the exception rather than the rule for colliery directorates to build up a reserve for the purpose of meeting the cost of modernizing the colliery equipment from time to time, and that lack of funds is therefore sometimes the final and compelling reason for continuing obsolete plant in use for long years after it has served its time and generation. For these reasons many colliery undertakings hesitate long before deciding to use current from an outside source.

The following is, in the author's view, the conclusion of this matter. In many cases the point at issue is regarded too narrowly. It is often determined mainly or solely by a comparison of actual or estimated generating costs with the cost at which power can be purchased, leaving more or less completely out of account the advantages, many of them considerable, which go with the purchase of current from an outside source. Assuming a fairly close degree of correspondence between the rival sets of figures, the question goes some way towards answering itself if its implications are thoroughly appreciated.

The practical advantages which follow from the purchase of current from an outside source are very important. Amongst them are: (1) The ease and quickness with which new machinery can be introduced without the necessity of additional capital outlay on generating plant; (2) the greater reliability, in general, of the supply, because it is the exception rather than the rule to see adequate spare plant provided at a colliery; (3) the convenience of having current "on tap," so that power and light are available at all hours of the day and night, at week-ends and on holidays, without the necessity of employing at these odd times more than the minimum of labour, and (4) the saving of time, money and worry, arising from the fact that the hitherto constantly recurring power problem has been, once and for all, definitely and finally settled. It is of course very difficult to give each of these facilities a cash value, but each of them definitely assists production by enabling the management to reduce idle time, one of the important factors tending towards the present-day diminution of output per employee in British coal mines. The matter of output per employee touches at once upon the most important result which usually follows from an unlimited supply of power, namely the increased *use* of mechanical power. It is only by this means that the output per employee can be increased and the cost of coal lowered without affecting the daily wages of the workers.

There is one other point. The adoption of electricity for winding purposes without heavy first cost, already possible in two or three of the coal-fields, is gradually being made possible elsewhere by the largely increased size of the units of generating plant now being installed in the stations of public supply authorities. Partial electrification of a colliery, leaving out the winding engines and the larger steam engines such as the fan engine, involving only partial shutting down of the colliery boiler plant, sometimes gives a somewhat disappointing result. Many schemes which have been only moderately successful as partial electrifications, have been greatly improved by a complete change-over. The winding engines are usually the last item to be converted, and they are, of course, the largest steam users and the most wasteful of all colliery steam engines.*

For these reasons the author is of opinion that the future will show a growing tendency towards the purchase of power from an outside source. In support of this conclusion it may be pointed out that in the newly developed South Yorkshire and Nottinghamshire coal-fields the larger collieries are gradually being interconnected by a system of transmission mains, so as to cheapen the cost of power by enabling most of the power plants to be shut down at week-ends and on holidays and by utilizing more completely the available reserves of surplus power and spare plant. The collieries are beginning to appreciate that there is, after all, some merit in co-operative working. That is a short step, but a definite one, in the right direction.

The relative importance of the coal-mining and metal-mining industries, and the extent to which electricity is at present being utilized in mines, may be gauged by the information given below, which has been abstracted from Mines Department records:

Coal mines.—The total amount of coal raised in Great Britain in 1924 was 267 061 027 tons, and the number of persons employed 1 213 724.

The total number of coal mines at work in 1924 was 2 855, of which 1 629 were wholly or partly electrically equipped. It follows that 1 226 mines, probably most of them small mines, were still at the end of 1924 without any electrical equipment.

The horse-power of motors installed in and about coal mines at the end of 1924 is given below:

Surface	671 036 h.p.
Underground	810 896 h.p.
Total	1 481 932 h.p.

An analysis of the motive power employed above and below ground shows the following:—

	h.p.
Winding	107 139
Haulage	411 816
Pumping	348 803
Ventilation	102 911
Coal cleaning..	112 660
Coal cutting	92 121
Miscellaneous uses	306 482
Total	1 481 932

* In the December (1925) number of *World Power* there is an interesting statement by Mr. J. F. Perry on the subject of the efficiency of power production at collieries. He says: "It is very clear that even if the efficiency of the power plant is substantially increased it would have little, if any, effect on the present crisis, which only a difference of several shillings per ton can effect." Mr. Perry is of course quite correct, and what he adds later must be read with the general conclusion just mentioned in mind. He goes on to estimate that if the whole of the collieries were electrified the annual consumption of energy would be 4 430 million units, and the annual coal consumption for colliery purposes 3 950 000 tons. The actual coal consumption in 1924 was approximately 16 000 000 tons. A possible saving of 75 per cent of the coal used for colliery purposes is indicated, and even though it is quite clear that Mr. Perry has in mind some approach to a counsel of perfection, the result of his calculation is still very striking.

Taken over the last 10 years the average rate of increase per annum of the horse-power of electric motors installed below ground has been 6·83 per cent. The actual percentage increase of the total horse-power of motors installed below ground at the end of 1924 over the total horse-power installed below ground at the end of 1915 is 73 per cent.

Metalliferous mines.—With reference to the amount of metalliferous ore raised in Great Britain in 1924, the following are the principal items: Iron ore 11 050 589 tons; lead ore 14 294 tons; tin ore 3 546 tons; manganese ore 2 457 tons; zinc ore 2 317 tons. The number of persons employed in metal mining was 19 481.

The total horse-power of motors installed in and about metalliferous mines at the end of 1924 was 23 524. Of this total, 11 753 h.p. is installed on the surface and 11 761 h.p. underground. The chief uses are for pumping (9 391 h.p.) and ore-dressing (2 806 h.p.). The Mines Department records show that the horse-power of electric motors installed above and below ground in metal mines has increased by 17 per cent in 5 years.

The statistics above quoted do not of course give any indication whatever of the total amount of power of all kinds installed in and about the mines, and there is no definite information available from which an up-to-date estimate can be made. The last census of production of the United Kingdom published in 1912 refers to data collected during the year 1907. It was then estimated that the total horse-power of engines in mines and quarries amounted to 2 495 134. It is certain that the horse-power utilized in quarries is comparatively small, and it is, the author thinks, fair to assume that the power utilized in coal mines cannot now be much, if any, less than 3 million h.p. If that total is anywhere near to being correct, it follows from data already given that about one-half the engine capacity in the mines of Great Britain still remains non-electric.

The increase of electrical horse-power in each year is made up of (*a*) conversions from other forms of motive power and (*b*) additional motors. It is probable that the newly installed horse-power due to the former still greatly exceeds the newly installed horse-power due to the latter, and important conversions will continue to be made, for there are coal mines which continue to distribute compressed air from the surface, and more which remain reluctant to carry current beyond the shaft bottom. These decisions may be wise in a few cases, but it is difficult to believe that they are justified in every case that exists.

The above is the main direction in which electrical engineers may look for further extension in the use of electricity in mines. Other important directions are (1) the greater use of inbye machinery in place of hand-putting and pit ponies, (2) the extended use of coal-face machinery, and (3) the extended use of electric safety lamps.

As to (1), the number of pit ponies is steadily, if slowly, decreasing, but in 1924 there were still more that 65 000 employed below ground in British mines. It is reasonable to expect, and to hope for, an accelerated rate of decrease in this number and the gradual establishment of a complete system of mechanical haulage, wherever possible, from the coal face to the shaft.

With regard to (2), there are few places where the increased use of machinery is more desirable than at the working face. The coal-face worker's task is the most severe, and statistics show it to be the most dangerous, of all underground occupations; he therefore needs all the relief that improved conditions of working and efficient mechanical appliances can offer. On the other hand, it may be pointed out that the growth in the use of coal-cutting and coal-conveying machinery in British mines from year to year is disappointingly small. The question involved is one upon which it would be rather out of place for an electrical engineer to hold too decided an opinion, but with less than 20 per cent of the coal output machine-cut, it may reasonably be asked whether an accelerated rate of increase in the number of coal-cutting machines employed, if practicable, would not be one unobjectionable method of increasing the output per employee, the gradual shrinkage of which in most of the coal-fields is one of the present difficulties of the coal-mining industry.

On the subject of (3), no survey would be complete without reference to the continuous and rapid progress which has been made during the last 10 or 15 years in the use of electric safety lamps. In the year 1912 there were only 10 727 electric lamps in use, but progress is best indicated by a short table compiled from the Mines Department records:

Year	Number of electric lamps in use	Number of oil safety lamps in use
1912	10 727	697 664
1916	126 784	610 821
1920	245 900	635 127
1924	356 817	576 318

Miners' electric lamps as now used give not less than 1 candle-power at the end of 9 hours' use. They are fitted into a 2-volt acid or a 2·5-volt alkaline battery, and weigh about 6 lb. More light can of course be obtained, but only at the expense of added bulk and weight, and it has always been a debatable point whether the advantage of additional light is worth the handicap of added weight. Larger and heavier lamps giving more light are, however, beginning to come into use for hewers and others able to hang up their lamps while they are at work. It is unlikely that the electric hand-lamp will displace the oil safety-lamp entirely, but it seems clear that the number of electric lamps will soon exceed the number of oil lamps in use.

In conclusion the author would refer briefly to two further directions in which electrical enterprise and research may hope to be of added assistance. The first is the prospect held out by Prof. W. M. Thornton's experiments of a great improvement in the matter of underground illumination from the ordinary power distribution system, with due and proper regard to all the requirements of safety. The details were explained

by Prof. Thornton in his paper of which mention has already been made. The second has reference to storage-battery locomotives for underground use. This development may well prove to be a very important contribution towards the solution of the pit-pony problem. Electrical engineering is in fact building up the reputation of an ever-ready help to the mining industry. The steam engine in its early days was often referred to as "the right arm of mining operations." It may not unreasonably be claimed that the position once held by the steam engine is now, in 1926, firmly occupied by electricity.

Discussion before the Institution, 8 April, 1926, on the Three Papers by Mr. S. Mavor, Mr. L. Miller and Mr. R. Nelson, Respectively.

Mr. J. A. B. Horsley: Mr. Mavor refers to the priceless advantage possessed by electrically-operated machinery in that the power can be easily and accurately measured, and it may be of interest to mention that portable graphic recorders are used in at least one colliery to check the working of electrical coal-cutters. Critical examination of the charts enables the management to compare the handling of the machine by different men and to correct errors of operation. The extraordinary conditions which have to be faced by the designer as if they were normal are well illustrated in the paper. Nature and man seem to conspire to destroy the machine, and I may illustrate this by reciting the circumstances of a fatal accident described in my Annual Report for 1924. A bar coal-cutting machine had become wedged between roof and floor in a 19-in. seam, and, in the attempt to free it by using the power of the motor, first the haulage drum was broken, next the haulage prop and then the haulage rope. The drum was designed with an adjustable slipping clutch to limit the stress and there were fuses in the circuit at the gate-end box, but these "safety valves" had been "attended to." The victim in this case was working under the direction of an under-official of the mine. The difficulty of maintaining flame-proof enclosures intact under conditions which this accident illustrates is indeed great. In the Prussian code of mining regulations there is a requirement that for underground use the covers of electrical apparatus shall be so fixed that they can only be removed by the use of a special tool. The principle implied is one that I have suggested to manufacturers here, i.e. that it should be made difficult for unauthorized persons to meddle with such enclosures. I am inclined to agree with Mr. Mavor's view that the permissibility of electrical equipment, i.e. the avoidance of the risk of explosion, lies rather with the maintenance of adequate ventilation than with the design of the electrical enclosure, but much may be done to facilitate proper maintenance.

Coming to Mr. Miller's paper, that there is a field for storage-battery locomotives in coal mines must be admitted in view of the considerable use made of such tractors in America and in Germany, and it is unfortunate that Mr. Miller has not been able to support his advocacy by figures of the actual operating costs. There are about a dozen collieries and half as many metalliferous mines in Britain where storage-battery locomotives have been introduced. In one of the latter the battery is also used to furnish the energy for operating rotary drills. Although the service required of locomotives is in no way comparable with that required of coal-face machinery, the same problem of proper maintenance must be faced by the management, for the battery is not amenable to design which can make it proof against continued misuse. Mr. Miller refers to the competition for a prize offered by Mr. Markham, a coal-owner, and as one of the judges in that competition I may say that our report will shortly be published by the Mines Department. Some of the provisions of our Specification were criticized on the ground that it would have been more logical to have adapted a mine to suit the characteristics of the storage-battery locomotive than to have called for a freak locomotive to meet the existing mining conditions, but the makers of coal-face machinery, as we have heard to-night, did not find that short cut to success, although one willingly agrees that to get the best results it is necessary to adapt or modify mining methods to the medium that is employed. The field trials of the locomotives proved, so far as the competing vehicles were concerned, the superior efficiency of the single-motor design, provided the design is skilful and adapted to the peculiar service conditions to be met. The prize-winning vehicle only required one-third of the capacity of the battery as compared with one-half for the next most efficient vehicle, while running over a test route which was designed to represent the average work of one shift. Autographic records, obtained with the assistance of Mr. George Watson's dynamometer, showed the rather surprising figure of 57 lb. per ton for the rolling resistance of the load. The actual draw-bar pull recorded ranged from 740 to 775 lb. with a load of 5 tons on a gradient of 1 in 24. On the subject of flame-proof enclosure, nothing better than total enclosure with plain machined flanges can be applied to the enclosure of electrical apparatus for which free ventilation is not essential. The use of gauze or of anything approximating in fragility to that medium should be avoided, and intricate devices, however ingenious, are quite unsuitable for colliery conditions as they exist to-day. Ventilation may be necessary for the battery; it is certainly not required elsewhere, and if some flame-proof ventilating device is employed it should be subject to the same sort of daily scrutiny as that which the miners' safety lamps undergo.

Coming to Mr. Nelson's paper, perhaps I can most usefully contribute to the discussion by supplementing the statistical data that he quotes, and I shall refer first to the proportion of mines without electrical equipment, for this varies widely in different parts of the coal-field. For example, in Scotland 72 per cent have electrical equipment as compared with less than 54 per cent for the rest of the country. In South

Wales and Monmouth 58 per cent are equipped, whilst for Northumberland and Durham the figure is 59½ per cent and for Nottinghamshire 88 per cent. South and West Yorkshire taken together approximate to South Wales, having 57½ per cent equipped. Taking North Staffordshire with Cannock Chase the figure is 55½ per cent, falling to 53 per cent for Lancashire and Cheshire and to less than 17 per cent for South Staffordshire and Worcestershire. The horse-power of electrical motors installed both above and below ground per mine also varies considerably in different areas. The average for the whole country is 910 h.p. Reviewing the 25 districts, mostly separate counties which are detailed in my annual report, there were 4 averaging 300 h.p. or thereabouts per mine, 9 averaging 600 h.p. or thereabouts, and 12 averaging from 900 to 1 600 h.p. per mine. As we have been discussing coal-cutting and other coal-face machinery it may be interesting if I give some figures showing the proportion of the total h.p. installed for these services. For the whole country the figure was 6·22 per cent; for Scotland alone the proportion was 16·6 per cent, and in South Wales two-thirds of 1 per cent. In the Newport and Cardiff division of South Wales 362 000 tons of coal were cut by electrical means and 2 070 000 tons by compressed air, out of a total of nearly 37 million tons got. In the Swansea division the position as to electricity and compressed air is reversed, 168 500 tons being cut by the former and 19 500 by the latter, out of a total of rather more than 15 million tons. All my figures refer to the year 1924. It can therefore be seen that, great as has been the growth of electrical equipment at collieries since 1912, there is still ample scope for development if and when the mining engineer succeeds in so controlling the natural conditions—where they are in his opinion at present antagonistic to the introduction of electricity—as to make it safe to do so. I suggest that the advantage of electricity in mining lies not so much in the lesser consumption of low-grade fuel for the production of the power, but in the greater output that can be obtained by its use and in the ease and flexibility, to use general terms, of its application.

Mr. Roger T. Smith: Mr. Miller points out in his paper that a case can only be made out in this country for the use of battery locomotives in thin seams, either for gathering or for marshalling, and that where there are thick seams the conveyor will beat the locomotive. I think, however, that that has yet to be proved, as there are so comparatively few battery locomotives in use, and, as Mr. Miller confesses, he has no figures to offer for working costs. Therefore we have yet to find out how many pit ponies, on the average, a locomotive can replace. On page 1004 Mr. Miller gives the limitations placed on the design. In the third limitation he says "ample clearance must be allowed underneath the locomotive to clear obstructions on the main haulage road." When, as in the Markham competition, the height of the locomotive is limited to 42 in. (which is about the height that will normally be necessary for a battery locomotive in this country), the wheel diameter cannot be greater than 22 in., and then only if worm gear is used. In the design that won the prize, worm gear was used, with that maximum diameter of wheel. In such a case it is quite easy to design a locomotive to clear all the obstructions which there are—tub-greasers, pulleys and other things—on the track. Mr. Miller, however, later on advocates chain gearing. If chain gearing is adopted the diameter of the wheel is decreased. Not only does chain gearing decrease the clearance but it adds the danger that in derailment the locomotive might be so placed across the rails that the whole or much of its weight comes on the gear case; and it is very expensive to design a gear case which will stand that. In limitation No. (4) the author says: "The locomotive must also be capable of giving sufficient adhesion to pull at least a load of 5 tons on a grade of 1 in 20 and have a speed on the level of about 3½ miles per hour when pulling the same load." I think he has been a little pessimistic in his speeds. It is quite easy to design a locomotive to pull 5 tons at 3½ m.p.h. up a gradient of 1 in 20, and to have a corresponding speed of 5 or 6 m.p.h. on the level. In the trials of the five locomotives for the Markham Prize every single locomotive which competed fulfilled that condition, which was one of the specified conditions, but with a gradient of 1 in 24 instead of 1 in 20. Mr. Horsley has dealt with the question of one electric motor as against two. I would only add that I think there is a very good reason why one motor should be more efficient than two from a consideration of their size. After all, in such little locomotives as were tested for the Markham Prize the one which won the prize had only an 8-h.p. motor, and when two motors of 4 h.p. are used the efficiency falls very considerably. It ought also to be mentioned that all the advice which Mr. Miller gives in his paper about the use of ball bearings and roller bearings on every possible rolling surface had been faithfully carried out in the winning locomotive, and it was due to that, as well as to the single motor, that it was so appreciably more efficient than any of the others.

Mr. W. B. Woodhouse: I have been interested in using power in mines for a good many years, and I know there has been a very marked change of practice. To-day, although air measurements are not general and although even electrical measurements are not as general as they should be, the mining engineer is beginning to measure accurately; and the more accurate he becomes in his measurements the more is he convinced of the advantages of certain pieces of apparatus such as the electrical cutters which Mr. Mavor has described. I think we owe him a debt of gratitude for having emphasized for so many years the importance of getting accurate data on which to base conclusions. The comparison of the amount of power taken by the electric coal-cutter and the compressed-air coal-cutter is perhaps an interesting comment on a recent statement which compared the relative efficiency of transmitting electricity and compressed air. I believe that compressed air was stated to be the more efficient and the more efficiently transmitted. The really important matter which was omitted and with which Mr. Mavor has dealt, was the efficiency of use.

As to Mr. Miller's paper, the use of electric batteries in coal mines in those parts of England in which I am interested is not, I think, likely to be very great, but there must be a field for them, and it is satisfactory to

know that electrical engineers are dealing with the matter so efficiently.

Mr. Nelson makes one reference which is of special interest to me, and that is to the question of the source of power for collieries. I found, as he says, that many estimates of the relative cost of producing power on the spot or buying it from somewhere else are made in the absence of measurement of the amount of power. I have been solemnly informed in many cases that the cost of production was a certain fraction of a penny, whereas I have discovered by observation that there were no means of arriving at the number of units used, that the total consumption was merely estimated, and that the price per unit was guessed at. With regard to estimating costs, I have found the difficulty as to capital charges which Mr. Nelson mentions, partly due to the habit of the mining people—which is perhaps also the habit of people in any fluctuating trade—of spending money when they have it and not making any regular allocation of capital charges. The principal obstacle in the way of a general adoption of a public supply of electricity has, I think, been the steam winder. The very high cost of electric winders before the war was an obstacle. There was the additional obstacle to which Mr. Nelson refers, namely, the absence of a sufficiently powerful system of public supply to deal with winders. To-day, however, we have large systems with very large amounts of power behind them, and the fluctuation of load due to a 1 000- or 2 000-h.p. winder is negligible; the system can deal with it. Therefore we can use, and are using, three-phase winders at a much reduced first cost. I feel sure that as existing steam winders fall out of use, and as the complications and inefficiency of the exhaust turbine steam-winder combination become emphasized by age, the number of pits without any steam at all will increase and the public supply will be more and more used.

Mr. E. T. Williams: I should like to support Mr. Mavor's contention with reference to the inefficiency of compressed air. Extensive experience of compressed air and electrical operations running side by side has convinced me that those who used compressed air very often failed to realize the true factors. It was only when those factors were pointed out to them by technical people that they realized how great was the inefficiency of the compressed-air systems. One point alone which they often overlooked was that where there were very long compressed-air pipe lines there were often a large number of small leakages. These small leakages in the aggregate constituted a very large loss in a 24-hour day. In connection with cables, we know it is a serious problem to get cables to withstand the arduous conditions in mines. I may state that a cable has been devised for the use of the Navy in which a tough rubber sheathing is reinforced with a cord canvas. We have carried out a great many trials both in the works and at sea, and this cable has given most satisfactory results. I think that mining engineers should know of this recent advance in cable design.

I believe that we are coming to a transition period when things are going to change very much in both coal-mining and in electricity supply. Referring to Mr. Nelson's paper, in his summary he says: "The conclusion is ultimately drawn that one-half the motive power of the mines of Great Britain still remains non-electric." Then in Mr. Mavor's paper there is the remark: "It must be accepted that electricity will continue to be excluded from the coal face in many collieries, but the number of these may be reduced by fuller knowledge," and in the very last paragraph of the paper it is stated: "By mechanical and electrical aids to production the output per man can be increased, wages and the status of the miner can be raised, and the cost and price of coal can be reduced." I should like to submit that the importance of the coal industry to this country, the economic crisis through which we are passing, and the new developments which are about to take place electrically, are such that the Council should consider the appointment of a Committee to examine the question of how the use of electricity in mines might be extended and developed.

Mr. F. T. Hall: I should like to ask Mr. Mavor if it is now the practice in any of the mines where it is not considered safe by the management to have electric coal-cutters at the face, to employ an electrically driven compressor in some neighbouring place which is well ventilated. In my early days I was employed by a company which did a good deal of pioneer work on coal-cutters, and we found it was expedient sometimes to get in by that means. One of our arguments was that we thereby improved the ventilation at the face by the exhaust from the compressor.

Dr. W. M. Thornton: My feeling is that, in its flexibility and efficiency, electricity is really ideal for mines. If there were no such thing as gas in mines, electricity would be universally used. Therefore the question really resolves itself into one of safety. My own feeling is that where there is gas, electricity ought not to be used except at voltages at which it is more than usually safe—25 volts, for example. If it were practicable to run a flood-lighting system at 25 volts at the face I am quite sure it would have an extraordinary beneficial effect in mining, especially from the psychological point of view. I take it that underground we are still in the candle-light stage. When we are able to get underground the same amount of lighting as we have in this lecture theatre I think the psychological effect and stimulus will be very great. With regard to the use of locomotives, I think the chief motive has been a humanitarian one rather than any question of economy in haulage. I suggest that there is a very important field still to be worked with regard to mining, and that is in connection with the education of the young miner. Mr. Horsley and other speakers have said that one thing which is acting against the use of electricity in mines at the present time is imperfect maintenance. It will never be possible to ensure maintenance until those who are working with the apparatus have a thorough knowledge of it. When that happens there will not be those deplorable slips in maintenance with which we are all familiar at the present time. I suggest that this question of education might be taken up, if not by this Institution then by some allied Association.

Mr. C. E. Sayer: At the end of his paper Mr. Mavor says, after speaking of the services which the mechanical

and electrical engineer have rendered to the mining industry: " The output per underground worker is too low, therefore too many men are in the industry—that is why wages are low and costs are high." This seems rather to support the case of the average worker, that if they abandon the " go-slow " principle they will cause more unemployment by throwing men out of work. This perhaps might be better expressed by saying that under existing conditions there are too many men in any given pit, and that by the adoption of more mechanical processes in the coal-field and raising the output per man the return obtainable from mining would become so increased that, although fewer men would be required in any given pit for its present total output, the balance would be adjusted, and the number of men employed in the industry would even be increased by the impetus which would be given to coal-mining in general.

Mr. Christopher Jones: Mr. Horsley has raised some very interesting points, one in particular referring to the Prussian Government specification regarding concealed bolts and nuts. This could with advantage be taken up by British manufacturers in connection with coal-cutter and conveying machinery, as my experience is that it is quite common for the engineer in charge to have to be continually instructing workmen as to the necessity of making sure that all such bolts and nuts are in proper order. The question of using recording meters in connection with coal-cutter circuits is also very interesting. Certainly such meters are of great assistance in checking consumption in the operation of the machines, as pointed out by Mr. Mavor in regard to faulty picks. It is, however, not always convenient to adopt such instruments inbye in mines, owing to their delicacy. I should like to know whether an inkless type of recording meter is made. We are now introducing portable watt-hour meters in connection with gate-end switches for this purpose. Mr. Mavor has not referred to the Arcwall machine, which is a type now being largely introduced in the mines. With such machines the question of a proper design of trailing cable is a very important matter. I have been a strong advocate of a trailing cable designed with all cores protected by means of Ferflex braiding and have had one in use successfully for three years, but recent supplies of similar cable have proved unsatisfactory. Such cables are trailed considerable distances when 30 to 40 heads are cut per shift. Mr. Williams has referred to a special cable used by the Admiralty and I should be glad to have further particulars of this type. Mr. Mavor has referred to the electric rock drill as not being a success. This is also my experience and mining engineers would welcome a design similar in weight to the compressed-air rock and coal drill as it generally means the installation of an inbye compressor, and, with the advent of coal-cutters and conveyors, hand-drilling operations for blasting purposes delay matters considerably. Mr. Mavor refers to the increased use of coal-cutters since the introduction of alternating current to the mines, but I know of a d.c. coal-cutter installation which has been running successfully for the past 16 years. Mr. Foggo, the manager of Cannock Chase Colliery, has recently been to the United States investigating machine mining. He informs me that most of the installations which he visited had d.c. supplies.

With regard to electric locomotives generally, the conditions in this country are not suitable for adopting these without a great deal of expenditure in alteration of roadways and the replacement of light rails by those of heavier type, which is found necessary. For new mines no doubt there is a large field and a good case can be made for the introduction of such locomotives.

I am in general agreement with the points raised in Mr. Nelson's paper.

Mr. H. Rainford (*communicated*): Under the heading of " Flame-proof enclosure of the electrical gear," Mr. Miller draws attention to the Safety in Mines Research Board Paper No. 5, by Statham and Wheeler, on " Flange Protection." He states that although Messrs. Statham and Wheeler have not dealt with the alternative methods of protection, the matter has been dealt with by the American Bureau of Mines and several Continental investigators. I should like to take this opportunity, therefore, of pointing out that the report on " Flange Protection " was Part I of a research on " Flame-proof electrical apparatus " and that since its publication a considerable amount of work has been done by the Safety in Mines Research Board in conjunction with the British Electrical and Allied Industries Research Association on the alternative methods of protection. Experimental work has been carried out on gauze and perforated-plate protection and a report on this work is now in course of publication as Part II of the researches already mentioned. Experimental work has also recently been completed on a " Plate protective device " of the " annular ring " type, and a report on this device is in the hands of the E.R.A. The author states that nowadays none of these alternative methods is being used, reliance being placed almost entirely on flange protection. Whilst, undoubtedly, flange protection is used in a large number of instances, it is worth while noting that of the pieces of apparatus which have been tested for " flame-proofness " by the Mining Department of Sheffield University (under the direction of Professor Statham) quite a number (33 per cent during the past twelve months) have been fitted with other protective devices. In particular the plate protective device, both of the rectangular-plate and annular-ring types, has been used quite successfully. With regard to the strength of these devices, the gauze and perforated-plate types are undoubtedly mechanically weak and it is necessary to protect them by means of some form of wire grid or spring cover. The plate-protective device of the annular-ring type, however, is of a robust nature, the rings being assembled by threading them on bolts and spacing them apart by means of washers. To keep the rings in position and to close the inner hole, a strong metal plate is bolted down to them. This plate, especially if it is extended down the sides of the rings in the form of an inverted metal cap, gives ample protection to the rings from damage by outside forces. The question of incorrect assembly of any of these devices depends entirely on the maintenance of the apparatus and it is essential that flame-proof apparatus should be periodically examined by one who can

appreciate the difference between a flame-proof enclosure and an ordinary enclosure, and who is familiar with the devices used. Mr. Miller raises the important question of the evolution of hydrogen in the battery casing of the locomotive, when the battery is being charged. Ventilation of the casing is therefore important and it is suggested that one or more flame-proof relief devices could be mounted on the casing, so arranged that the windage of the motor would promote ventilation through them.

The Authors' Replies to the Discussion.

Mr. S. Mavor (*in reply*) : The discussion on my paper, being chiefly supplementary, calls for cordial acknowledgment to the contributors and only brief reply. Mr. Horsley and Mr. Woodhouse emphasize the value of measurement, especially by recording instruments. Graphic records both of pressures and quantities of electricity and compressed air, when interpreted with intimate knowledge of the nature of the operations concerned, are most instructive and suggestive guides to improved efficiency in application of such machines as coal-cutters and conveyors, and also to economy in the use of power.

In reply to Mr. Hall's question regarding the use of inbye air-compressors for the supply of compressed air to coal-cutters, it may be said that this arrangement is technically, but not economically, feasible. It is necessary with such an arrangement that the power of the motor driving the compressor shall be between 3 and 4 times the power to be developed by the coal-cutter ; the stand-by losses and light-load losses, even when automatic control gear is used, are further handicaps. The arrangement referred to has been tried in a few cases, but so far as I know no example survives in service. Many portable or semi-portable electrically-driven inbye compressors of comparatively small size are used for power supply to percussive drills. The drills, one or two from each compressor, are for boring shot-holes in the coal face, or for shot-holes in stone ripped to make height in roadways. When compressed-air drills are used in the confined space of a heading the air exhausted from them contributes materially to ventilation ; but in the case of a longwall coal-cutter, although it uses from 6 to 12 times the amount of air required by a drill, the volume of air exhausted is so little compared with the ventilating air current that is swept along the face, that its effect on ventilation is almost negligible.

Mr. L. Miller (*in reply*) : I am very glad to hear that Mr. Horsley is of opinion that there is a field for battery locomotives. I presume he agrees that their application will be considered in such cases where the conveyor system would not be justified on the score of expense. I agree with Mr. Horsley that it would be economically impossible to ask the collieries to re-design their roadways to suit the battery locomotive.

Mr. Horsley and Mr. Roger Smith both refer to the trials of the Markham Competition locomotives as having proved, as far as the competing vehicles were concerned, that the single-motor drive was more efficient. Mr. Roger Smith is of opinion that the better performance obtained was partly due to the higher efficiency of a single 8-h.p. motor as compared to two 4-h.p. motors, but I have read through the report of the trials and I cannot agree with the conclusion that both these gentlemen have arrived at. In the first case I should like to point out that the winning locomotive was not the only single-motor design tested ; there was at least one other that competed in the trials. This, however, had a very much larger consumption than the two-motor design ; therefore, on the face of it, the conclusion that a single-motor design is more efficient cannot be arrived at as a result of these tests. As a matter of fact, a single 8-h.p. motor as compared with a 4-h.p. motor of a design that will be used on such a locomotive would have a higher efficiency. This difference of efficiency would amount to at the most about 4 per cent. I should like to add that all I claim for the two-motor design is that it enables resistances to be done away with. I think that Mr. Horsley and Mr. Roger Smith will both agree that it is possible to absorb considerably more than 4 per cent in resistances if very much manœuvring at low speeds has to be done. I think that the results obtained with the other single-motor drive partly prove this. Apart from this, however, there is the resistance to be accommodated on the locomotive. This has to be fitted in a flame-proof cover and should be ventilated if it is to be kept to reasonable dimensions. This is not a difficult thing to accomplish but it adds a piece of apparatus which is likely to break down unless made of very considerable dimensions. It is only fair to observe that the enclosure of the resistances on the winning locomotive was not flame-proof.

Mr. Horsley refers to the consumption figures obtained on the locomotive trials. I am definitely of opinion that such consumption figures are of very little value as far as a comparison of the locomotive is concerned. I presume there is some reason why so much importance was attached to these consumption figures but, as I explained in the first part of the paper, the cost of power is such a very small item in colliery costs that the power consumed by these locomotives cannot have any bearing on them. The only advantage a lower consumption gives is a reduction in the size of the battery. These figures appear to have been regarded as a measure of the efficiency of the locomotive and it appears to have been forgotten that they also include a measure of the efficiency of the driver and to a certain extent a measure of the condition of the rails. For instance, if the rails are greasy due to rain, slipping will take place and power will be lost. If the single-motor drive having the very large consumption be compared with the winner, since the power required to pull the load must be the same, it is quite impossible to believe that this difference is due to the higher efficiency of the motor, gearing and axle bearings on the winning locomotive. The motor may be responsible for 2 per cent difference, the gearing for perhaps 3 per cent, and even assuming the axle bearings to take 57 lb. per ton to

overcome friction, such a figure could not be obtained for the consumption unless the driver were running on resistance notches for a large proportion of the time and not taking full advantage of coasting at the ends of the journeys and wherever possible. This is an example of very bad driving. The winning locomotive is an example of extremely efficient driving. To prove this I have analysed the figures for the winning locomotive. In making this analysis I have taken a load of 5·03 tons over the test route as shown in the chart attached to the report. The calculation is as follows :—

Power consumption for 30 trips consisting of 10 trips on each of the 3 routes shown on the plan attached to the judges' report of the trials of mining locomotives entered for the Markham Competition.

Weight of locomotive = 3·15 tons.
Weight of load = 5·03 tons.

Total weight = 8·18 tons.

I shall ignore the power required to drive the locomotive and take the drawbar pull as 57 lb. per ton as given in Mr. Watson's report.

Route (1) *including water-splash*.—This is the route on which the two diagrams showing the pull were obtained by Mr. Watson.

Section (*a*). 57 yds. ; 1 in 30 gradient.

Outward journey :

Work done (friction) (ft.-lb.)

$$= 57 \times 5{\cdot}03 \times 57 \times 3 \times 10 = 490\,274$$

Work done (gravity)

$$= \frac{8{\cdot}18 \times 2\,240}{30} \times 57 \times 3 \times 10 = 1\,045\,000$$

Inward journey : Train coasts.

Section (*b*). 50 yds. ; 1 in 24 gradient.

Outward journey :

Work done (friction)

$$= 57 \times 5{\cdot}03 \times 50 \times 3 \times 10 = 430\,000$$

Work done (gravity)

$$= \frac{8{\cdot}18 \times 2\,240}{24} \times 50 \times 3 \times 10 = 1\,146\,000$$

Inward journey : Train coasts.

Section (*c*). 100 yds. level.

Outward journey :

Work done (friction)

$$= 57 \times 5{\cdot}03 \times 100 \times 3 \times 10 = 860\,130$$

Inward journey :

Work done (friction)

$$= 57 \times 5{\cdot}03 \times 100 \times 3 \times 10 = 860\,130$$

Total 4 831 534

This figure ignores flange friction at curves.

If we take the diagrams prepared by Mr. Watson showing the pull required for this route, the average pull for the first test comes out at 555 lb. and for the second test at 568 lb. (average 560 lb.). This is only for the outward journeys.

∴ Work done

$$= 207 \times 3 \times 10 \times 560 + 860\,000 = 4\,340\,000 \text{ ft.-lb.}$$

This checks as closely as can be expected with the first figure obtained of 4 831 534 ft.-lb. Since the latter figure is, however, likely to be more accurate this will be taken for the purpose of the calculation.

$$\text{Consumption} = \frac{4\,340\,000}{2\,650\,000} = 1{\cdot}64 \text{ kWh}$$

Route (2).—This is the route proceeding up the same road as No. 1 but turning off at about the centre.

Section (*a*). 57 yds. ; 1 in 30 gradient.

Outward journey :

Work done (friction and gravity)—same as Section (*a*) (Route 1) = 1 535 274 ft.-lb.

Inward journey : Train coasts.

Section (*b*). 100 yds. ; 1 in 72 gradient.

Outward journey :

Work done (friction)

$$= 57 \times 5{\cdot}03 \times 100 \times 3 \times 10 = 860\,130$$

Work done (gravity)

$$= \frac{8{\cdot}18 \times 2\,240}{72} \times 100 \times 3 \times 10 = 763\,440$$

Inward journey :

$$\left[(57 \times 5{\cdot}03) - \frac{(8{\cdot}18 \times 2\,240)}{72}\right] \times 100 \times 3 \times 10 = 96\,000$$

3 254 844

No diagram is given for this route so that this cannot be checked.

$$\text{Consumption} = \frac{3\,254\,844}{2\,650\,000} = 1{\cdot}23 \text{ kWh}$$

Route (3).—This is the route along the road marked " Main Haulage Road " on the plan.

132 yds. ; 1 in 36 gradient.

Outward journey :

Work done (friction) (ft.-lb.)

$$= 57 \times 5{\cdot}03 \times 132 \times 3 \times 10 = 1\,135\,371$$

Work done (gravity)

$$= \frac{8{\cdot}18 \times 2\,240}{36} \times 132 \times 3 \times 10 = 2\,016\,000$$

3 151 371

Inward journey : Train coasts.

$$\text{Consumption} = \frac{3\,151\,371}{2\,650\,000} = 1{\cdot}19 \text{ kWh}$$

Total kWh for 30 journeys over 3 routes :—

	kWh
Route (1)	1·64
„ (2)	1·23
„ (3)	1·1
	4·06

If this is reduced in the ratio of miles calculated to miles given in schedule, the figure becomes

$$\frac{5\cdot 36}{5\cdot 63} \times \frac{4\cdot 06}{1} = 3\cdot 87 \text{ kWh.}$$

In making this calculation it will be observed that no allowance at all has been made for the friction of the locomotive axles, flange friction of the locomotive, losses in braking at the end of the journeys, and losses in resistances, motors and gearing; also the mileage appears to be slightly different from that given in the schedule.

In the case worked out above a mileage of **3·95** with power and **1·68** coasting, totalling **5·63** miles, has been included; the figures given for mileage in the schedule are **3·25** miles with power, **2·11** miles coasting, giving a total of 5·36 miles. It would appear from these latter figures that the gradient of 1 in 72 has been included as one on which coasting can be accomplished; this is not true, however, if a train resistance of 57 lb. per ton is experienced. However, since the mileage given in the schedule is slightly different, the total kWh have been adjusted in proportion and become **3·87** kWh for the load.

The motors of the size employed on these locomotives will have an efficiency of not higher than 87 per cent, and the gearing, including connecting rods, etc., cannot have a much higher efficiency than 95 per cent. The energy at the axle of the locomotive will therefore be $5\cdot 7 \times 0\cdot 87 \times 0\cdot 95 = 4\cdot 7$ kWh. Subtracting from this the energy required to move the load, which is **3·87** kWh, 0·83 kWh is left to overcome locomotive friction, losses in the resistances, energy loss in braking at the ends of the journeys and flange friction of the locomotive. This indicates a very remarkable performance on the part of the driver, especially when it is realized that if the whole of this power was absorbed in friction at the axles and flange friction it only represents a resistance of 35 lb. per ton for the locomotive.

Such an analysis as is made here on the trial figures can only be approximate on the data which is available, and is only intended to show that great importance cannot be attached to them. It seems a pity that while the trial track and locomotives were available, considerably more detailed information was not obtained and that the report did not analyse more fully the data so as to indicate where losses were taking place. An opportunity appears to have been missed to obtain very valuable design data.

It is also quite clear that the ball bearings on the locomotive have had an even larger influence in reducing the consumption than has been indicated in the paper. The losses due to wheels slipping must be very small indeed and the track must have been in perfect condition. It is also perfectly clear that practically no losses have taken place in the resistances and that the driver never ran for any length of time on the resistance notches. This is a condition which would not obtain in practice and therefore these figures cannot be used to prove that the two-motor design is less efficient in actual operation than the single motor.

With regard to the question of flame-proof enclosure, I am glad to see that Mr. Horsley agrees with me that plain machine flanges represent the best solution of this problem.

I quite agree with Mr. Roger Smith that the statement made with regard to the scope of the battery locomotive in this country is only an expression of opinion and has yet to be proved. With regard to the question of wheel diameter, I should like to point out that if a wheel diameter of 22 in. is adopted this will result in a reduction in the height of the battery box which is certainly not desirable on a locomotive performing the rough service which this mining locomotive will be called upon to do. I cannot follow Mr. Roger Smith in his argument that the adoption of chain gearing restricts the size of the driving wheel; the restriction to the size of the wheel is in the height of the battery box, not the adoption of chain drive. I also do not agree with Mr. Roger Smith in his assumption that in the case of derailment the gear case enclosing the chain drive is likely to get damaged. There is no difficulty in avoiding any danger of damage to the gear due to such an accident. There is, however, some slight difficulty in avoiding a similar danger with the connecting rod which is usually employed with the single-motor drive. Mr. Roger Smith is quite correct with regard to the question of speed. The 3½ miles per hour given in the paper is a figure put in so as not to clash with a similar figure given in the specification issued for the Markham Competition. The desirable speed will depend very greatly on the type of mine in which the locomotive is to be installed, but in the majority of cases it is advantageous to run at a higher speed than the one given. The final point which Mr. Roger Smith raises has been dealt with in the reply to Mr. Horsley's remarks.

With regard to Dr. Thornton's remarks, I think that Mr. Markham was certainly influenced from the humanitarian point of view in offering a prize, but, of course, there is always the question of economy to consider.

I do not entirely agree with Mr. Jones with regard to the question of the expenditure entailed in altering roadways and replacing light rails when it is intended to use a locomotive. This may be true of certain pits, but in others a locomotive can be substituted with practically no alteration at all to the weight of rails. A locomotive of the type suggested in the paper will function on almost any colliery rail.

With regard to Mr. Rainford's remarks, I was referring to the time at which the paper was written when I made the statement that Messrs. Statham and Wheeler had not dealt with the alternative method of protection. I knew that their report on flange protection would be followed by further reports. Mr. Rainford credits me with saying that none of the alternative methods is being used. This is incorrect; the statement made was as follows: "It is significant that 15 years ago manufacturers were experimenting with devices of this kind, but nowadays none of these are being used by the people concerned in these experiments. They have practically all adopted flange protection." It is the people who were conducting experiments 15 years ago who have adopted flange protection and I think I am correct in this statement.

I have read Mr. Rainford's description of the plate protecting device which is similar to one experimented

with many years ago. I am still of opinion that in ordinary colliery service such a device is not satisfactory.

With regard to the battery casing, surely the easiest way is to provide the whole casing with a sufficiently wide flange to enable a reasonable gap to be maintained which will be sufficient to provide ample ventilation and yet maintain its flame-proof characteristic.

Mr. R. Nelson (*in reply*) : In replying to the short discussion on my paper, I should like first to make the general comment that no one appeared to differ from the view expressed on the main point I tried to make, namely that it is better in most cases to purchase current, where that procedure is possible, than to generate it. Apart from this, I have chiefly to acknowledge contributions from various speakers, notably Mr. Horsley and Mr. Woodhouse, to the general information on the subject matter of the paper. It is clear from the data given by Mr. Mavor on the subject of machine mining in Scotland, supplemented by Mr. Horsley's statistics for the rest of the country, that Scotland at any rate compares favourably with America in the matter of the use of coal-face machinery. That fact is encouraging, even if certain of the English districts still lag well behind. Mr. Horsley will perhaps allow me to repeat and endorse his last observation, which was to the effect that the advantage of electricity in mining lies mainly in the greater output that can be obtained by its use and in the ease and flexibility of its application.

One of Mr. Woodhouse's most interesting statements was that in which he expressed the belief that as the complications and inefficiencies of the once fashionable steam-winder and exhaust-turbine combination become emphasized by age, the number of pits without any steam at all will increase and the public supply will be more and more used. That statement will, I think, prove to be a correct forecast of future development.

Mr. Williams directed attention to a conclusion drawn by me from published statistics, namely that about one-half the motive power of the mines of Great Britain still remains non-electric, and also to two statements by Mr. Mavor, namely that " it must be accepted that electricity will continue to be excluded from the coal face in many collieries, but the number of these may be reduced by fuller knowledge," and that " by mechanical and electrical aids to production the output per man can be increased, wages and the status of the miner can be raised, and the cost and price of coal can be reduced." Mr. Williams went on to suggest that the Council of this Institution might consider the appointment of a Committee to examine the question of how far the extended use of electricity in mines might assist the mining industry in its present difficulties. That is, I think, an interesting and helpful suggestion, but one which would be more likely to have a practical result if the Institution of Mining Engineers could be induced to assist by appointing one-half of such a Joint Committee of investigation.

In acknowledging Dr. Thornton's contribution, I only desire to endorse his view that flood-lighting a coal face would probably have important psychological as well as practical results. The chief difficulty of the miner's occupation, and the direction in which he most deserves sympathy and consideration, arises from the dim, uncertain light in which he is obliged to spend the greater part of each working day. . It is probable that better lighting below ground, progressively introduced, as no doubt it will be, will tend definitely to diminish "absenteeism," which, as the Royal Commission's Report shows, is one of the major difficulties of the mining industry.

It is gratifying to me to find general support for the views and opinions expressed in the paper.

THE FREQUENCY CHARACTERISTICS OF TELEPHONE SYSTEMS AND AUDIO-FREQUENCY APPARATUS, AND THEIR MEASUREMENT.

By B. S. Cohen, Member, A. J. Aldridge, Associate Member, and W. West, B.A., Student.

(*Paper first received* 19*th January, and in final form* 23*rd March,* 1926; *read before* The Institution 29*th April,* 1926.)

Summary.

The value is demonstrated of the frequency/amplitude characteristics of telephone systems or apparatus in determining the transmission efficiency, including volume and articulation efficiency. The audio-frequency ranges of importance for speech and music are then considered.

Methods are described for the direct and indirect production of constant acoustic output over the audio range, and the calibration of acoustic measuring instruments is dealt with.

The next section of the paper deals with the production of electrical energy of constant value over the required frequency range, and a description is given of a special form of oscillator, together with associated apparatus for the direct recording of frequency characteristics.

The concluding part of the paper gives frequency characteristics of each part of the apparatus used in a telephone connection, and also of audio-frequency amplifiers and loud-speakers. For the purely electrical portions of the circuit, current or voltage characteristics are given, whilst for apparatus such as transmitters and receivers the characteristics are given in terms of acoustic pressures on the diaphragm. The characteristics of some commercial types of granular transmitters are first given, then under the heading of receivers will be found the characteristics of both the Bell pattern and some typical loud-speakers of the horn and hornless types. Particulars are given of apparatus designed to measure diaphragm motion, some results obtained by an aural balancing method being included.

In the section dealing with lines will be found characteristics for unloaded open wires and cables and for loaded cables. An impedance/frequency characteristic is also given and its application to fault location illustrated.

Some notes on telephone line repeater characteristics are included, and the next section deals with exchange cord circuits and subscriber's instrument characteristics.

Under audio-frequency amplifiers some typical intervalve transformers of the type used for broadcast reception are characterized, and an extension is given of the theory of this type of transformer covering the effects of resistance and capacity loads.

Introduction.

The determination of the transmission efficiency of telephone lines, circuits and apparatus is of fundamental importance in telephone engineering. Many electrical and acoustical problems are involved in the efficient transmission of speech, and these problems become more severe when efficient transmission of music is also required, as for example, owing to the use of land lines in connection with simultaneous broadcasting.

With respect to the development of wireless telephone apparatus, the radio engineer has to deal with problems similar to those involved in the transmission efficiency of wire telephony systems.

It may correctly be stated that the frequency/amplitude characteristic of a telephone system or of its component parts over the audio-frequency range required for efficient reproduction of speech and music, is a record of primary importance in determining the transmission efficiency of the system or component part in question. This will include both the volume and articulation efficiencies.

Volume may be stated to be a function of the amplitude of the frequency characteristic, whilst articulation is a function of the perfection of reproduction of the originating wave-form. It is not such a definitely quantitative factor as volume.

In the case of the transmission of ordinary telephone messages, it is obvious that these may be accurately received, even when the wave-forms are badly distorted, by the efficient co-operation of the receiving ear and brain.

When the context does not form an idea, such as in transmitting code messages and isolated words or sounds, the articulation of the system requires to be at a much higher level for efficient reception.

Perfect reproduction of the originating wave-form necessitates a system with a uniform frequency response or frequency characteristic at all volume-levels with which such a system is employed.

In addition, when transmitting drama, or vocal and instrumental music, the frequency response should not only be uniform but also approximate to the input level, so that the ratio of input to output over the audio-frequency range should approximate to unity.

Naturalness is also a factor of importance in the transmission and reception of music, etc., but one which does not necessarily enter into consideration of intelligibility. As a result of the elimination, reduction or amplification of single frequencies or bands of frequencies, unnatural and unpleasing reproduction may be obtained which, however, may be of high efficiency from the standpoint of intelligibility.

If, with any particular frequency and volume, an overtone is produced, this is termed non-linear distortion. This form of distortion will be produced by the overloading of transmitters, transformers, amplifiers and receivers (particularly loud-speakers, owing to the greater liability of their being overloaded). A further form of distortion is that due to the persistence of particular frequencies after the stimulus has finished, due to insufficient damping.

Whilst in connection with the production of basic reference telephone standards it is desirable that the transmitting, attenuating and receiving portions should have uniform frequency characteristics, it is frequently necessary to have the frequency characteristics of receiving apparatus, amplifiers, repeaters, etc., so shaped as to compensate for distortion which may be unavoidable in lines or transmitting apparatus.

Frequency and Amplitude Range of Speech and Music.

It has been shown that speech energy extends from a little below 100 cycles up to 6 000 cycles per second, i.e. a range of 6 octaves, and the range for music is somewhat greater.*

Experiments with high- and low-pass filters indicate that good-quality speech is transmitted by a telephone system with an upper cut-off point of about 2 500 cycles, and a system which faithfully transmits up to 5 000 cycles is practically perfect for speech and is good for music, although by no means perfect.

It is probable that a system with a cut-off lying between 5 000 cycles and 10 000 cycles, and nearer to the higher value than to the lower, is required for practically perfect music transmission. The exact value does not appear to have yet been definitely ascertained.

With regard to lower cut-off points, a system cutting off at frequencies below 500 cycles gives very high-grade articulation for speech but unsatisfactory and colourless reproduction of music. Frequencies down to 50 cycles are required for the perfect reproduction of instrumental music.

The mean frequency in speech from the articulation standpoint is about 1 500 cycles. That is to say, a system with a cut-off of all frequencies above 1 500 cycles gives the same quality articulation as one cutting off all below this frequency.

R. L. Jones also finds that a system transmitting only up to 1 000 cycles gives 40 per cent articulation, whilst a system transmitting all above 1 000 cycles gives 86 per cent articulation. The maximum energy for English speech has been found to occur at about 200 cycles and to fall off very rapidly below, and more slowly above, this frequency. If the average energy is expressed by the numeric 6 at 200 cycles, it has fallen to 3 at 400 cycles, 2 at 800 cycles, and 1 at 1 200 cycles. From thence to 5 000 cycles it remains at an average level of 0·5.†

With a normal voice the average speech power entering a telephone transmitter is about 100 ergs per sec., or 10 microwatts; owing, however, to the high mechanical impedance of the diaphragm only a fraction of this performs useful work. Some interesting measurements of the acoustical power of certain sound sources in absolute units were made by Paul E. Sabine.*

A violoncello bowed strongly had an acoustic output varying from 1 000 ergs per sec. at 128 cycles to 10 ergs per sec. at 650 cycles.

A good violin gave a fairly uniform output of 600 ergs per sec. between 192 cycles and 1 300 cycles.

A male voice intoning 12 vowel sounds at conversational loudness with a fundamental of 129 cycles had an output of 56 ergs per sec. approximately.

A female voice intoning a vowel with a fundamental of 258 cycles had an output of 40 ergs per sec. at conversational volume. With the voice raised to suit a small audience, the output was 145 ergs per sec. and when speaking loudly a maximum of 510 ergs per sec. was reached.

Response of the Ear to Variations in the Frequency and Intensity of Sounds.

A knowledge of the characteristics of the ear is necessary in order to arrive at a correct interpretation of the comparative effects of various frequency characteristics. Much work has been done in the last few years on this subject, particularly in America, and some data and references follow :—

The minimum sound intensity, often termed the "threshold of audibility," for a normal ear varies from an acoustic pressure of 0·15 dyne per cm^2 at 60 cycles to 0·001 dyne per cm^2 at 1 000 cycles. Between 1 000 cycles and 4 000 cycles the sensitivity remains approximately constant at 0·001 dyne per cm^2.†

Harvey Fletcher ‡ determines the sensitivity of the normal ear by averaging the results of Wien (1903), Fletcher and Wegel (1922) and Kranz (1923), weighted 3, 72, and 14 in accordance with the number of ears tested, and obtains the values shown in Table 1.

Table 1.

Frequency in cycles per sec. ..	64	128	256	512	1 024	2 048	4 096
Sensitivity in dynes per cm^2 ..	0·12	0·021	0·0039	0·001	0·00052	0·00041	0·00042

These notes only refer to a few of the acoustical values of importance from the telephonic standpoint. A list of the more important recent papers dealing with this subject will be found in the bibliography at the end of this paper.

Production of Constant Acoustic Output over Audio Range.

For the proper examination of the output of a transmitter it is necessary to have a reliable source of acoustic energy to put into the transmitter and one which can be measured and is of suitable magnitude,

* R. L. Jones: "The Nature of Language," *Journal of the American Institute of Electrical Engineers*, 1924, vol. 43, p. 321.
† I. B. Crandall and D. MacKenzie: "Analysis of the Energy Distribution in Speech," *Physical Review*, 1922, vol. 19, p. 221.

* *Physical Review*, 1923, vol. 22, p. 303.
† H. Fletcher and R. L. Wegel: "The Frequency-Sensitivity of Normal Ears," *Physical Review*, 1922, vol. 19, p. 553.
‡ *The Bell System Technical Journal*, 1925, vol. 4, p. 375.

and a means of measuring the resultant electrical output. For a receiver the conditions are reversed. A great many devices can be used which are completely reversible, that is, are capable of emitting acoustic energy when electrically excited, and vice versa, and a device which can be used either as a transmitter or as a receiver would obviously be the most suitable one to adopt.

To obtain frequency characteristics of transmitters and receivers the following are the necessary requirements :

(1) Apparatus producing approximately constant acoustic output over the required frequency range, for energizing transmitters.
(2) Apparatus having approximately constant acoustic "pick-up" efficiency, for measuring the output of receivers.
(3) Means for measuring and, possibly, photographically recording the acoustic and electric quantities over the range.

Direct acoustic generators.—For the excitation of transmitters the simplest method would appear to be the direct production of sounds from wind instruments. Organ pipes are stated to produce pure tones when blown with a constant air pressure, provided this is small, but they are very inconvenient in practical use. A large pipe would be required to produce a reasonable volume of sound, and it is awkward to handle; another serious objection lies in the fact that a series of pipes would be required to produce sounds of different frequencies, which, moreover, could not be continuously varied. Organ pipes are also difficult to calibrate absolutely as to the volume output by the only means which is at present available, viz. a Rayleigh disc, on account of the large air disturbances in the neighbourhood of an operating pipe.

A more promising instrument would appear to be a centrifugal type of siren. This, when driven at a constant speed under constant atmospheric conditions, will give a constant output of considerable intensity; the frequency is, however, directly dependent upon the speed, so that whilst a continuously variable frequency is possible the volume of the sound produced increases with the speed and frequency.

Some attempts were made to produce a siren of this type, not so much for use in the examination of frequency characteristics as to obtain a source of sound energy of constant value. It was abandoned on account of the difficulty experienced in designing a siren to give a note of single frequency. A siren built with openings which varied in area according to a sine function with time would, it was suggested, produce a pure note. This was found to be far from the case, due in all probability to the fact that the volume of air issuing from the orifices will only be proportional to the area of the opening if there is available a considerable reservoir of air under pressure, and if the speed be low.

Toothed-wheel sirens with teeth cut to special shapes and periodically obstructing a jet of air under constant pressure have also been suggested and tested. The difficulty with these devices, apart from the question of elimination of harmonics, is in avoidance of hissing effects from the eddies in the air jet and of vibrations at the edges of the wheels.

Specially designed whistles have been proposed as standards of sound, but they are unsuitable for the lower audible frequencies, the frequency is not continuously variable in any convenient manner, and the wave-form is bad.

Vibrating bars and tuning forks have been suggested, but very large instruments would be necessary to obtain a reasonable volume of sound, involving massive base plates; the position of the actual origin of the sound is uncertain (and this is frequently required), and again continuous variation of frequency is impossible.

Indirect acoustic generators.—An electrically operated piece of apparatus seemed far more promising than any other. As described elsewhere in the paper, means had already been obtained for the production of a constant-voltage supply of uniformly varying frequency, and it only remained to select a suitable form of instrument for the conversion of this into acoustic energy. A great many different types of instrument have been investigated, partly with a view to their use in such measurements as are described here, and partly for use as telephonic standards of transmission.

Piezo-electric devices.—The introduction of valve amplifiers renders possible the utilization of many effects which have been known for years but have so far been too minute for practical use. One of the most promising of these is the piezo-electric effect. Certain crystalline substances, of which Rochelle salt, quartz and tourmaline appear to be the most noteworthy, have the property of producing on portions of their surfaces an electric charge upon being mechanically compressed. The effect is completely reversible. There is a very considerable amount of literature on the subject, but there has not been much work published on its application to telephone problems.

A. McL. Nicholson * has given the results of his work in this connection, and has described the production of suitable Rochelle salt crystals. Rochelle salt gives by far the most powerful piezo effect of any substance so far known, and this was investigated by the authors. Excellent results were obtained at first, and transmitters were constructed with apparently very flat frequency characteristics, though no direct measurements were made. It was, however, found impossible to maintain constancy. The piezo effect is largely due to internal strain in the crystal, and with a fragile material like Rochelle salt, and one which is moreover affected by moisture, reliability could not be obtained. Quartz is mechanically an ideal substance, its drawback being its lack of sensitivity. It has recently been extensively used for wave-meters, as suggested originally by W. G. Cady.† The use of this material as both transmitter and receiver in conjunction with suitable amplifiers is now being investigated.

Electrostatic transmitters.—That a condenser having its plates not rigidly clamped would, when actuated electrically with an alternating voltage, produce a sound of twice the frequency was first pointed out, it is believed, by Dolezalek.

* *Journal of the American Institute of Electrical Engineers*, 1919, vol. 38, p. 1467.
† *Proceedings of the Institute of Radio Engineers*, 1922, vol. 10, p. 83.

By polarizing the condenser with a battery the condenser will reproduce the input frequency, the effect being analogous to that occurring with non-polarized and polarized receivers. The use of condensers as transmitters and receivers has been known for a very long time, but on account of their lack of sensitivity it was only the advent of the thermionic valve which enabled a practical use to be made of them.

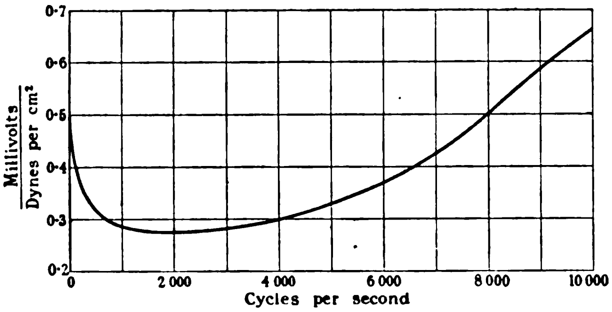

Fig. 1.—Calibration of electrostatic transmitter.

A full description, with the theory, of an instrument which has been developed by the Western Electric Company of America for use as a standard is given by E. C. Wente.* This instrument consists of a two-plate condenser, one plate, which receives the incoming sound, being a thin stretched diaphragm separated from the second plate, which is massive, by a small air-gap. Incoming sounds vary the capacity of this condenser and, by suitably designed filter and amplifier circuits, the effects are amplified for measurement.

A frequency characteristic of one of these instruments taken from the original paper is shown in Fig. 1. It has been used to a very considerable extent in America in a number of diverse investigations both in connection with telephone transmission and in more purely acoustic investigations. It is stated to be very reliable and stable.

This instrument has not been used by the authors, but a number of other forms of electrostatic transmitter have been examined. A loud-speaker can be produced from a few loose sheets of foil with paper or gutta-percha separators, but it has obvious disadvantages for the present purposes.

Another arrangement being investigated consists of a two-plate condenser, one plate being formed of a thin sheet of aluminium foil stretched just sufficiently taut to hold it plane and held a few thousandths of an inch away from a rigid back plate. This condenser forms part of a special circuit which is similar to that devised by J. J. Dowling for the measurement of minute lengths and termed by him the ultra-micrometer.* The circuit employed is shown in Fig. 2. It will be noted that the electrostatic transmitter is unpolarized and is connected to a pick-up coil of an oscillator which is arranged to oscillate at some convenient radio frequency (about 800 000 cycles has been found suitable in London).

The pick-up coil is connected to a detector valve and a 1- or 2-stage transformer-coupled audio-frequency amplifier, and thence to a measuring instrument, which may be a Moullin voltmeter. The oscillator is set to oscillate slightly out of tune with the circuit formed by the condenser transmitter and oscillator output coil, the amount of mistuning being shown by the ammeter in the detector plate circuit, a definite plate current being worked to. Sounds incoming to the transmitter modify the degree of tuning, with the result that the potential of the detector grid is modified accordingly.

This scheme is sensitive and promises to be of value, but has not yet been very fully investigated.

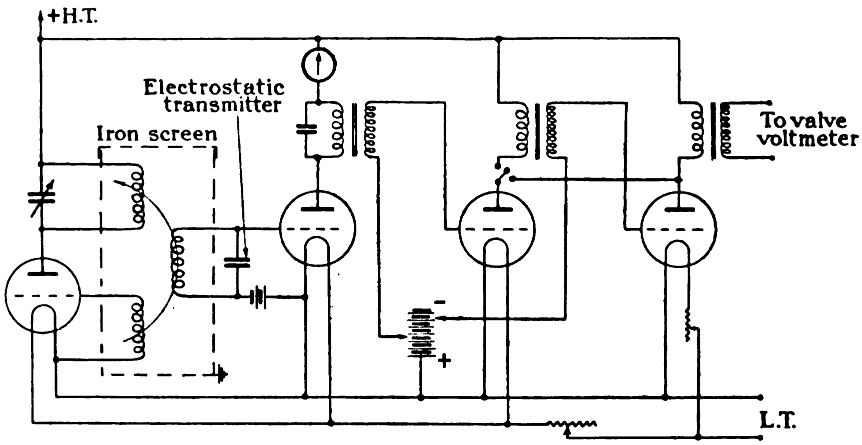

Fig. 2.—Sensitive electrostatic transmitter circuit.

Thermophones.—Of recent years numerous devices have been brought out for the conversion of acoustic into electric vibrations, and vice versa, based on the variation in resistance of a fine wire when subjected to acoustic vibrations. Commercial telephone instruments have been produced in Holland and Germany, and considerable use was made of similar apparatus in the late war. A thermophone, as this type of instrument is called, has been used in America as a means of standardizing the electrostatic transmitter.† A great deal of work has also been done by Major Tucker with hot-wire microphones for acoustic experiments.

There is much to be said for the use of thermophones

* *Physical Review*, 1917, vol. 10, p. 22, and 1922, vol. 19, p. 498.

* *Philosophical Magazine*, 1923, vol. 46, p. 81.
† H. D. Arnold and I. B. Crandall: *Physical Review*, 1917, vol. 10, p. 22; and E. C. Wente, *ibid.*, 1922, vol. 19, p. 333.

in acoustic measurements; they are small, cheap and, in some respects, simple in use. It is necessary, however, partly to obtain sensitivity, and partly to reproduce the impressed frequency and not double this, for the thermophones to be polarized with a direct current (analogous to the use of the polarizing magnet in an ordinary receiver). This polarizing current must be large in comparison with the alternating current in order to avoid second harmonics and to get the necessary sensitivity, and in practice the number of burn-outs is inconveniently large. The instrument must also be very carefully screened from draughts and mechanical vibration, and in addition the sensitivity also falls off with the frequency.

Thermionic devices.—The electronic discharge in air from a heated cathode can be directly operated upon by a sound wave which will vary the electron flow. This effect has been utilized in America and in Germany to produce a transmitter for broadcasting purposes. The great advantage of such an instrument is its freedom from resonance, and, if a reliable instrument could be made, it would be ideal for measurement purposes. A few preliminary experiments with the German type of instrument indicated, however, that considerable variability would be experienced and that, although the principle was simple enough, numerous protective devices, etc., were needed and greatly reduced its simplicity. The arrangement is not reversible.

Electromagnetic devices.—Apparatus based upon electromagnetic action appeared to offer the best prospect of producing an instrument satisfactory for the purpose required, and different types were examined. They have the great advantage over electrostatic instruments in that no trouble is experienced such as is found with condensers owing to the relatively small capacity of an electrostatic transmitter in comparison with the leads connecting it with its amplifier.

The ordinary electromagnetic receiver of commerce is a robust and sensitive instrument but has a very pronounced diaphragm resonance at about 1 000 cycles per sec., and usually others of a higher value as well. By reducing the air space at the back of the diaphragm the sharpness of this resonance can be reduced and its frequency considerably raised, and for many purposes this will make a very satisfactory sound source or pick-up device. Its efficiency at frequencies away from its resonant frequencies is, however, comparatively low.

The moving-coil type of instrument with either a flat or solenoidal coil operating in a strong annular magnetic field offers many possibilities. A loud-speaker on this principle has been described by Lodge,* and successful loud-speakers operating on this principle are in use to-day. The standard microphone adopted by the British Broadcasting Company is also of this type.

A number of instruments of this type, with a solenoidal moving-coil on a mica cylinder and working in a powerful annular magnetic field were made for a special purpose in 1915. Some of these, suitably modified to operate with inertia control, are being used as high-quality receivers and transmitters.

In the best form, the space behind the moving parts is kept open to the air to prevent acoustic loading, and the back of the instrument is at the same time enclosed in a padded box to prevent interaction between the back and the front. This interaction would otherwise be particularly noticeable at the lower frequencies.

Another type of instrument has been suggested by Siemens and Halske of Berlin and used, it is believed, in Germany for broadcasting and also as a loud-speaker. It consists of a strip of thin aluminium foil about 12 cm × 1 cm lightly clamped at the ends and placed in a strong magnetic field. Acoustic vibrations falling upon this strip will cause it to vibrate and generate an e.m.f. The reverse may also take place, viz. currents in the strip will cause it to vibrate and generate sound waves. The chief interest in the arrangement lies in the fact that if the strip be vibrating, due to impact

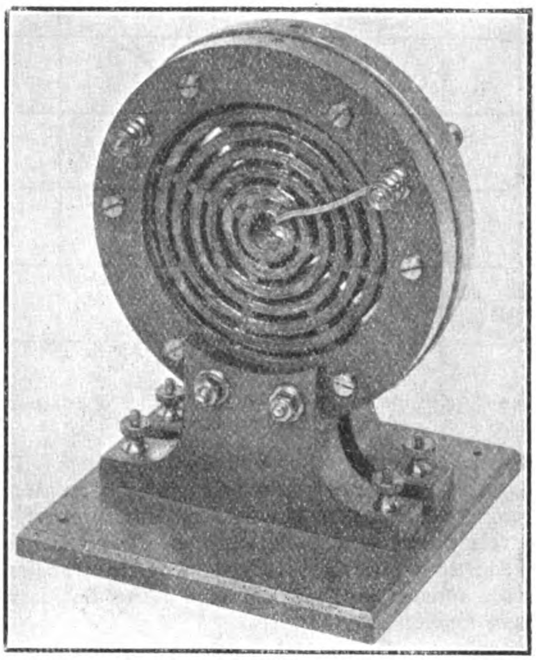

FIG. 3.—Eddy-current instrument.

of acoustic waves, it may be brought to rest by passing a current of correct amplitude and phase through it; this current will be some measure of the acoustic output.

The theory does not appear to have been completely worked out, the correction to be made for air leakage round the edges of the strip being rather uncertain.

Eddy-current instrument.—An instrument which has been found to be of great value is that known as a Hewlett tone generator. This is the name given the instrument by its inventor, C. W. Hewlett, but eddy-current transmitter or receiver would appear to be a more suitable name. A description of the instrument, with the theory of its action, and particulars of its performance are given in the *Physical Review* (1922, vol. 19, p. 52).

The construction of the instrument is as follows: Two pancake coils, each consisting of a number of concentric coils arranged with annular air spaces between, are fixed face to face about 50 mils apart. In the

* *Journal I.E.E.*, 1898, vol. 27, p. 799.

centre of this space is clamped a diaphragm of thin aluminium foil, stretched just sufficiently taut to keep it plane. In the two pancake coils a direct current is caused to flow in such a way as to produce opposing magnetic fields. The aluminium diaphragm is thus situated in a radial magnetic field. If, now, a sound wave falls upon the diaphragm and sets it in vibration, eddy currents will be induced in it and will, in turn,

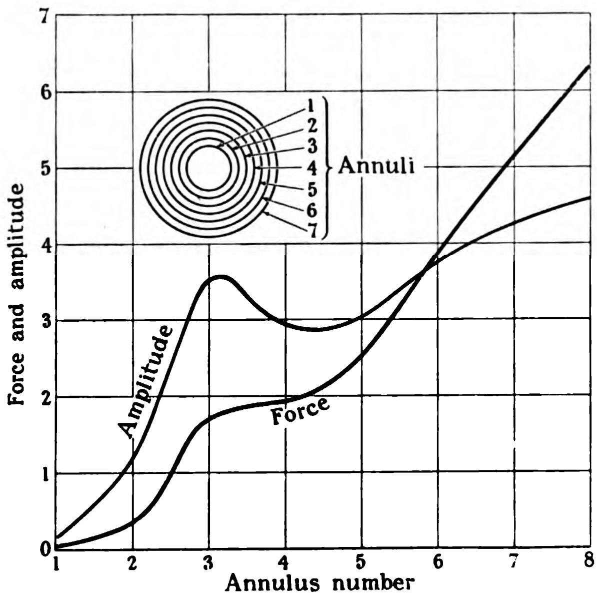

FIG. 4.—Amplitude of motion of, and force on, diaphragm of eddy-current instrument.

induce voltages in the pancake windings. These voltages can be tapped and utilized as a measure of the sound vibrations. There is no iron present, and from this cause, and the nature of the construction, the acoustic-electric and electric-acoustic transformations are remarkably pure. Fig. 3 shows one form of the instrument.

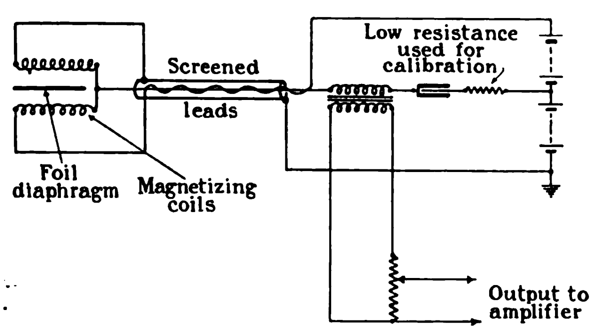

FIG. 5.—Eddy-current instrument circuit.

Hewlett has made measurements and calculations of his original instrument and found them to be in close agreement, the instrument being used as a source of sound. Fig. 4 shows the relationship between the amplitude of motion of, and also the force acting upon, each annulus of the diaphragm, annulus No. 1 being that near the centre. It will be seen, therefore, that the maximum motions, unlike those in most vibrating diaphragms, occur near the edge, and that the centre is practically at rest. The forces acting upon the different annuli are nearly in phase, so that the diaphragm is vibrating as a whole. Hewlett shows that, when used as a sound generator for voice frequencies, the force acting upon the diaphragm is directly proportional to the frequency, and the amplitude of vibration is inversely proportional to the frequency.

The first transmitter made for the authors was in accordance with Hewlett's design, in which the same coils are used to polarize the instrument as for picking up the E.M.F.'s induced from the diaphragm currents. The circuit of the instrument is shown in Fig. 5. Another form has been designed in the Post Office Research Laboratories. In this model separate polarizing and output windings are used. By making the output winding with a large number of turns the instrument can be caused to operate efficiently directly upon the grid of the first amplifier valve, thus eliminating the iron-cored input transformer shown in Fig. 5. The separation of the two windings also renders the circuit arrangements more flexible. From two to five stages of amplification are required with eddy-current transmitters.

All leads from the transmitter must be screened, and the transmitter itself is placed within a cage of heavy copper wires. This is mainly required to prevent direct electric and magnetic induction from the electrically operated sound source to the transmitter.

METHOD OF CALIBRATING ACOUSTIC MEASURING INSTRUMENTS.

Although according to Hewlett the operation of the instrument is calculable, it was thought that a direct measurement of its performance would be more satisfactory.

The calibration, which is, of course, applicable to other types of instrument when used as a transmitter, was made by means of a Rayleigh disc. A description of the Rayleigh disc instrument, and the method of calibrating it by means of a continuous flow of air, have recently been published by E. Mallett and G. F. Dutton in the *Journal* * and need not be repeated in detail. Calibrations were made with air flowing in both directions past the disc, and, to ensure uniform flow of air, each end of the calibrating tube was filled with a bundle of small tubes, each about 3 in. long by $\frac{1}{8}$ in. bore.

Mallett and Dutton, in the same publication, showed that a chamber lined with 4 in. of cotton waste on each wall was practically non-reflecting, and a similar arrangement was used by the authors. The Rayleigh disc used consisted of a thin piece of mica 0·75 cm in diameter and carrying a small mirror at its centre; it was suspended approximately in the centre of the chamber, which was 4 ft. each way and lined with the cotton waste.

The eddy-current transmitter was suspended, with diaphragm vertical, about 6 in. behind the disc, and with the centre of the diaphragm in the same horizontal plane as the centre of the disc. Fixed in the side of the chamber, also in the same horizontal plane, was a brass tube in which could be made to slide a telephone

* *Journal I.E.E.*, 1925, vol. 63, p. 502.

receiver used as a source of sound. The brass tube itself could also be moved in and out in order to bring its mouth within varying distances of the disc and eddy-current transmitter, these two remaining fixed.

The adjustable air column in front of the receiver was used, as by Mallett and Dutton, to reinforce and purify the sound. The range of frequency which can be covered in this way is, however, limited. It was extended up to 3 000 cycles by fitting an adjustable perforated cap immediately in front of the diaphragm, thus providing a small air chamber which served as a Helmholtz resonator. A value at about 4 000 cycles was obtained by utilizing the nodal circle resonance of the diaphragm. The heterodyne oscillator, described elsewhere in the paper, energized the telephone receiver used as a source of sound.

Preliminary tests were made at frequencies of 1 000 cycles and 3 500 cycles by means of a loose receiver inside the chamber, and these confirmed Mallett and Dutton's results that the wave-front a few centimetres in front of the receiver is spherical; also that this is not perceptibly affected by the presence of the eddy-current transmitter.

TABLE 2.

					25·6	3·45	89
					26·5	3·40	90
					27·4	3·4	93
					28·3	3·34	94
Mean	..	..	16·6	..	..	..	90·6

A series of voltmeter readings were taken from the amplifier at several different frequencies for various distances between the source of sound and transmitter. Two of these are shown in Table 2, together with the value of the product r_2E, r_2 being the distance between the centres of the source and the diaphragm. It will be seen that r_2E is a constant.

Mallet and Dutton have shown that for a spherical wave the R.M.S. pressure p at a distance r_2 from the source is given by

$$pr_2 = \frac{A\rho\omega}{4\pi\sqrt{2}}$$

where A = a constant, ρ = air density, and $\omega = 2\pi \times$ frequency.

It follows, therefore, that at a given frequency the voltage indicated from the transmitter is proportional to the pressure of the sound wave.

Frequency characteristic of the transmitter.—This is obtained by simultaneous measurements made of the deflections of the Rayleigh disc and the transmitter voltage.

The deflection of the disc is proportional to the square of the velocity v of the air particles, the relation being obtained by a measurement of the deflection for various steady currents of air, as previously explained.

With the disc and suspension used it was found that if δ be the deflection

$$v = 0\cdot153\sqrt{\delta} \text{ cm per sec.}$$

With a spherical wave

$$v = \frac{A}{4\pi\sqrt{2}}\sqrt{\left(\frac{1}{r_1^2}\cdot\frac{\omega^2}{c^2} + \frac{1}{r_1^4}\right)}$$

where A = a constant, as above,
r_1 = distance between disc and source,
c = velocity of propagation of sound,
$\omega = 2\pi \times$ frequency.

As previously stated, if p is the pressure at the transmitter diaphragm situated r_2 cm from the source

$$p = \frac{A\rho\omega}{4\pi r_2\sqrt{2}}$$

$$\therefore p = \frac{v\rho\omega}{r_2\sqrt{\left(\frac{1}{r_1^2}\cdot\frac{\omega^2}{c^2} + \frac{1}{r_1^4}\right)}}$$

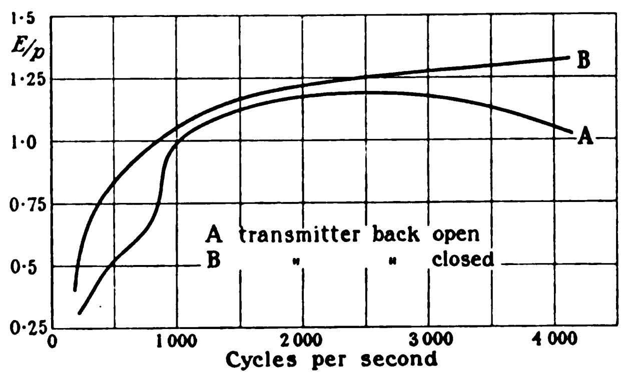

FIG. 6.—Calibration of eddy-current transmitter.

This value of p was obtained for different frequencies, together with the corresponding values of E. Since, as previously stated, it had been found that p is proportional to E, the potential difference from the transmitter, E/p will be the output voltage for a constant pressure. This is plotted in Fig. 6 against the frequency.

At each frequency several values of r_1 and r_2 were taken. It was found that E/p was not always quite constant, due to the fact that as r_2 became great enough at the higher frequencies a certain amount of reflection was found. Its effect could, however, always be allowed for.

It will be seen the transmitter output rises steadily to about 1 000 cycles, after which it is substantially constant.

The characteristic is considerably improved by enclosing the back of the instrument by sound-absorbing material (see curve B). A similar result is obtained by putting a baffle plate round the diaphragm.

Apparatus for the Production of Electrical Energy of Constant Value over the Required Range of Frequency.

Before the introduction of thermionic oscillators recourse was had to alternators, interrupters and electromagnetic vibratory apparatus for the production of audio-frequency alternating currents. Reference will be made to some of these.

Alternators.—A number of alternators have been specially designed to produce pure wave-form alternating current at audio frequency. Reference may be made to the machines of Duddell, Franke, Pollock and Brown. The alternator of Duddell gives alternating current of good wave-form up to 2 000 cycles. The machine has to be driven at a speed of 8 000 r.p.m. to give this frequency. The Pollock alternator gives up to 6 000 cycles at 6 000 r.p.m.

Microphone hummers utilizing the interaction between a microphone and an electromagnet to maintain a reed, bar, or tuning fork in vibration are widely in use for measurements at one frequency.

All the devices so far referred to, with the exception of alternators, are of no value for the production of alternating current which can be varied continuously over the required range of frequency.

The thermionic oscillator can, however, be arranged to cover all the requirements.

Thermionic oscillators.—The production of an ordinary type oscillator, giving a pure wave-form and constant output, with a frequency continuously variable over the audio range, is extremely difficult, even if possible. During some preliminary work on a means of obtaining a range of sinusoidal frequencies, the use of two ultra-audio oscillators heterodyning with one another was

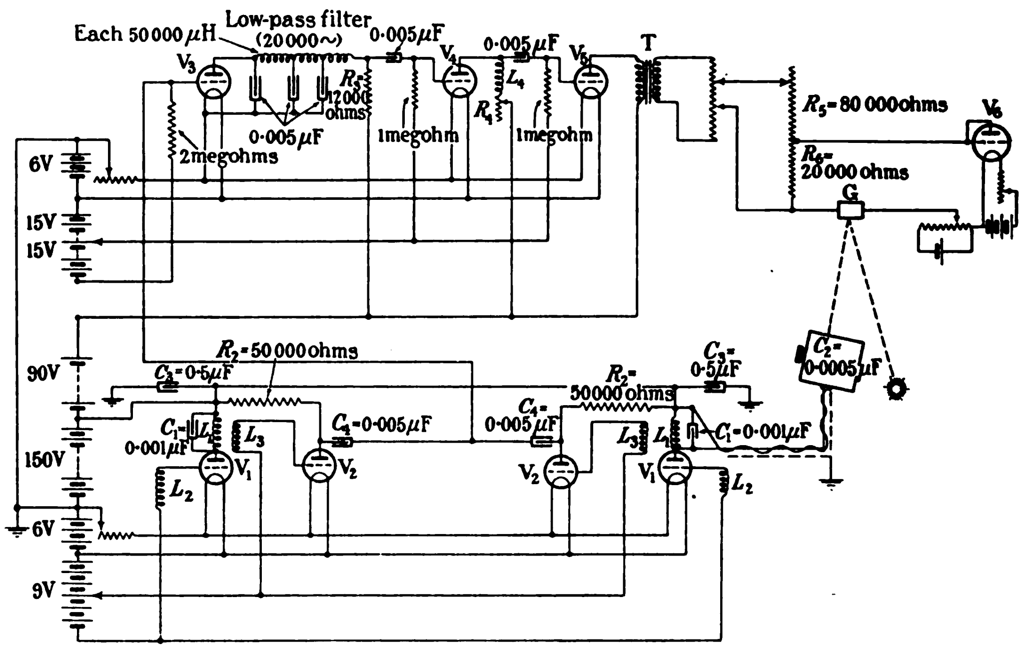

Fig. 7.—Complete circuit of heterodyne oscillator.

These instruments are particularly useful when very considerable output is required.

Interrupters.—Vibrating wires operated electromagnetically and with mercury-cup interrupters have been used for the production of audio-frequency alternating currents. By the addition of tuned circuits, trains of oscillations were obtained on make or on break, and were also combined on both make and break to give a more or less continuous wave.*

Interrupter commutators consisting of a series of segments regularly graduated in width have been used to produce alternating currents rhythmically varying over a desired range of audio frequency, and this apparatus is still in use for certain testing purposes.†

tried with promising results, and this appeared to be a method which could be usefully applied to the present problem.

If an oscillator working at a frequency of, say, 25 000 cycles per sec. is coupled loosely with another which is caused to oscillate at any point between 25 000 and 30 000 cycles, the fundamental of each oscillator will be inaudible, but a "beat" frequency will be introduced varying between 0 and 5 000 cycles. No difficulty is experienced in obtaining the "beat" frequency, but considerable difficulties are encountered in rendering it sinusoidal in shape and constant in value, and it is essential to secure these qualities if the maximum use and convenience are to be obtained from the instrument.

At frequencies of 25 000 cycles a change of frequency of 5 000 cycles can be effected by changing the oscillator capacity by a small amount, which car be covered in

* B. S. Cohen: "The Production of Small Variable-Frequency Alternating Currents suitable for Telephonic Measurements," *Philosophical Magazine*, 1908, vol. 16, p. 480.

† B. S. Cohen: "Telephonometry", *Institution of Post Office Electrical Engineers*, Paper No. 70, 1916.

a 180° movement of a small air condenser. This means that the whole range of audio frequencies normally required (say 0 to 5 000 cycles) can be obtained by the rotation through 180° of a single dial. The range can, of course, be altered by modifying the ultra-audio oscillators, or the small variable condenser.

The general method of operation is to cause the oscillator to actuate the apparatus under investigation, the result of this actuation being measured as a galvanometer deflection recorded photographically on paper on a drum which is rotated with the variable air condenser used to obtain the variation in frequency. This method of operation required the use of receivers or transmitters having equal outputs over the range of frequencies under consideration. For example, in examining a transmitter for resonance it would be actuated by a special non-resonant receiver operated from the oscillator, and the a.c. output would be rectified and passed through a d.c. galvanometer, the deflections of which would be recorded, as described above. A receiver would be tested by operating it from the oscillator, and causing it to actuate a non-resonant transmitter. Non-acoustic apparatus such as transformers, induction coils, etc., are examined by current or voltage measurements.

In designing the apparatus at present in use the following requirements have been covered :—

(1) The range of audio frequencies covered by the rotation of the dial of the operating variable condenser through 180° is from 0 to 5 000 cycles.

(2) The output at all frequencies within the range is practically sinusoidal.

(3) The output voltage is practically constant for all frequencies within the range.

(4) The high frequencies of the oscillators are eliminated before reaching the audio-frequency output, in order to prevent interference with current measurements on the galvanometer.

Heterodyne oscillator circuit.—The circuit diagram of the heterodyne oscillator used by the authors is shown in Fig. 7, which illustrates also the method employed for taking photographic records. Each high-frequency oscillator circuit comprises a grid coil L_2 of 50 000 μH, coupled to a plate coil L_1 of 20 000 μH, tuned by a fixed condenser C_1 (about 0·001 μF). A variable condenser C_2 with a maximum value of 0·0005 μF is connected in parallel with one of the condensers C_1, to cover a frequency range of about 5 000 cycles. Output coils L_3 of 10 000 μH introduce the high frequencies from each oscillator into the high-frequency amplifying valves V_2, which serve to prevent, as far as possible, interaction between the two oscillators ; each oscillator, with its associated high-frequency amplifier, is also enclosed in an iron box. The high frequencies are taken by resistance-capacity coupling and a common input lead to the grid of the detector valve V_3, which operates on the anode rectification principle. In the plate circuit of this valve is a low-pass filter having a cut-off at about 20 000 cycles ; the filter serves to reduce to a negligible quantity the high frequencies in the audio-frequency output ; moreover it provides, for the high frequencies, a sufficiently low-impedance path from the plate to the filament to ensure efficient operation of the detector valve. Two stages of resistance-capacity coupling bring the audio frequencies to the output transformer of the set.

Output/frequency characteristic.—With an ordinary-type output transformer, the output/frequency characteristic was found to be unsatisfactory, the output increasing too slowly as the frequency was raised from zero, and falling off again at the higher frequencies. Output transformers for the heterodyne oscillator are

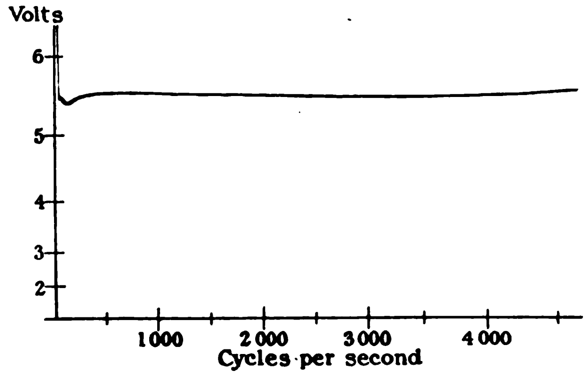

FIG. 8.—Heterodyne oscillator voltage/frequency characteristic.

accordingly built on 1-in. square cores of stalloy stampings, the windings consisting of a number of interleaved wave-wound slab coils. It is, of course, essential that the secondary winding should terminate with a non-reactive load, a generally useful value for which has been found to be 800 ohms, through which a current of about 10 mA is obtainable. When more current is required this load may be increased to, say, 100 ohms,

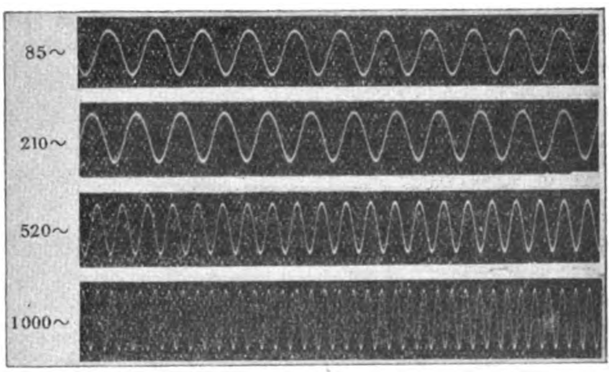

FIG. 9.—Wave-forms of heterodyne oscillator.

and the transformer ratio and resistance of the secondary winding may conveniently be adjusted by joining in parallel certain of the slab coils.

Whilst such a transformer gives a satisfactory output at the low frequencies, there is a tendency for the output to fall off at the higher frequencies. In order, therefore, to flatten out the characteristic, the output at the lower frequencies is cut down to the same value as that obtainable at the high frequencies. To effect this, a 0·2 henry air-cored inductance L_4 was inserted in the anode circuit of the first audio amplifying valve in series

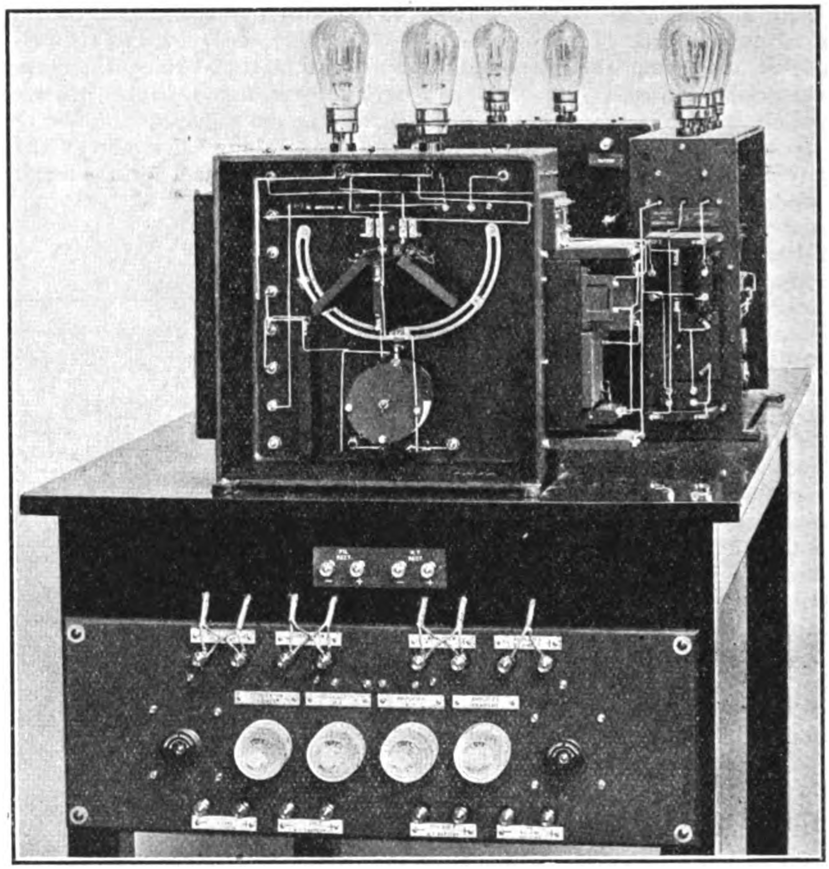

FIG. 10.—General view of heterodyne oscillator.

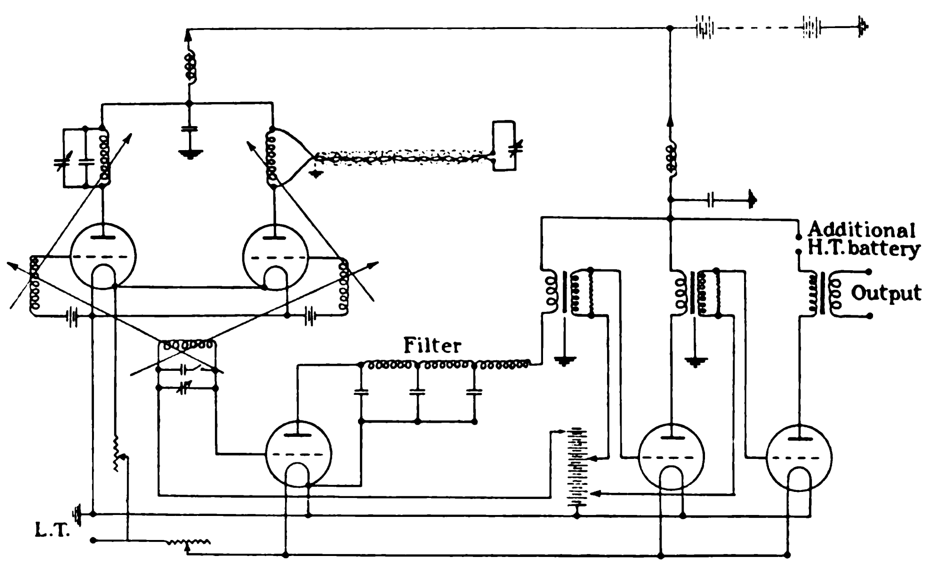

FIG. 11.—Circuit diagram of portable heterodyne oscillator.

with a variable non-inductive resistance R_4, the impedance of this circuit thus having a rising characteristic with frequency. A photographic record of the output/frequency characteristic of the oscillator is reproduced in Fig. 8.

The method of measurement is illustrated in Fig. 7. A rectifying valve V_6 has in circuit a quick-moving reflecting galvanometer G, the spot of light from which falls on photographic paper wound round the drum of the condenser camera C_2. In the illustration V_6 is shown as a diode rectifier. As a general rule, however, it is preferred to use a triode with anode rectification.

For many purposes it is convenient to substitute for the condenser camera a pair of variable condensers in parallel, one of say one-half the capacity of the other, and one equipped with a vernier. This vernier can be adjusted so that the beat frequency is zero when both condensers are set at zero. One condenser will then give half the available frequency range of the oscillator for a 180° rotation of its dial, whilst the whole frequency

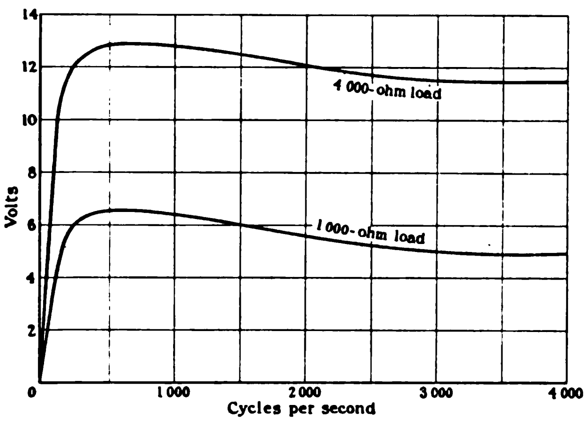

FIG. 12.—Voltage/frequency characteristics of portable heterodyne oscillator.

range is obtainable from the other condenser. The dials of both condensers may be engraved in frequencies.

Wave-form.—Oscillograms showing the wave-form of the output at different frequencies are reproduced in Fig. 9, the frequencies being 85 cycles, 210 cycles, 520 cycles and 1 000 cycles. The impurity is almost entirely due to a second harmonic, as was tested by tuning out first the fundamental and then the second harmonic. From a measurement, with the impure wave-form, of the capacity of a condenser, the impurity was found to be less than 5 per cent of the fundamental.

A variable condenser (about $0 \cdot 001\ \mu F$ maximum) shunted across the input to the detector valve has been found to be a useful addition to the heterodyne oscillator. As the value of this capacity is increased, so the output from the oscillator is reduced and, at the same time, the wave-form is improved. Hence, whenever the maximum output from the oscillator is not required, a suitable adjustment of this capacity is made in order to obtain the best wave-form available. The operation of the condenser in this respect is two-fold, by reducing the magnitudes of the alternating voltages in the audio-frequency amplifier it lessens the percentage of harmonics generated therein, and by providing, in the plate circuits of the high-frequency amplifying valves, an impedance, which is lower for the harmonics than for the fundamental, it tends to purify the wave-form of the high frequencies introduced into the detector valve.

Method of use.—The general method preferred for making frequency characteristic tests with the heterodyne oscillators is to introduce a constant voltage from the oscillator across a non-reactive resistance, which forms a part of the normal input connections to the apparatus under test, and to record the voltage output, with the circuit terminated by an impedance equivalent to that used under working conditions. This method involves the use of a suitable non-reactive attenuator, placed between the output transformer of the oscillator and the apparatus under test. This will serve to maintain a non-reactive load on the transformer and also to retain the normal impedance, on the input side of the apparatus under test, uninfluenced by the presence of the transformer.

Fig. 10 shows one of the ultra-audio oscillators.

Portable heterodyne oscillator.—A smaller and more portable pattern of heterodyne oscillator has also been constructed. The arrangement is somewhat different from that of the large instrument, and the circuit is shown in Fig. 11. It will be observed that no high-frequency amplifier stages are used in conjunction with the oscillators.

Fig. 12 shows frequency characteristic curves for two outputs of this instrument.

THE FREQUENCY CHARACTERISTICS OF TELEPHONE TRANSMITTERS.

The most suitable sound source available for operating the transmitters was a receiver of the moving-coil type mentioned on page 1027. The output of sound from this instrument was ascertained indirectly by using an electrostatic transmitter, working on the circuit shown in Fig. 2 and calibrated by means of the Rayleigh disc; and also, for frequencies up to 1 500 cycles, by direct measurements on the Rayleigh disc. At frequencies higher than about 1 500 cycles the sound velocities were too low to be accurately recorded by the disc. The two records of sound output so obtained were found to be in very close agreement, and on these are based the sound-input curves to the transmitter, which are shown in Figs. 13 (*a*) and 14 (*a*). These values of sound input represent what would be the pressure of the sound wave at the position of the aperture of the transmitter if the latter were removed. That is to say, no account is taken of local irregularities in the sound wave due to the presence of the transmitter.

The transmitter was fed with about 40 milliamperes of direct current through a transformer and a resistance of 300 ohms, and the alternating E.M.F. generated by the sound was amplified, rectified and photographically recorded. Sound source and transmitter were placed for the test in the previously described acoustic chamber.

The records shown can only be accepted as indicating the order of performance, owing to the fact that ordinary granular transmitters when operated upon by a constant sound input tend to "pack." A record taken with a rising frequency is usually somewhat different from that

taken with a falling frequency. The resonant frequencies also seem to differ to some extent both in relative amplitude and in frequency when taken at different times.

Fig. 13 (*a*) shows the characteristic of an "inset" transmitter of the type used in this country on local-battery instruments. This instrument has a small carbon diaphragm, and considerable damping is introduced by the large chamber, three-quarters full of

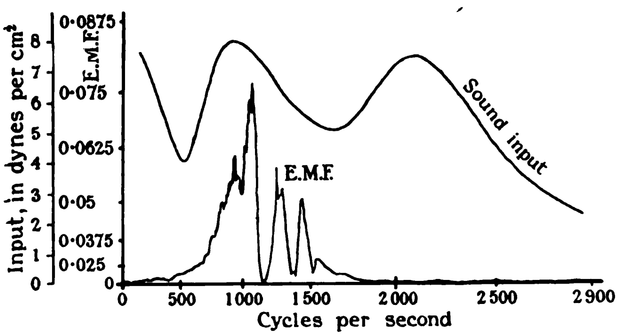

FIG. 13 (*a*).—Characteristic of local-battery transmitter with mouthpiece.

granules held in place by cotton wool cemented to the diaphragm. The record is typical, but considerable variation occurs between different specimens. This instrument is particularly susceptible to "packing" under the conditions of the test.

Fig. 13 (*b*) shows the characteristic of a granular transmitter specially designed to give good articulation. It has a 40-mil carbon diaphragm separated from a massive back plate by an air space of 7 mils. The granules are held in a small central chamber in a felt

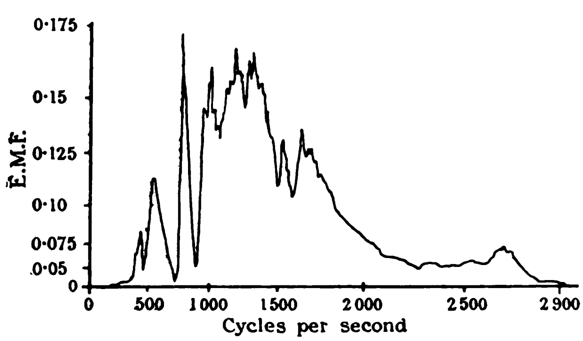

FIG. 13 (*b*).—Characteristic of special transmitter.

ring lightly resting against the diaphragm. This latter is open to the speaker, no mouthpiece being used. It will be seen that the characteristic is much more uniform. The articulation of this transmitter is of a very high order.

Fig. 14 (*a*) shows the characteristic of a standard-type common-battery transmitter with mouthpiece. This type of instrument, which possesses much greater uniformity in volume output than the local-battery pattern, is a somewhat complicated structure. It contains a small central chamber holding the granules. The back electrode is fixed. The front one is held in place by a thin annular mica diaphragm which, with its associated loads, has a natural frequency of the order of 1 200 cycles. Rigidly clamped to this front electrode is the larger aluminium diaphragm which receives the sounds. This diaphragm is not clamped at the circumference, but is encased there in a rubber ring and held down on its seating by two stiff, steel, felt-padded springs, one bearing on the diaphragm near the centre and the other near the edge. It will be

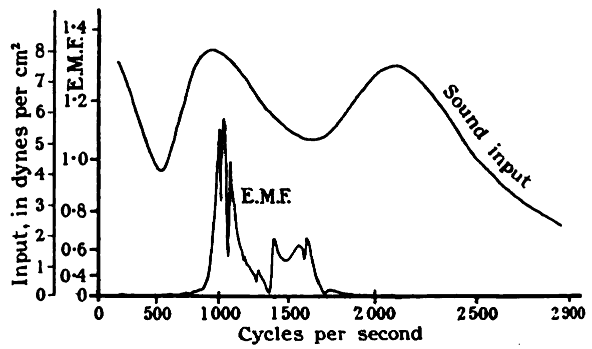

FIG. 14 (*a*).—Characteristic of common-battery transmitter with mouthpiece.

seen that a complicated series of mechanical resonances are possible. These transmitters usually show pronounced resonance between 900 and 1 500 cycles, but this often takes the form of two or more adjacent peaks.

There is also an acoustic resonance of the air in the chamber in front of the diaphragm and in the mouthpiece. This takes the form of a blunt, irregular peak,

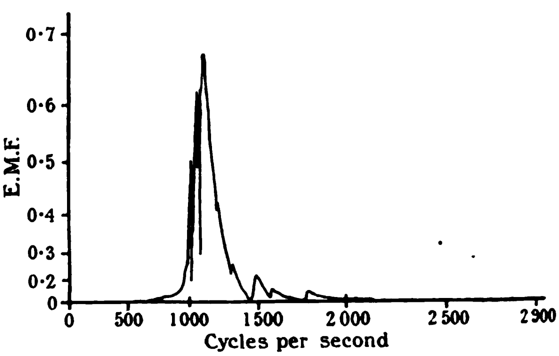

FIG. 14 (*b*).—Characteristic of common-battery transmitter without mouthpiece.

between 1 500 and 2 000 cycles, and smaller than that of the main mechanical resonance. When the mouthpiece is removed the acoustic resonance peak appears at about 2 900 cycles, but it is small and cannot usually be detected unless the curve is taken on a magnified scale. With this exception, therefore, it is considered probable that the peaks shown on the transmitter curves, when taken without a mouthpiece, are entirely due to mechanical resonances of the vibrating parts.

Fig. 14 (*b*) shows the characteristic of the same transmitter without mouthpiece.

THE FREQUENCY CHARACTERISTICS OF TELEPHONE RECEIVERS.

Under working conditions the receiver is held to the ear, and its performance is thereby modified as compared with the condition when it is exposed freely to the air.

Table 3 shows the effect upon the main resonant frequency of the acoustic loading introduced when the receiver is held against the head.

TABLE 3.

Receiver number	Fundamental diaphragm resonance	
	With earcap aperture free	With earcap against ear
1	960	1 180
2	960	1 180
3	1 000	1 260
4	960	1 180
5	890	1 120
6	890	1 190

The average free diaphragm resonance is 943 cycles and average loaded resonance 1 185 cycles.

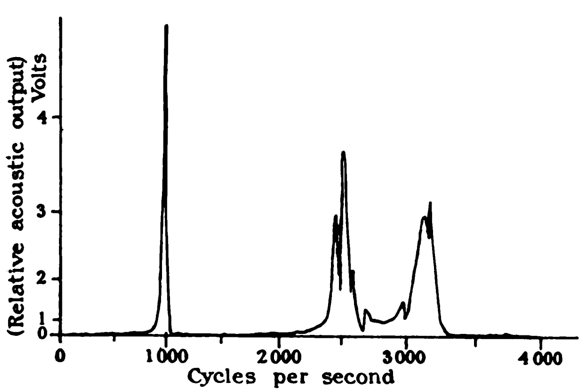

FIG. 15.—Characteristic of Bell receiver with earcap normal.

[This has an important bearing upon the method of using basic standard receivers. A small change in the position of the receiver may appreciably alter its characteristics. The most stable condition for the use of such a standard is with the diaphragm free to the atmosphere. For example, a guard ring may be fixed to the receiver earcap so that the ear is always at a definite distance.]

Interesting results as to the nature and positions of the mechanical resonances of the diaphragm are given by the sand figure method,* which shows that within the frequency range 0 to 4 500 cycles the diaphragm can vibrate in four different modes, namely the fundamental, the single-line mode, the two-lines mode and the single-circle mode. Owing to the central position of the pole-pieces, however, the response at the two intermediate modes is relatively feeble.

Using a Bell receiver, operated from the substantially constant output of the heterodyne oscillator, to actuate the eddy-current transmitter, the authors have obtained photographic records of the characteristics of telephone receivers.

Fig. 15 shows the frequency characteristic of a Bell telephone receiver placed at a distance of 17 cm from the diaphragm of the eddy-current transmitter. By using the calibration curve A of Fig. 6, the voltage output can be converted into sound pressures at the transmitter diaphragm at any desired frequency where the output is measurable.

Fig. 16 shows the performance of the same receiver, similarly placed, but with the earcap replaced by one which had been cut away to the clamping surface of the diaphragm. Sand figures observed with the receiver in this condition showed the fundamental at 970 cycles, the single-line mode at 1 660 cycles, the two-lines mode at 2 250 cycles—the response at this frequency was of sufficient strength to record in Fig. 16—and the nodal circle mode at 2 900 cycles per sec. These two curves show that the presence of the earcap introduces on the diaphragm an acoustic load which, even apart from the addition of an acoustic resonance, appreciably alters the characteristic.

All the records so far obtained for Bell receivers show

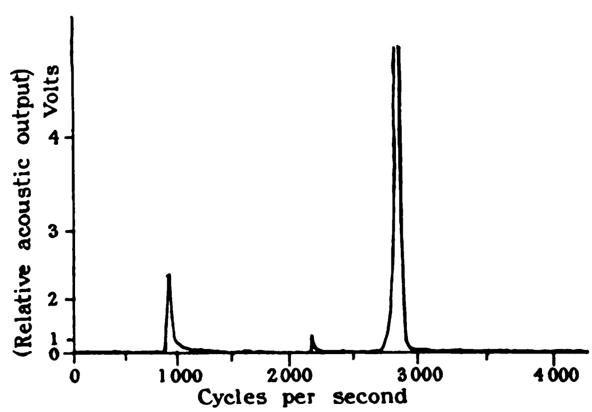

FIG. 16.—Characteristic of Bell receiver with earcap cut away.

three outstanding resonance peaks within the frequency range. Of these, the one at the lowest frequency, namely about 1 000 cycles, is that of the diaphragm vibrating at its fundamental mode. That at the highest frequency, usually 3 000 to 3 500 cycles, is due to the diaphragm vibrating at its single-circle mode. The intermediate peak occurs usually between 2 500 and 3 000 cycles per sec., is of less regular form and is caused by the acoustic resonance of the air chamber in front of the diaphragm. The two-lines mode of vibration may nearly coincide with this intermediate resonance but its response is comparatively small, as to a greater extent is the response at all other frequencies not in the vicinity of any of the three resonant peaks.

FREQUENCY CHARACTERISTICS OF TELEPHONE RECEIVERS MEASURED BY AURAL BALANCING.

It is of interest to investigate the frequency characteristics of receivers directly by the ear, and various

* J. T. MACGREGOR-MORRIS and E. MALLETT: *Journal I.E.E.*, 1923, vol. 61, p. 1134.

methods have been used for this purpose. The method so far found to give the most accurate results makes use, for balancing, of a fixed constant-frequency voltage which is applied to the receiver under investigation, the voltage being such as to give a suitable acoustic output.

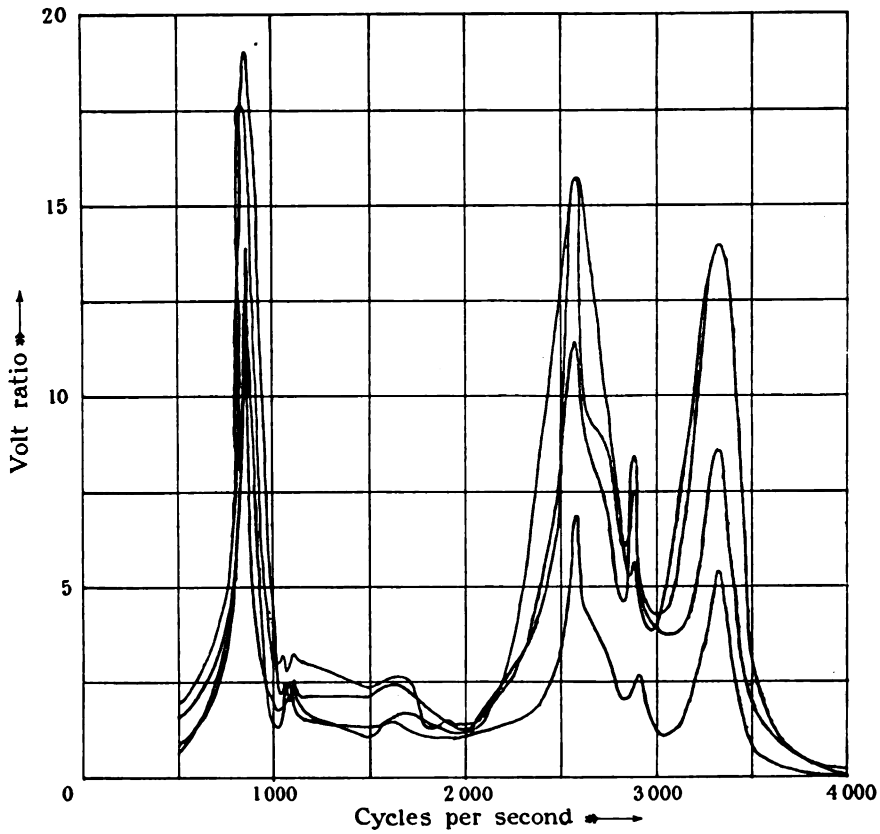

Fig. 17.—Characteristics of Bell receiver by aural balancing (4 observers).

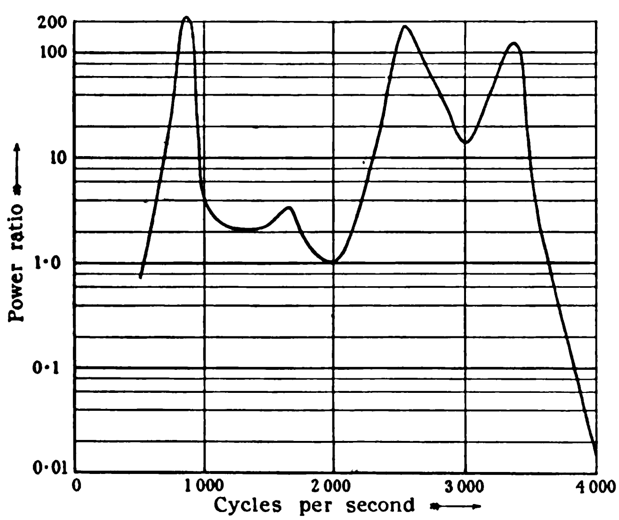

Fig. 18.—Frequency/power characteristic of Bell receiver by aural balancing.

The observer alternately applies to the receiver a voltage of this balancing frequency and of the particular frequency under comparison, the voltage of the latter being varied until the two sounds appear, to the ear, equal in volume. Although the frequency difference makes the balance more difficult, the method is capable of giving reasonably consistent results, as will be seen from the curves in Fig. 17, which gives the results for a particular 60-ohm Bell receiver. Tests were made by four observers, and using a balancing tone of 2 000 cycles. The receiver was tested at a distance of 1·5 in. from the ear.

The frequency responses, for convenience of measurement, are expressed as the ratios of the voltages of the two frequencies when balanced. The average result converted to ratios of power dissipated in the receiver is plotted in Fig. 18. This curve should be compared with Fig. 15, which shows the output characteristic as obtained by means of the eddy-current transmitter.

Receiver Diaphragm Movements.

Various methods of observing and measuring the motions of a receiver diaphragm have been described. Reference may be made to Wien, Shaw, Abraham, Duddell, Kennelly, Irwin and Kranz. The last-mentioned observer uses both vibrating mirrors and direct observation of a quartz fibre under the microscope.*

A modification of Kranz's methods has been experimented with and will now be described. Preliminary

* *Physical Review*, 1923, vol. 21, p. 573.

experiments were made using indicators attached to the diaphragm with sealing wax. These indicators consisted of small blown-glass cones or pieces of straw about 1 in. long, one end of which (the base in the case of glass cones) was attached to the diaphragm and the other end carried a small piece of microscope cover-glass. The glass was covered with acetylene soot and sprayed with mercury globules by means of an aerograph. Globules could be produced only a few microns in diameter and, when viewed by reflected light under the microscope, at a magnification of the order of 1 000 diameters, appeared as small stars on a dark background.

By flooding these cover glasses with Canada balsam in benzole, the mercury globules were firmly embedded and indefinitely preserved from tarnishing. The weights of the complete indicators varied between 13 and 40 milligrams, and it was found that a load of 40 milligrams attached to the centre of an ordinary receiver diaphragm weighing 3 227 milligrams had only a slight effect on the amplitude and frequency response for the fundamental diaphragm resonance. Indicators of this type enable the diaphragm motions, which are in the plane of the microscope field, to be measured by means of a micrometer eyepiece. When the motions are at right angles to the microscope field, the reflected points of light become, of course, blurs, but with a calibrated fine adjustment to the microscope these motions can also be measured. When any motions, other than normal to the diaphragm, occur, they will be due to angular motions of the attached indicator due to the bending of the diaphragm, and may occur at any mode of vibration other than the fundamental. The length of the indicator being known, the angle of bending can be obtained, provided the movement is brought within the plane of the microscope field. The effect on the diaphragm due to the stiffening over the area covered by the base of the indicator has so far been undetermined and may be considerable at the higher modes of vibration, and, until further examination, the results at the fundamental frequency only are dealt with.

By fixing the receiver to an electromagnetically operated reed vibrating a few times per second and at right angles to the normal diaphragm motion, the apparatus has been used to investigate transient diaphragm motions such as the clicks set up by condenser discharges and so on.

Bifilar vibrating indicator.—The following method has also been used for the examination of the diaphragm motion. A small hard-wood indicator is supported by bifilar suspenders of fine tungsten wire tightly stretched; it carries at one end a cover glass prepared as previously described. The other end of the indicator can be brought into contact with any point on a receiver diaphragm by suitable screw adjustments which move the receiver in two dimensions.

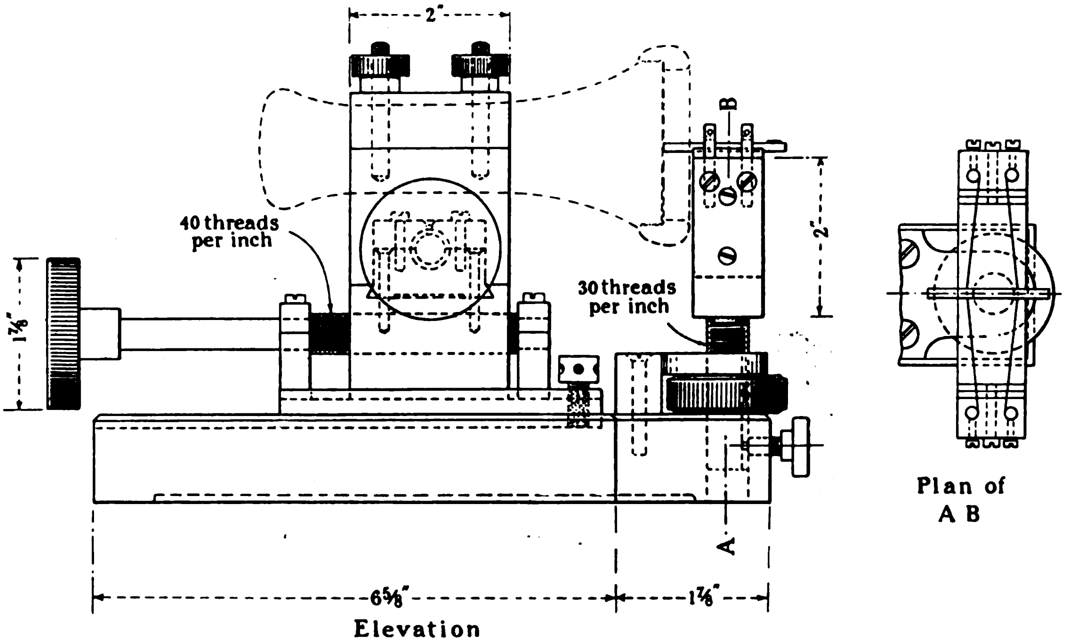

FIG. 19.—Diagram of bifilar instrument to measure diaphragm motion.

By calibrating, in terms of the pressure in milligrams, the steady deflections of the indicator when the diaphragm is pressed against it, suitable and similar pressures can be ensured for all points explored. A simple calibrating device is included. This consists of a small lever rocking on a jewel and engaging with the wooden indicators, to which it applies known pressures for calibration by means of a scale pan and weights. The weight of the wooden indicator and cover glass is of the order of 110 milligrams. The apparatus is illustrated in Fig. 19.

Results.—A number of observations have been made on various types of telephone receivers, and particulars of some of these will now be given :—

Tests have been made of the resonant frequency of the fundamental of a Bell receiver, by listening, by the cemented-on type of indicator, and by the bifilar indicator, and all agree to within about 50 cycles. The amplitudes of motion by the two methods of

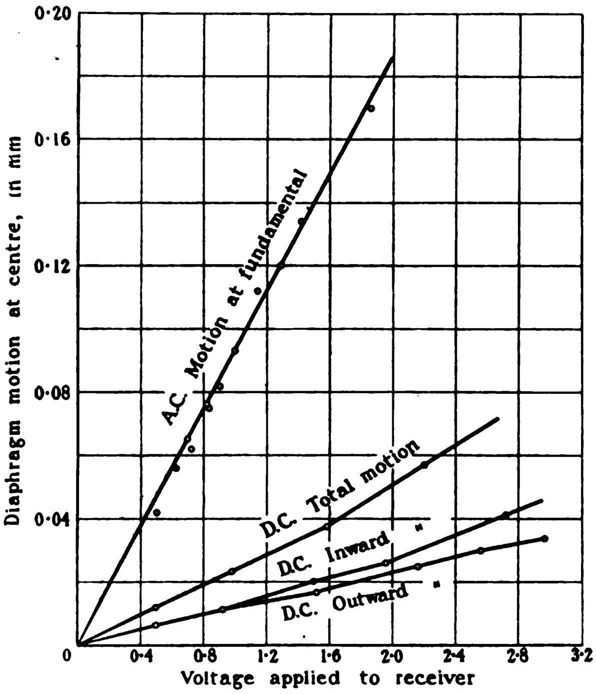

FIG. 20.—Amplitude of motion at centre of Bell receiver diaphragm for direct current and alternating current at fundamental.

diaphragm measurement are in approximate agreement.

Amplitudes of motion at centre of diaphragms for alternating currents at the fundamental frequency, and for direct currents.—The amplitude of motion of the centre point of the diaphragm of a 60-ohm Bell receiver

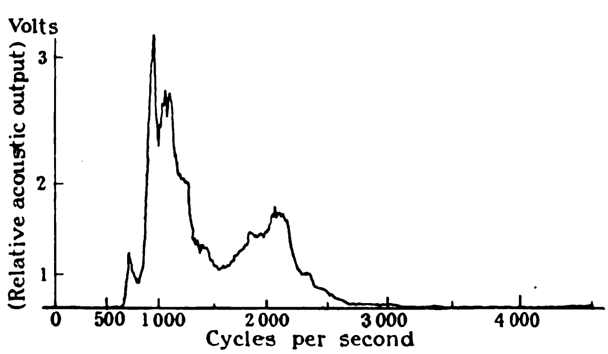

FIG. 21.—Characteristic of horn-type loud-speaker (type 1).

of the ordinary pattern was measured for various d.c. voltages across the receiver for both directions of application.

Fig. 20 gives curves for the motions towards and away from the poles, and it will be noted that for values above 1 volt the motions towards are greater than those away from the poles. In the same figure a curve is also given showing the sum of the inward and outward motions, and also a curve for the motion with alternating voltages at the fundamental diaphragm frequency. It will be noted that, for the limits investigated, this relationship follows a straight-line law and also that a steady voltage of 1 volt applied in both directions gives a diaphragm motion of 0·024 mm, whilst 1 volt (R.M.S.) at the fundamental frequency of the diaphragm gives a motion of 0·093 mm, or about four times as much.

Frequency Characteristics of Loud-Speakers.

By means of the eddy-current transmitter and the heterodyne oscillator, photographic records were obtained of different types of loud-speakers. Some typical examples of these are reproduced, brief details of which follow. The voltages shown on these curves bear no relationship to the eddy-current transmitter calibration which appears in Fig. 6.

Fig. 21 is the characteristic of a horn-type loud-

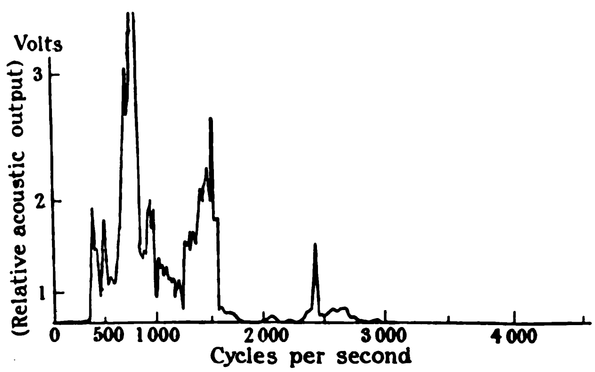

FIG. 22.—Characteristic of horn-type loud-speaker (type 2).

speaker having a circumferentially corrugated diaphragm the centre of which is connected to an armature. The horn expands from an internal cross-sectional area of

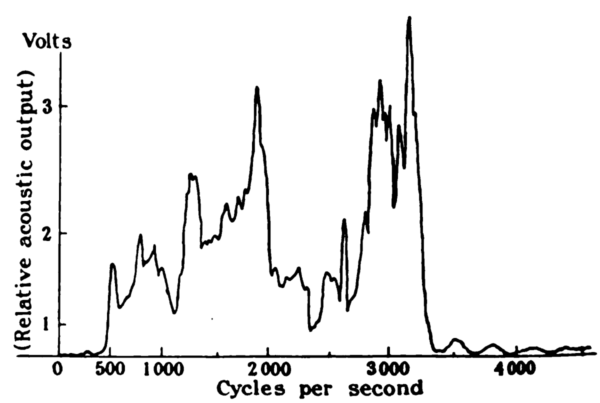

FIG. 23.—Characteristic of horn-type loud-speaker (type 3).

0·32 sq. in. to one of 0·5 sq. ft., the axial length being approximately 20 in. This record was taken with the loud-speaker and transmitter in the open air at some distance from buildings.

Fig. 22 was taken using another horn-type loud-speaker; in this case the diaphragm was a stalloy disc, $2\frac{3}{4}$ in. free diameter by 0·015 in. thick. The horn was

of metal, the extreme cross-sections being 0·25 sq. in. and 1 sq. ft., and the axial length about 28 in.

Fig. 23 shows the characteristic of a telephone head-gear watch-type receiver, used as a loud-speaker, with

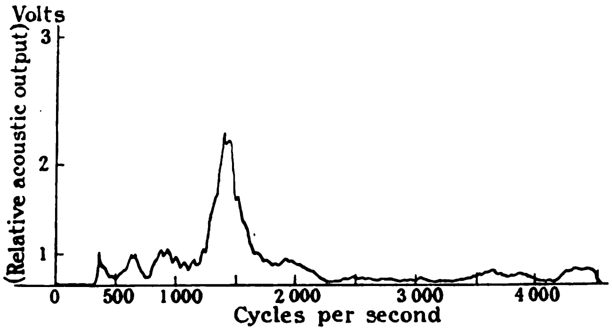

FIG. 24.—Characteristic of hornless loud-speaker (type A).

an exceptionally well-designed horn. This horn expands, according to an exponential law, from a cross-section of 0·2 sq. in. to one of 1 sq. ft.; the axis of the horn is straight and 3 ft. in length.

Figs. 24 and 25 show the performance of two types of hornless loud-speakers. That in Fig. 24 is of the pleated diaphragm type, the diaphragm having a diameter of about 1 ft.; whilst the diaphragm of the one shown in Fig. 25 is umbrella-shaped and very light. In both

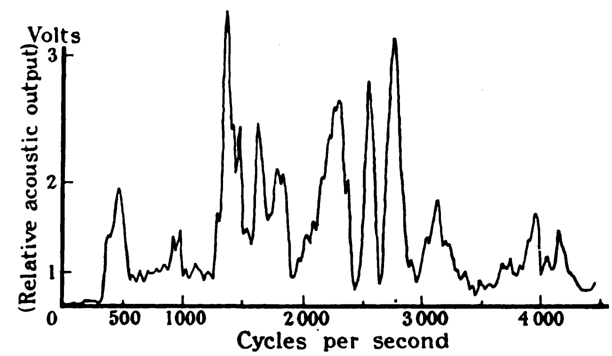

FIG. 25.—Characteristic of hornless loud-speaker (type B).

cases the centre of the diaphragm is connected by a pin to the armature of an electromagnetic system.

The curves of Figs. 22, 23 and 24 were taken in a cabinet which had been draped to minimize sound reflections, whilst that of Fig. 25 was taken in a large room without any special precautions to overcome reflections, which may have considerably modified the characteristic.

FREQUENCY CHARACTERISTICS OF LINES.

Uniform lines.—This covers all types of unloaded and unrepeatered lines, both underground and aerial. The well-known formula for the voltage or current attenuation along a uniform line is

$$a = \sqrt{\{\tfrac{1}{2}\sqrt{[(R^2 + L^2\omega^2)(G^2 + C^2\omega^2)]} + \tfrac{1}{2}(RG - LC\omega^2)\}}$$

where R = resistance per unit length of circuit,
L = inductance ,, ,,
C = capacity ,, ,,
and G = leakance.

Fig. 26 shows the value of a calculated for two typical lines: (1) a 20-lb. underground cable and (2) a 400-lb. aerial line. It will be seen that the attenuation of the unloaded cable increases with the frequency, being, in fact, proportional to $\sqrt{}$(frequency), whereas the attenuation of the heavy-gauge open wire is substantially constant.

These curves explain the well-known fact that unloaded cable circuits, when of any length, are always "drummy," due to the greater attenuation of the higher frequencies, whereas the open-wire line, when in good condition, is nearly perfect.

The line constants per mile of circuit are :—

20-lb. cable.—$R = 88$ ohms, $L = 0$, $C = 0{\cdot}06\mu$F, $G = 0$.

400-lb. open wire.—$R = 4{\cdot}5$ ohms, $C = 0{\cdot}0092\mu$F, $L = 3{\cdot}44 \times 10^{-3}$ H, $G = 10^{-6}$ mho.

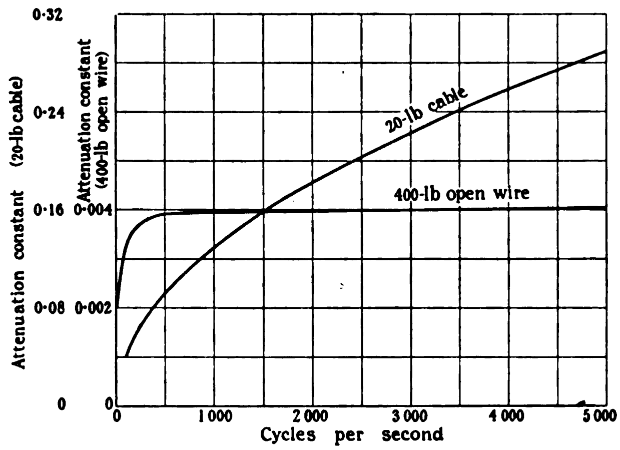

FIG. 26.—Characteristic of unloaded cable and open wire.

Loaded lines.—In spite of the electrical efficiency of open-wire circuits, the obvious maintenance difficulties and the physical impossibility of finding room for the large numbers of circuits necessary for modern requirements, even apart from the question of cost, have resulted in the development of loaded lines. Most modern long-distance lines in the British Isles consist of 20-lb. or 40-lb. conductors with different types of loading coils spaced at different intervals. The following are the standard loadings adopted :—

Extra light, heavy	0·044-henry coils spaced at	1·125 m
Light, light ..	0·136 ,, ,, ,, ,,	2·6 m
Half medium, heavy	0·089 ,, ,, ,, ,,	1·125 m
Medium, medium..	0·177 ,, ,, ,, ,,	1·6 m
Medium, heavy ..	0·177 ,, ,, ,, ,,	1·125 m
Heavy, heavy ..	0·250 ,, ,, ,, ,,	1·125 m

The theory of the action of inductive blocks in a telephone line was worked out by M. I. Pupin and G. A. Campbell.* The latter showed that when $\frac{1}{2}\omega d\sqrt{(LC)}$ (where $\omega = 2\pi \times$ frequency, L = coil inductance per unit length, C = capacity per unit length,

* *Philosophical Magazine*, 1903, vol. 5, p. 313.

and d = distance between coils), became equal to or greater than unity, the character of the transmission changed. The attenuation becomes largely independent of resistance, is caused by reflections between coils, and increases very rapidly with frequency, whereas below unity the attenuation is practically independent of frequency.

This curious change in transmission, which is the basis of all electrical filter circuits, obviously has a most important bearing upon the design of loaded lines. The greater the number of coils used in any line to give any specified inductance the higher will be the value of the frequency at which $\frac{1}{2}\omega d\sqrt{(LC)}$ becomes 1, and hence the higher will be the frequency at which the attenuation begins rapidly to increase, i.e. the "cut off" point. For economic reasons, however, as few coils as possible must be used, so that it is necessary to determine the maximum frequency which it is desired to transmit without serious attenuation. In the early days of loading it was found for the lengths of loaded

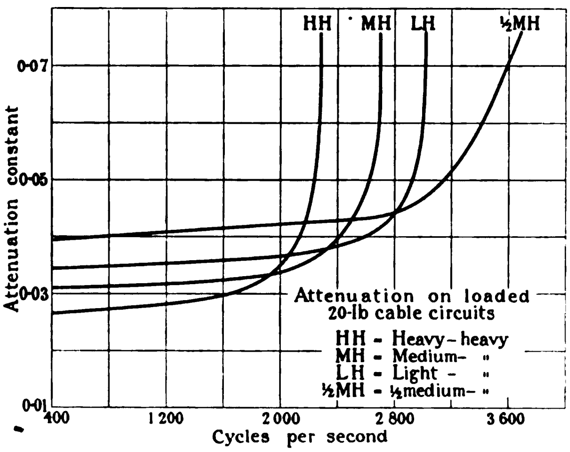

FIG. 27.—Characteristics of 20-lb. cable with various loadings.

circuit in use that a maximum frequency of about 1 800 cycles was sufficient for the transmission of commercial speech. With the introduction of thermionic repeaters, however, and consequent increase in length of loaded underground circuits, the effects, which are cumulative, of the somewhat greater attenuation of the higher frequencies in each repeater section, become important, and it has been found necessary to increase the cut-off point.

On existing loaded circuits the cut-off frequency varies between 2 000 cycles for the heavy-heavy loading to 5 600 for the extra light-heavy.

Fig. 27 shows the attenuation, calculated at different frequencies, of a number of 20-lb. circuits loaded with different coils at different spacings.

The constants taken for the cable were :—$R = 88$ ohms, $C = 0{\cdot}062\mu$F, $L = 1{\cdot}5 \times 10^{-3}$ H, $G = 10^{-6}$ mho.

Electrical transmission lines, when their constants are known, are simple structures which lend themselves readily to calculation. For this reason the curves shown in Figs. 26 and 27 have been calculated.

A direct measurement can, however, readily be made by means of the apparatus previously described. For this purpose the line under test must be terminated at the far end with an impedance equal to itself at all frequencies. This is most simply done, whenever possible, by using a line of sufficient length to prevent appreciable reflection from the far end reaching the measuring point. If E_s be the voltage input to the line at the sending end and E_l the voltage l miles down the line, then

$$\frac{E_l}{E_s} = e^{-\alpha l}$$

where α = attenuation constant per mile, and
e = base of Napierian logarithms.

TELEPHONE LINE REPEATERS.

Two systems of operating thermionic repeaters, known as the two-wire and four-wire, are in use. In the former, one pair of wires is used between stations and is used by each speaker, the repeater being duplex. In the four-wire system the subscriber receives incoming speech over one pair of wires and sends out his own speech over the other pair, and the repeaters in each pair are simplex, working in one direction only.

Fig. 28 shows the repeater connections in a two-wire circuit. As is well known, in a circuit of this type

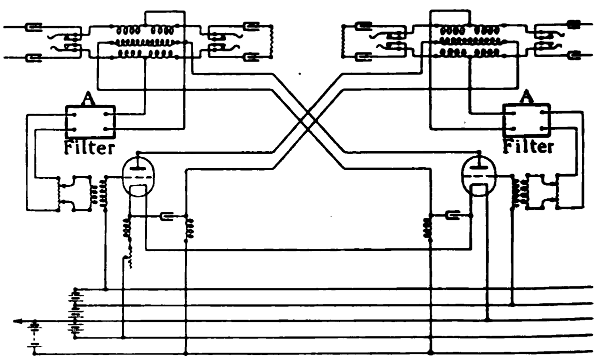

FIG. 28.—Two-wire repeater.

where a balanced transformer is used, unless the balance is kept within fairly close limits self-oscillation will occur, and this introduces a limiting frequency condition. The balances for any circuit are calculated from measurements made, over the frequency range, on the cable in which the repeater is to be used. Fig. 29 shows the measured values of resistance and reactance for an actual cable, together with those of the balancing circuit designed to be as nearly as possible equal to them.

The cable is 20-lb., with medium-heavy loading and the following constants :—$R = 88$ ohms, $C = 0{\cdot}065\mu$F, $L = 10^{-3}$ H, $G = 10^{-6}$ mho.

The small irregularities in the cable figures are due to irregularities in the constants of the cable or coils, or the spacing of the latter, and it will be seen that beyond about 1 900 cycles these irregularities become serious. In order to eliminate these effects the filter circuit shown at A in Fig. 28 is inserted. This filter is usually designed to cut off nominally at 2 200 cycles. Fig. 30 shows the amplification obtained with a commercial duplex repeater such as is shown in Fig. 28. For the test the repeater was inserted in the centre of 40 miles of non-reactive line of line impedance $1\,000\underline{/0}$ ohms, this being the line impedance for which the repeater

was designed. Each line, as is usually the case in practice, was terminated at the repeater with a balanced transformer. The voltage measurements were made at the two extreme ends of the 40 miles of line, the far end being terminated with the line impedance, viz. $1\,000\underline{/0}$ ohms. The curves shown give the amplification

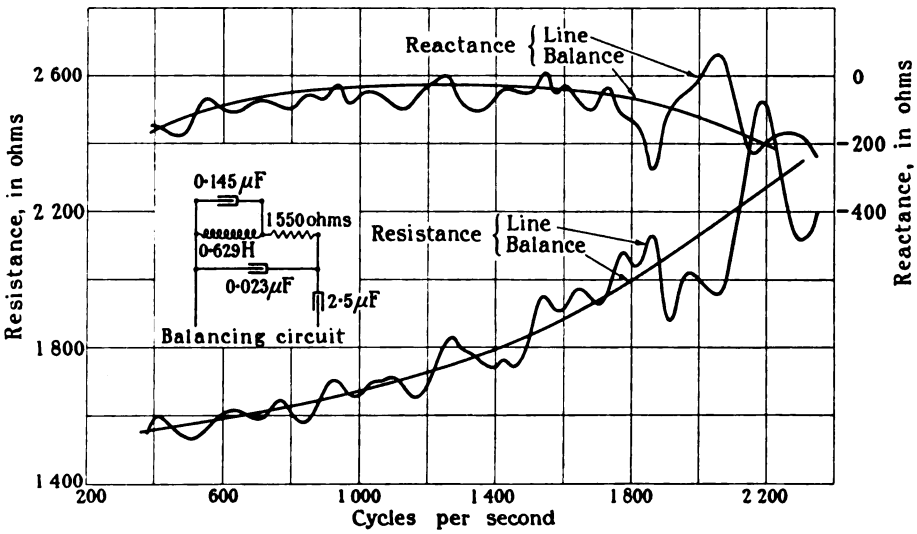

FIG. 29.—Impedance characteristics for loaded line and equivalent balancing circuit.

of the repeater alone, correction having been made for the voltage-drop in the two lines.

On these repeaters the degree of amplification can be adjusted by the potentiometer shown in Fig. 28, but the shapes of the two curves, with and without the filter, will not be sensibly changed.

It will be seen, therefore, that duplex repeaters impose an upper frequency limit of, at present, about 2 200 cycles, and also a lower limit of about 150 to 200 cycles.

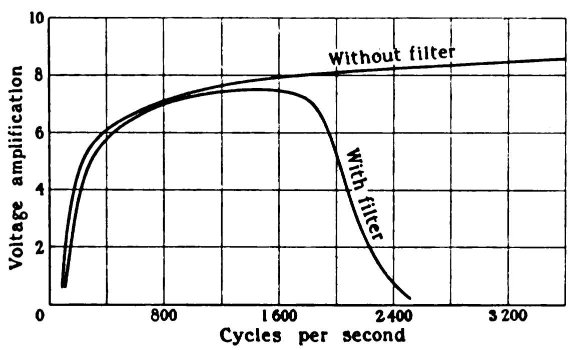

FIG. 30.—Characteristic of 2-wire repeater with and without filter.

Four-wire repeaters.—With four-wire repeater circuits no repeater balances are required and the frequency limitation is given by the loading of the line. As previously mentioned, there is an effect due to the cumulative slightly greater attenuation of the higher frequencies, which is only noticeable owing to the greater length of circuit permissible with repeaters.

IMPEDANCE AND POWER MEASUREMENTS BY MEANS OF HETERODYNE OSCILLATOR.

Another important use of the heterodyne oscillator and recording apparatus lies in the measurement of impedance and power. By adding a resistance in series with the apparatus under test and recording the oscillator P.D., the P.D. across the series resistance and the P.D. across the apparatus under test, a series of "three voltmeter" readings can be obtained at any desired frequency within the frequency range, and the power dissipated in the apparatus calculated from the well-known formula

$$\text{Watts} = \frac{1}{2R}(E_1^2 - E_2^2 - E_3^2)$$

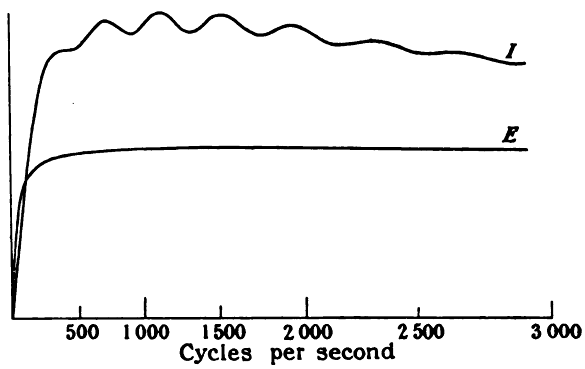

FIG. 31.—Input current on aerial line with fault.

A particularly valuable application to impedance measurements lies in the use of the heterodyne oscillator for the location of faults in telephone lines. Should there be any discontinuity in the uniformity of a telephone line carrying an alternating current, the irregularity, as is no doubt well known, will cause partial reflection of the current wave, with the result

that standing waves of current and voltage will be produced along the line. Advantage is taken of this to locate the position of the irregularity.

In the normal way impedance tests are made* at the sending end of the line over a considerable range of frequencies, and these are plotted against frequency. If there is a single irregularity the curve will be a wavy

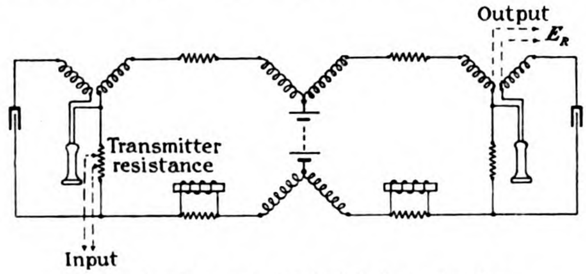

FIG. 32.—Repeating coil "A" connection.

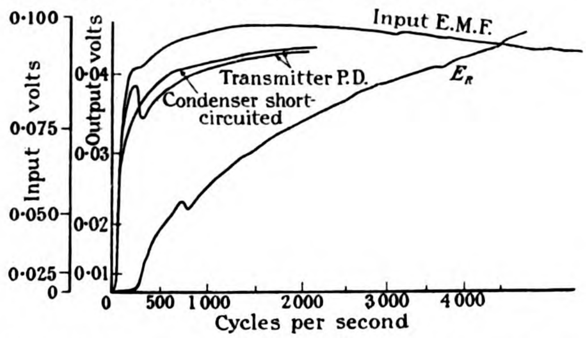

FIG. 32 (*a*).—Characteristics of repeating coil "A" connection.

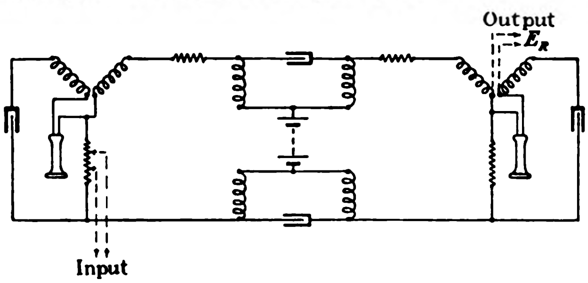

FIG. 33.—Stone "A" connection.

line, the distance between peaks depending upon the distance of the irregularity as follows :—

If d = distance of the irregularity,

f_1, f_2 = frequencies at two adjacent peaks,

λ_1, λ_2 = corresponding wave-lengths,

v_1, v_2 = corresponding velocities of propagation,

N = number of wave-lengths travelled by the reflected wave to and from the irregularity, i.e. in $2d$,

then $N = 2d/\lambda_1$ and $N + 1 = 2d/\lambda_2$.

Also, as $\lambda_1 = v_1/f_1$ and $\lambda_2 = v_2/f_2$,

$N = 2df_1/v_1$ and $N + 1 = 2df_2/v_2$;

from which, $$d = \frac{v_1 v_2}{2(f_2 v_1 - f_1 v_2)}$$

* See C. ROBINSON and R. M. CHAMNEY: Institution of Post Office Electrical Engineers, Paper No. 76.

Fig. 31 shows the input current for a constant applied voltage at the sending end of 500 miles of 200-lb. aerial line, terminated by its characteristic impedance, but with a shunt of 400 ohms across the line at 200 miles from the sending end. This is from a record taken by means of the heterodyne oscillator. Taking the three pairs of adjacent maximum impedance points (occurring

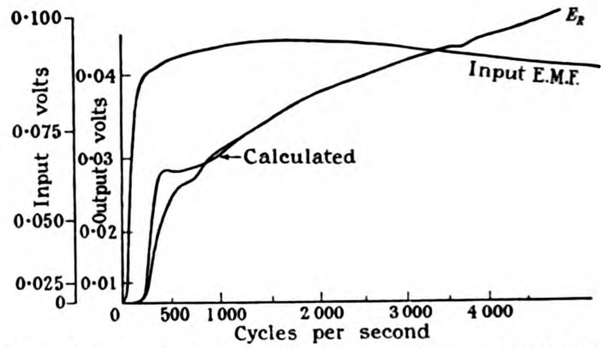

FIG. 33 (*a*).—Characteristics of "Stone" "A" connection.

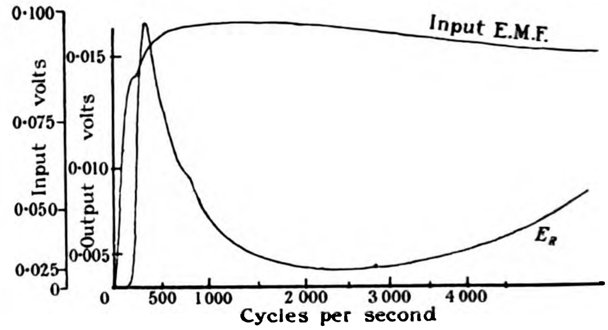

FIG. 33 (*b*).—Characteristic of Stone "A" connection; both induction coils reversed.

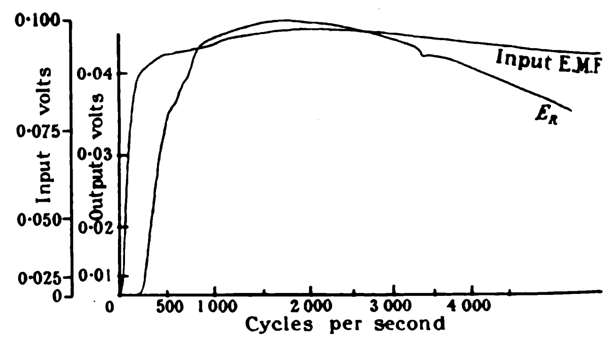

FIG. 33 (*c*).—Characteristic of Stone "A" connection; receiving-end induction coil reversed.

at 910 and 1 340 cycles, 1 340 and 1 760 cycles, 1 760 and 2 170 cycles) the values found for d are respectively 195, 196 and 200 miles.

It is obvious that the test made with the oscillator is very much quicker and less laborious than the corresponding tests of impedance made by means of a bridge.

TELEPHONE EXCHANGE CONNECTIONS.

Figs. 32, 33 and 34 show three typical exchange connections with their corresponding frequency charac-

teristics. The effects of exchange apparatus depend upon the lines on which it is used, and it was thought that the most satisfactory way of indicating results would be to make an overall voltage measurement of sent and received voltages over a complete telephone connection. It is known that a telephone transmitter in operation may be represented by a steady resistance in which an E.M.F. may be supposed to exist, and advantage was taken of this. The

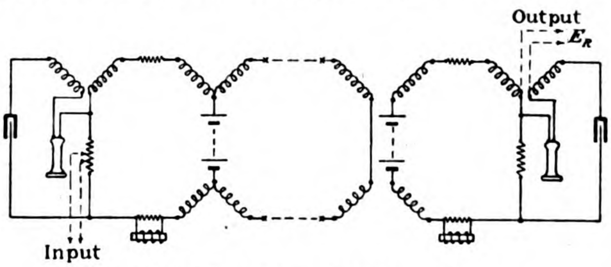

FIG. 34.—Local junction connection.

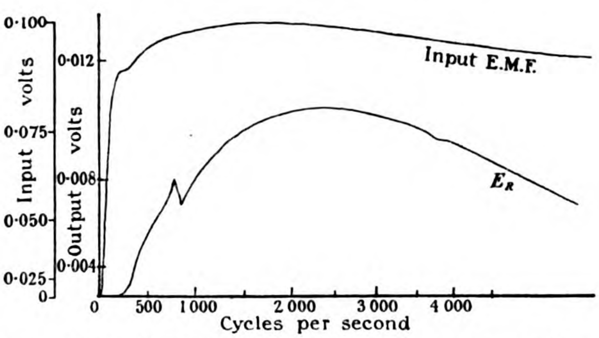

FIG. 34 (*a*).—Characteristics of local junction connection, with non-reactive cable.

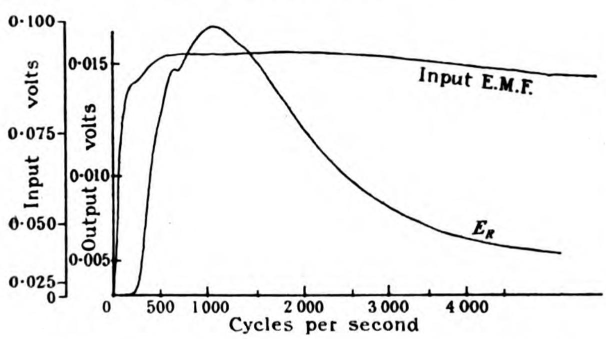

FIG. 34 (*b*).—Characteristics of local junction connection, with 20 lb. cable.

transmitter of the sending-end instrument is replaced by a resistance of 50 ohms. A fraction of this forms part of the non-inductive load of the heterodyne oscillator. The P.D.'s across this fraction and also across the receiver at the far end are recorded photographically.

Fig. 32 (*a*) shows the normal " A " repeater cord circuit, transmitter E.M.F., transmitter P.D., and transmitter P.D. with sending-end condenser short-circuited

Fig. 33 (*a*) shows the normal " A " cord circuit (Stone type); (*b*) is the " A " Stone circuit with one of the induction-coil windings at each end reversed; (*c*) shows one coil winding reversed at the receiving end.

Fig. 34 (*a*) shows the characteristic of a junction circuit with 8 miles of non-reactive cable, and (*b*) the same with 8 miles of 20-lb. cable.

The most noticeable feature of each characteristic is the fact that there is practically no voltage on the receiver terminals until a frequency of about 250 cycles is reached, at which point there is a very rapid rise of voltage, followed by a more or less uniform value. The explanation lies in the rather unusual connections of the standard-type common-battery instrument circuit. It can be shown that the circuit given in Fig. 33, for example, is equivalent to that shown in Fig. 35, the

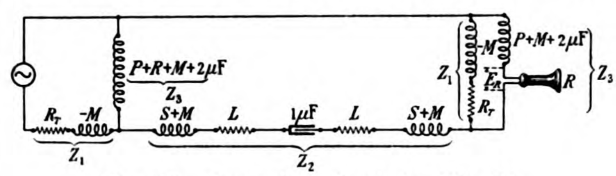

FIG. 35.—Equivalent circuit for Fig. 33.

relatively high-impedance current-feeding coils being neglected.

In Fig. 35:—

R_T = transmitter resistance,
M = mutual impedance of instrument induction coil,
S = impedance of secondary of coil,
P = impedance of primary of coil,
R = impedance of receiver,
L = local line resistance.

Inserting the values for the different quantities, Table 4 shows the value of Z_1, Z_2, Z_3, at different frequencies, together with the calculated voltage upon the far-end receiver for a constant input E.M.F.

TABLE 4.

Frequency	Z_1	Z_2	Z_3	E_R (Relative P.D. on receiver)
64	66/33	2 570/90	1 170/89	—
160	100/64	690/75	285/71	8
240	142/72	235/45	96/7	68
320	186/76	235/45	230/66	220
400	225/79	465/69	377/75	246
480	270/81	690/76	525/78	239
640	360/85	1 120/78	800/79	239
1 120	630/87	1 860/82	1 340/79	272

It will be seen that both Z_2 and Z_3 have a minimum impedance at about 250 cycles and that calculation

gives the same sharp rise of voltage at about this frequency, as shown by the experimental records. The effect is mainly caused by the effect of frequency upon Z_3. The calculated curve is plotted upon the photographic record in Fig. 33 (*a*). The same effect is obtained if the retard coil feed is replaced by a repeater coil feed. The general shape is the same in the calculated and experimental cases, the differences being no doubt due to the fact that the exact values of the various constants have not been taken. At the low frequencies the receiving end portion of the circuit containing the receiver is of high impedance and is shunted by the low impedance Z_1 until resonance is reached.

The small dip in voltage noticeable in each curve at about 800 cycles is due to the drop in receiver impedance at the fundamental resonant frequency, and that noticeable at about 3 600 cycles is due to the nodal circle resonance. The exact shape and position of the dip at the fundamental frequency depends upon the amount of air damping on the diaphragm.

With no cable in circuit, the instrument and cord circuit characteristics, after the first sharp rise, are steady or rising. The effect of cable in attenuating the higher frequencies is well shown in Fig. 34 (*b*).

Referring to Fig. 33 (*a*), (*b*), (*c*), it will be seen that the effect of reversing the induction-coil windings is very pronounced and is due almost entirely to reversal at the sending end. As a matter of fact, reversal at this end causes a loss of about 8 miles of standard cable, and at the receiving end a gain of about 0·5 miles. The reversal changes + M to − M, and this practically reduces Z_3 to $R + 2\ \mu F$, thus producing a heavy shunt at the sending end.

In Fig. 32 (*a*) are shown the transmitter P.D., both with and without the condenser in circuit. At the commencement, owing to the high impedance of the circuits, the P.D. and E.M.F. are nearly the same. As Z_3 approaches resonance the increased current causes an increased voltage-drop in the transmitter, and hence a reduced P.D., which is shown on the transmitter P.D. curve. After passing resonance, the impedance of Z_3 rises continuously with frequency, and the voltage-drop in the transmitter falls. It will be seen, therefore, that the standard type of telephone instrument imposes a definite lower limit of about 250 cycles, just as the loaded line imposes a higher limit.

Frequency Characteristics of Audio-Frequency Amplifiers.

The heterodyne oscillator has proved a convenient means for the rapid determination of the frequency characteristics of telephone-frequency amplifiers. The word "amplifier" here is intended only to cover the use of valves for increasing an applied alternating voltage, and "the amplification of one stage" to refer to the ratio of the voltage on the grid of one valve of an amplifier to that on the grid of the preceding valve.

The majority of tests have been made on individual stages of amplification, mostly of the transformer-coupled type. The tests made on resistance-capacity couplings confirm the estimated performances of such circuits, but the tests on intervalve transformer circuits show such a variety of results—even with the same transformer, used in conjunction with different valves—that further remarks on this method of coupling seem to be justified.

The performance of the transformer depends largely on the constants of the circuit with which it is used, and especially on (*a*) the impedance of the valve used in the primary circuit, (*b*) the capacity load on the transformer secondary, and (*c*) the presence of grid current in the secondary winding. It is probable that the value of the impedance in the plate circuit of the second valve will, under some conditions, also exert an influence on the frequency characteristics of the transformer, but this point has not been investigated.

Methods of test.—An intervalve transformer was tested by inserting it, in the normal manner, between two valves of known constants, by recording the input to the grid of the first valve (this input is a fraction of the substantially constant output from the heterodyne oscillator), by taking a photographic record of the output, through a resistance-capacity coupling, from the second valve, and by ensuring that both valves were operating under normal conditions for amplification and that no grid currents were allowed to flow.

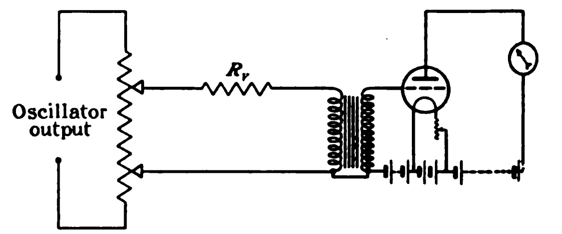

FIG. 36.—Intervalve transformer testing-circuit.

For an alternative method of test, the first valve was replaced by a non-inductive resistance R_1, and the second valve was operated as a rectifier on the anode rectification principle, the reflecting galvanometer being inserted in the plate circuit. (In this circuit—shown in Fig. 36—the direct current normally present in the primary winding of the transformer has been omitted, though current can be made to flow, if required, by the insertion of a high-tension battery. The effect of this current in magnetizing the transformer is usually negligible.) It is considered that this circuit represents, to a very close approximation, the normal working condition of an intervalve transformer so far as the frequency characteristic is concerned.

The amplification to be expected at a given frequency when a valve of amplification factor μ replaces the resistance R_1 will be the product of μ and the ratio of output to input voltages at that frequency. An advantage of this simplified circuit is the ease with which the characteristics are obtained for the equivalent of valves of different and known impedances in the primary circuit.

Intervalve Transformer Curves.

Some typical curves have been selected for reproduction in Figs. 37, 38, 39 and 40, of which those in Figs. 37, 38 and 39 were obtained from a transformer in circuit

between two valves, whilst for those in Fig. 40 the first valve was replaced by a non-inductive resistance, the circuit of Fig. 36 being used.

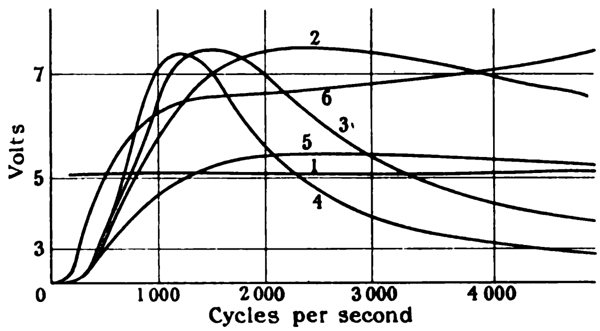

FIG. 37.—Characteristics of intervalve transformer " A."

Fig. 37 shows the performance, under different conditions, of transformer A, which is of ordinary type and commercial manufacture and has a 4 : 1 ratio of turns. In this figure, curve 1 is the oscillator output characteristic; curve 2 shows the performance of the transformer as normally connected (I.P. to plate, O.S. to grid); curves 3 and 4 were taken with loads of 100 and 200 $\mu\mu$F respectively on the secondary, and curve 5 with a load of 50 000 ohms on the primary; for all these curves a valve of about 20 000 ohms impedance was used in the primary circuit. Curve 6 was taken with the transformer normally connected but with this valve replaced by one of about 6 000 ohms impedance.

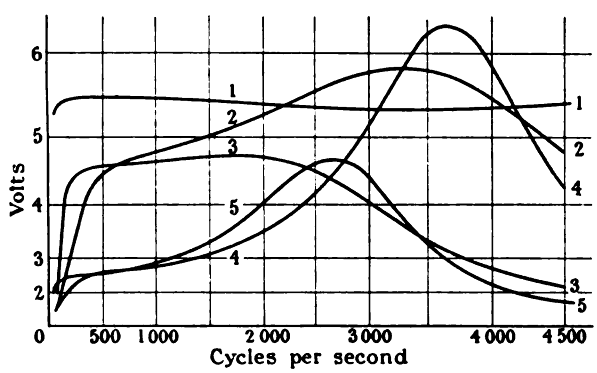

FIG. 38.—Characteristics of intervalve transformer " B."

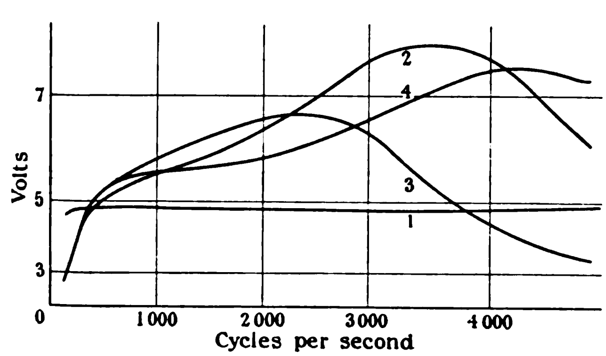

FIG. 39.—Characteristics of intervalve transformer " B."

Fig. 38 shows the performance of transformer B, also of commercial manufacture and having a 4 : 1 ratio of turns. This transformer was constructed in the form of slab coils round a heavy closed iron core, and from this construction an exceptionally high value of magnetic leakage is to be expected. Curve 1 shows the oscillator characteristic; curves 2 and 3 the performance of the transformer with the connections normal and with the secondary reversed, respectively, using a valve of 20 000 ohms in the primary circuit; and for curves 4 and 5 a 6 000-ohm valve was used, curve 4 representing normal connections and curve 5 a reversed secondary.

Transformer B was used for the curves of Fig. 39, in which curves 1 and 2 are for the same conditions as curves 1 and 2 of Fig. 38; curve 3 was taken with a capacity load of 50 $\mu\mu$F on the secondary, and curve 4 with a load of 1 000 $\mu\mu$F on the primary.

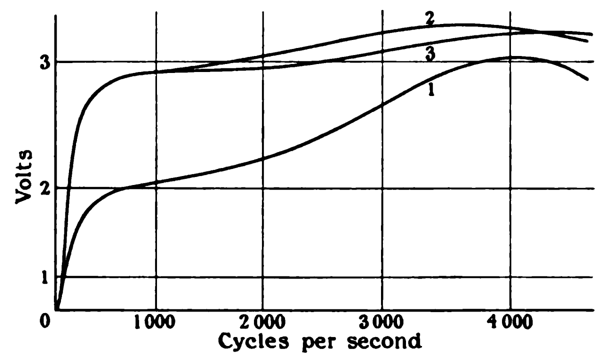

FIG. 40.—Characteristics of intervalve transformer " B."

The curves of Fig. 40 were obtained using a transformer of the same make as B on the circuit of Fig. 36, the resistance R_1 being 20 000 ohms. Curve 1 represents normal connections; curve 2 a load of 1 megohm on the secondary, and curve 3 loads of 1 megohm on the secondary and 750 $\mu\mu$F on the primary. The input voltage in the case of curves 2 and 3 was twice that of curve 1.

The appended analysis, using the equivalent T circuit of the transformer, is submitted in explanation of the results obtained from these tests.

CONCLUSION.

It will be observed that the greater part of this paper deals with the apparatus and methods required to measure and record directly the frequency/amplitude characteristics of lines, circuits, transformers, repeaters, transmitters, and receivers of ordinary and loud-speaker types.

It is obvious that in one paper it is impossible to deal adequately with the frequency characteristics of all apparatus used for the transmission of speech and music, and little attempt has been made to do more than indicate the results obtained with typical apparatus of each of the various classes. The few characteristics given indicate the highly resonant output of commercial telephone receivers and transmitters and the

extent to which the volume efficiency must depend upon resonance. These characteristics show that there is considerable room for improvement in the case of receivers and transmitters, and it is claimed that the apparatus described forms a ready means of enabling the effects of change in construction and design to be conveniently observed, measured and recorded.

The authors' acknowledgments are due to Colonel Purves, Engineer-in-Chief of the Post Office, for permission to present this paper, and to the staff of the Post Office Engineering Research Station for valuable assistance and co-operation.

APPENDIX.

Equivalent Circuits of Intervalve Transformers.

Fig. 41 shows the equivalent T circuit of an intervalve transformer referred to the primary circuit.* R_V represents the internal resistance of the first valve; L_1, R_1, and L_2, R_2, the primary and secondary (referred to the primary) leakage impedances respectively; L, R, the mutual impedance, and C_2 the combined secondary capacities, internal, mutual † and external, all referred to the primary circuit. The capacities of the primary winding have been omitted, since their effect is in

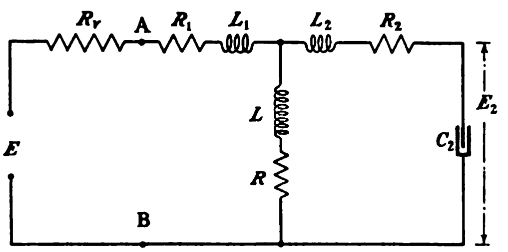

Fig. 41.—Equivalent intervalve transformer circuit.

general negligibly small; the effect, under special circumstances, of adding capacity across the primary will be mentioned later.

Since the impedance to the right of the points A, B, will vary with the frequency of the impressed voltage E (which is $\mu \times$ voltage on the grid of the first valve), the proportion which is applied to the transformer terminals will depend upon the primary impedance of the transformer. This impedance increases with the frequency from a low to a high value as compared with R_V, up to a critical frequency determined by the resonance of L with C_2, after which it will decrease continuously (or at least as far as a frequency determined by the resonance of L_1 and L_2 with C_2). This explains the more or less gradual rise of the frequency/amplitude curves at low frequencies, and the greater rapidity of the rise obtained when a valve of lower impedance R_V is used. As the frequency is increased beyond this critical value the amplitude is liable to be affected by two opposing influences; one of these, due to the decreasing primary impedance, tends to decrease the voltage across A B and therefore across C_2; the other is the tendency of the voltage across C_2 to increase in proportion to that across A B as the frequency approaches a second critical value determined by the resonance of L_1 and L_2 with C_2. Beyond this point the amplitude may be expected to fall off continuously with an increase in the frequency.

An expression can be obtained for the ratio $E_2 : E$ from the circuit of Fig. 41, but it has little value since the quantities of the circuit are all more or less variable with the frequency. It is of interest, however, to investigate the performances of intervalve transformers from theoretical considerations by means of approximate equivalent circuits, which are generally applicable over a limited range of frequency.

Case 1. The Resonance of L with C_2.

It has been demonstrated * that for a wide range of frequencies in the neighbourhood of this resonance, which range extends down to very low frequencies, the performance of an intervalve transformer can be represented to a close approximation by that of the circuit shown in Fig. 42, in which the resistances R_3 and R_4 are considered to be invariable with the frequency. For this circuit

$$\left[\frac{E}{E_2}\right]^2 = \left[\frac{R_V R_4}{R_4^2 + \omega^2 L^2} + \frac{R_V}{R_3} + 1\right]^2 + \omega^2 R_V^2 \left[C_2 - \frac{L^2}{R_4^2 + \omega^2 L^2}\right]^2 . \quad (1)$$

The critical frequency giving a minimum value of E/E_2 is given by

$$\omega_1^2 = \frac{1}{C_2 L}\left\{-\frac{R_4^2 C_2}{L_2} + \sqrt{\left[\frac{2R_4^2 C_2}{L} + \frac{2R_4}{R_V}\left(\frac{R_V}{R_3}+1\right)+1\right]}\right\}$$

In general it will be found that the quantity $R_4^2 C_2/L$ is negligibly small, so that the equation becomes

$$\omega_1^2 = \frac{1}{C_2 L}\sqrt{\left[1 + \frac{2R_4}{R_V}\left(\frac{R_V}{R_3} + 1\right)\right]} \quad . \quad . \quad (2)$$

at which value

$$\left[\frac{E}{E_2}\right]^2 = \left\{1 + \frac{R_V}{R_3} + \frac{R_V R_4 C_2}{L\sqrt{\left[1+\frac{2R_4}{R_V}\left(\frac{R_V}{R_3}+1\right)\right]}}\right\}^2 + \frac{C_2 R_V}{L}\sqrt{\left[1+\frac{2R_4}{R_V}\left(\frac{R_V}{R_3}+1\right)\right]} \left\{1 - \frac{1}{\sqrt{\left[1+\frac{2R_4}{R_V}\left(\frac{R_V}{R_3}+1\right)\right]}}\right\}^2 \quad . \quad . \quad . \quad . \quad (3)$$

This quantity can never be less than unity, though, in general, it is nearly equal to unity. It should be remarked that if R_V be replaced by a valve of the same internal resistance and of amplification factor μ, then the amplification of the stage will be $\mu n E_2/E$, where n is the ratio of the secondary to the primary turns, and E_2/E is the value found from the equivalent circuit.

It is seen from equation (1) that the effect of using a lower resistance R_V will be to reduce the value of

* C. P. Steinmetz: "Alternating Current Phenomena."
† D. W. Dye: "The Performance and Properties of Telephone Frequency Intervalve Transformers," *Experimental Wireless*, 1924, vol. 1, p. 691, and vol. 2, pp. 12 and 74.

* D. W. Dye, loc. cit.

E/E_2, i.e. to raise the amplification, and that this effect is more marked as the frequency is made more remote from that given by ω_1, where the value of E/E_2 is normally nearly equal to unity. This effect is demonstrated in the cases of all the transformers that have been tested. It can also be shown that, for a given value of C_2L, i.e. approximately of ω_1, the frequency characteristic is improved by increasing the ratio $L : C_2$, a feature which is recognized in the design of some tranformers.

The effect of an external non-inductive load.—The effect, at the frequencies under consideration, of an external non-inductive load on either winding of the transformer may be investigated by means of the above equations. The presence of the external shunt will reduce the value of R_3.

At frequencies near the critical frequency the second term on the right of equation (1) is small as compared with the first, hence approximately

$$\frac{E}{E_2} = \left[\frac{R_V R_4}{R_4^2 + \omega^2 L^2} + \frac{R_V}{R_3} + 1\right]$$

Now, since a change in the value of E/E_2 for a given (small) change in ω is the same for any value of R_3, it

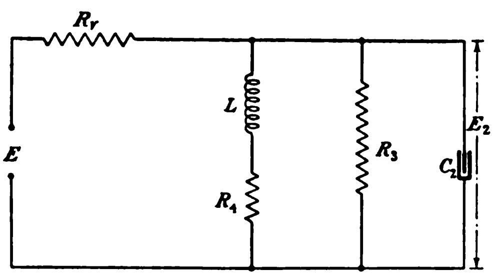

FIG. 42.—Equivalent transformer circuit; approximation for lower frequencies.

follows that the proportional change in E/E_2 will be less as the value of R_3 is reduced. Therefore the characteristic will, in the neighbourhood of the critical frequency, become more flattened out and reduced as to the value of its ordinates due to the presence of an external non-inductive shunt. Moreover, since the second term on the right of equation (1) is independent of R_3, it is clear that as this term becomes larger as compared with the first term (i.e. as the frequency is further removed from the critical value ω_1), so the effect of the shunt on the amplification becomes proportionately less.

CASE 2. THE RESONANCE OF L_1 AND L_2 WITH C_2.

Where this resonance occurs at a frequency considerably higher than that under Case 1, for the consideration of the performance of a transformer over a limited frequency range enclosing the resonance, the approximate equivalent circuit of Fig. 43 may be used. This circuit involves the assumption that the impedance L, R, is so large that its effect is negligible, and that, over the range of frequencies considered, variations in the values of $R_0(= R_1 + R_2)$ and $L_0(= L_1 + L_2)$ and C_2 with frequency may be neglected. In this case, therefore,

$$[E/E_2]^2 = (R_V + R_0)^2 C_2^2 \omega^2 + (L_0 C_2 \omega^2 - 1)^2 \quad . \quad (4)$$

This quantity is a minimum for a value ω_2 of ω given by

$$\omega_2^2 = \frac{1}{L_0 C_2}\left[1 - \frac{(R_V + R_0)^2 C_2}{2L_0}\right] \quad . \quad . \quad (5)$$

at which value

$$\left[\frac{E}{E_2}\right]^2 = \frac{(R_V + R_0)^2 C_2}{L_0}\left[1 - \frac{(R_V + R_0)^2 C_2}{4L_0}\right] \quad . \quad (6)$$

When ω_2 has a high value as compared with ω_1, in accordance with the above assumptions, it follows that $(R_V + R_0)^2 C_2/(2L_0)$ is less than unity, and for such values E/E_2 is less than unity, i.e. the amplification of the stage at the frequency given by ω_2 is greater than μn.

The effect of decreasing the value of $(R_V + R_0)^2 C_2/L_0$ by using a lower impedance R_V will be to raise the values of both ω_2 and the amplification at ω_2. Also, if C_2 be increased by means of an external capacity load on the secondary, the converse will apply.

The above equation for ω_2 may also be used to draw some general conclusions as to the influence on the characteristic of an intervalve transformer of the resonance of L_1 and L_2 with C_2. In the first place, it is

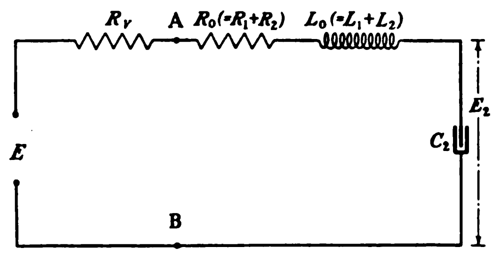

FIG. 43.—Equivalent transformer circuit; approximation for higher frequencies.

seen that there will be no real value for ω_2 unless $\frac{(R_V + R_0)^2 C_2}{2L_0} < 1$, and that as the value of this quantity is increased, the effect of this resonance on the characteristic will be reduced. Also for frequencies higher than ω_2 (or than ω_1 if $\omega_1 > \omega_2$) the amplification may be expected to fall off continuously as the frequency is raised.

Since the performance of the majority of intervalve transformers is chiefly open to criticism on account of their low amplification at frequencies below 1 000 cycles per sec. (especially when used with fairly high impedance valves, as is commonly the case), and since improvement in this direction can mainly be expected by lowering the value of ω_1 [see equation (2) above], it appears that this resonance of the leakage impedance is desirable at a frequency higher than that given by ω_1—at any rate when a high impedance R_V is used—in order to raise the point beyond which the amplification falls off continuously with increasing frequency, i.e. to increase the range of frequencies over which a large amplification is obtained. To effect this, since $(R_V + R_0)^2 C_2/(2L_0)$ must be < 1, and limits are set to

the values of R_V and C_2 by the external circuit conditions, it follows that L_0 should not be made too small, i.e. the coefficient of coupling between the windings should not be too high.

The effect of a capacity load on the primary.—It has been observed that the presence of a condenser across the primary winding of an intervalve transformer may have the effect of raising the value of the critical frequency given by ω_2 as well as of lowering the value of ω_1. (Similar effects have been observed with radio-frequency intervalve transformers.) This results in some cases in an improved characteristic, since the range of high amplification is extended; if, however, too large a capacity is used the characteristic will fall off before it rises to the final critical frequency.

An approximate analysis, using the equivalent circuit of Fig. 43 with an additional capacity included across the points A, B, shows that the above effects are to be expected, and that in the particular case where the added capacity is equal to C_2 (i.e. to the sum of the secondary capacities multiplied by the square of the ratio of secondary to primary turns) the decrease will occur if the value of $L_0/(R_V^2 C_2)$ is less than about 2.

The effect of a non-inductive load on the secondary winding.—Where resonance of the leakage inductance occurs, the effect of a non-inductive load on the secondary winding may be studied by considering a resistance S, representing this load, to be inserted across the condenser C_2 in Fig. 43.

For this circuit

$$\left[\frac{E}{E_2}\right]^2 = \left[\frac{R_V + R_0}{S} - (C_2 L_0 \omega^2 - 1)\right]^2 + \left[(R_V + R_0)C_2\omega + \frac{L_0\omega}{S}\right]^2 . \quad (7)$$

The critical value (the maximum value of E_2/E) is found at

$$\omega_2^2 = \frac{1}{C_2 L_0}\left[1 - \frac{(R_V + R_0)^2 C_2}{2L_0} - \frac{L_0}{2C_2 S^2}\right] \quad (8)$$

to be

$$\left[\frac{E}{E_2}\right]^2 = \left[(R_V+R_0)C_2+\frac{L_0}{S}\right]^2 \times \left[\frac{1}{C_2 L_0} - \frac{(R_V+R_0)^2}{4L_0^2} + \frac{1}{2SC_2}\left(\frac{R_V+R_0}{L_0} - \frac{1}{2SC_2}\right)\right] . \quad (9)$$

It is seen that the presence of S thus lowers the value of ω_2, and that unless $\frac{1}{S^2} < \frac{2C_2}{L_0} - (R_V + R_0)^2$ there can be no real value for ω_2. An examination of equation (9) shows that, as $1/S$ is increased from zero, the amplification at ω_2 is decreased continuously for all values of $1/S$ consistent with a real value of ω_2.

The use of a non-inductive shunt therefore tends to smooth out the frequency characteristic in both the cases considered above—at the expense of some sacrifice in amplification. It helps, moreover, to stabilize an amplifier which has any tendency to self-oscillation. It therefore provides a sometimes convenient alternative to replacing an intervalve transformer by one of a lower ratio, in cases where it is desired to replace the valve in the primary circuit by one of a higher impedance and higher amplification factor.

The foregoing analysis is applied only to individual stages of amplification. In general, the amplification of a multi-stage set will be the product of those of the individual stages at any given frequency. Exceptions occur, of course, when reaction is permitted and when the influence of the impedance in any plate circuit on a previous grid circuit is apparent.

A useful method of improving the performance of an intervalve transformer at the low frequencies is described in a paper by R. W. King in the *Bell System Technical Journal* for October 1923. The primary impedance of the transformer is tuned by an added series capacity, and the battery voltage is applied to the plate of the valve through a choke (or resistance) of suitable impedance.

DISCUSSION BEFORE THE INSTITUTION, 29 APRIL, 1926.

Mr. H. H. Harrison: The paper shows the steady growth of the interlinking of the technique of various branches of the weak-current art, also that we shall have presently to include in that statement the mechanical reproduction of speech by electro-mechanical means, such as the modern gramophone. The paper introduces us to the conception of the cut-off frequency as applied to transmission lines. The paper also lays stress on the importance of investigating the proportionality of response over a wide frequency range for all elements in the chain of whatever transmission means are under consideration. It is interesting to note that the idea of the band frequency has extended even to long-distance telegraphy. We find, for instance, that the best signal shape, in the case of long-distance telegraph cables or lines, is not necessarily attained by allowing all the frequencies which form the rectangular pulses to pass; it is much better to introduce band filters and cut off many of the components. This also helps to clear the line. The bibliography shows the vast amount of work which has been done in recent years, and the large number of workers. It is very gratifying to find that the Research Section of the British Post Office is not only cognizant of this work, but is itself making such weighty and original contributions. I am somewhat disappointed that the authors have made no reference to the transmission unit. I am myself a believer in the transmission unit, but we want to know, amongst other things, whether one or more lines having entirely dissimilar characteristics but the same value in transmission units can be considered as identical when receiving and sending conditions are the same. I should like to suggest two additions to the authors' bibliography. I believe I am correct in saying that Mr. Shepherd (of, I think, the Research Department of the Post Office) was the first to point out, in a short note in the *Electrician* a good many years ago, that an ordinary telephone line behaved as an electric filter and cut off at a definite frequency which could be calculated from the constants of the line. I would further suggest that the paper by Dr. Kennelly entitled "A Contribution to the Theory of Telephony," which also appeared in the *Electrician* and which dealt with the behaviour of a transmitter induction-coil line combination over a band of frequencies, be also included. The present paper is further evidence, if evidence be needed, of the fact that telephony—or perhaps it would be better to say "communication engineering"—is just as important as any other branch of electrical engineering The powers employed are insignificant—in many cases only of the order of milliwatts—and in the event of a short-circuit the results are not so spectacular as when dealing with 20 000, 30 000 or 40 000 kW, but the engineering considerations underlying the design of a telephone network are just as important as the design of a three-phase high-tension power transmission line.

Professor E. Mallett: The authors have collected together valuable information on work done by various investigators in various countries, and they have given us an exceedingly useful piece of apparatus of their own in the heterodyne oscillator. About two years ago Mr. Cohen exhibited this oscillator (or its predecessor) in this room, and showed how one could get a wide range of frequencies from it by simply turning one knob. That, of course, is extremely useful. The paper gives some details of how to set up the apparatus and make it work. The output is given in Fig. 8, but it should not be imagined that directly the apparatus is set up as shown in Fig. 7 the output shown in Fig. 8 will be obtained. At the City and Guilds College we have been trying for some considerable time to get the output as shown in Fig. 8 from an arrangement very similar to that shown in Fig. 7, and we have not quite succeeded. Although the paper deals with frequency characteristics it does not mention how the frequency is to be measured. We have had difficulties in that connection. It is not sufficient for accurate work to take the note frequency as the difference of the calculated frequencies of the two oscillators, because these frequencies (especially of high-frequency oscillators) do not remain constant. As another addition to the bibliography I should like to suggest Miller's book on "The Science of Musical Sounds." Miller shows that vowel sounds all consist of either one

frequency or two frequencies. It does not matter in what pitch one says the word "māā"; what really constitutes the "āā" sound is a frequency of 1 000 cycles. Other vowels are characterized by having two frequencies. For instance, the sound in "mat" has two frequencies, 800 and 1 840. For "met" the two are 691 and 1 593; for "mate," 488 and 1 427, and for "meat" 308 and 3 100. There are certain other sounds which have only one frequency: "mōō," for example, where the "ōō" sound has one frequency only—326. The result is that if one says "meat," the two frequencies for which are 308 and 3 100, and the telephone apparatus cuts off everything above 2 000 cycles, one is left with "moot," and if one says "tea" it sounds like "too." Judging from the diagrams of the output of the transmitters, one would certainly gather that with the ordinary local battery transmitter and the common-battery transmitter nothing above 2 000 cycles could ever get on to the line. So far as the receiver in Fig. 15 is concerned it receives well from 2 000 to 2 400 cycles, but there is nothing whatever between 1 000 and 2 000 cycles, so that these scientifically accurate pictures must be very carefully interpreted acoustically. As a matter of fact, one knows that the transmitter sends out some energy above 2 000 cycles, and the receiver is not wholly inert between 1 000 and 2 000 cycles. What happens apparently is that the ear does not appreciate differences of intensity of sound to the extent that one would expect. A sound with a particle velocity of, say, 2 cm per sec. would perhaps be judged only half as strong again as one with a velocity of 0·2 cm per sec. The ear very quickly gets saturated. Good music of the broadcast order seems to be in quite a different category from telephony; there we have to have everything transmitted. Broadcast can, in fact, be compared with the finished picture. As far as ordinary telephony is concerned, we are content with a rough sketch; so long as the main features are there, our intelligence enables us to fill in the rest and we get a proper idea of what is intended.

Mr. E. K. Sandeman: I am very interested in the heterodyne oscillator as a possible solution to the problem of producing a light-weight oscillator. A good oscillator of the Hartley type with all accessories, covering a range of 100–50 000 cycles, may weigh as much as 200 lb. Is there any chance of a heterodyne oscillator being made which would be appreciably lighter than this? The chief difficulty arises from the fact that large coils are necessary in order to filter at low frequencies. In the case of the heterodyne oscillator, filtering may be done at high frequencies, which is much simpler, and further, a fixed frequency filter can be used. In a good many cases it is not necessary to know the frequencies extremely accurately for the purpose of response-frequency measurement. In the present state of things, in interpreting response-frequency characteristics, it is not possible to discriminate seriously between, say, 3 000 cycles or 3 200, so that a slight error in frequency is not very serious. The accuracy of the heterodyne oscillator is capable of being maintained within much greater limits of accuracy than that. The accuracy of an ordinary valve oscillator operating with mica condensers and air-choke inductances is, I understand, of the order of 3 parts in 100 000 for a change in temperature of 1 deg. C. For a change in temperature of 20 deg. this means that in the case of a heterodyne oscillator employing beat frequencies of the order of 20 000 cycles there would be a maximum change at 100 cycles of 12 cycles in each oscillator, which seems quite a tolerable change for a great many purposes, even if both beat oscillators vary in different directions. Further, for very many purposes it would be possible to sacrifice constancy of output. It is stated on page 1033 that no account is taken of local irregularities in the sound wave due to the presence of the transmitter. This refers to the fact that when the transmitter is placed in the testing chamber it distorts the sound field, which, in the absence of the transmitter, is presumably of an intensity uniform throughout the chamber, and constant with frequency. It seems to me that the distortion in the sound field occasioned by the presence of the transmitter is part of the distortion caused by the transmitter, and should be reckoned as such, and therefore this particular point is perfectly justified, but it also seems that the attendant circumstances require clear definition. There is another point which should not be lost sight of, viz. that when a man is put in a sound field he also distorts it, and it is a nice question as to whether a microphone could not be said to be truly distortionless if it distorted the sound field in the same way as the human head, for some chosen position. It seems to me that the experiments described in the paper indicate that the time is coming when these points must be taken up seriously. Very similar experiments have been made in the research department of the Western Electric Co. at New York, where they have also been taking characteristics of acoustic apparatus and have obtained results similar to those of the authors. I do not quite understand why a great many of the characteristics were taken with the telephone transmitter placed opposite the sound-measuring device in free air, and it is difficult for me to see what meaning a response characteristic could have under these conditions. The only criterion of performance seems to me to be a response characteristic under actual operating conditions, and the performance of a telephone receiver operating into free air is a very different thing from that of a telephone receiver pressed against the ear. An approximate solution would appear to be given by the use of some form of artificial ear.

Mr. B. Mittell: Mr. Harrison has drawn attention to the various fields to which weak-current engineering is applied. I have here a gramophone of recent construction which has been designed largely on the principles that have been developed for telephone engineering and which have been applied by His Master's Voice Co. to the mechanical gramophone, chiefly through the leadership of the Western Electric Co. My particular purpose is to show the usefulness of this machine as a tone generator. In the beginning of the paper various generators—direct generators of acoustic tones—are dismissed as impracticable, but this one we find very useful for a number of measurements that do not justify the expense and complication of any kind of oscillator. Records are prepared of single frequencies, one disc

carrying 6 or 8 different tones, each separately calibrated. The response characteristic of the machine is measured and the total output from the machine is therefore known. I shall now demonstrate records of certain single frequencies. The obvious question that will be asked is how pure the tone is and what is the

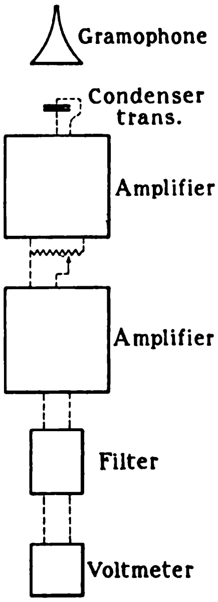

FIG. A.

good of it. No electrical frequency is pure. The authors have laid down a limit, but in the Gramophone Co.'s experience it is necessary, whatever oscillator is used, to insert a filter which will cut out harmonics. All that is necessary, therefore, is that the tone should be reasonably pure within limits, so that after the

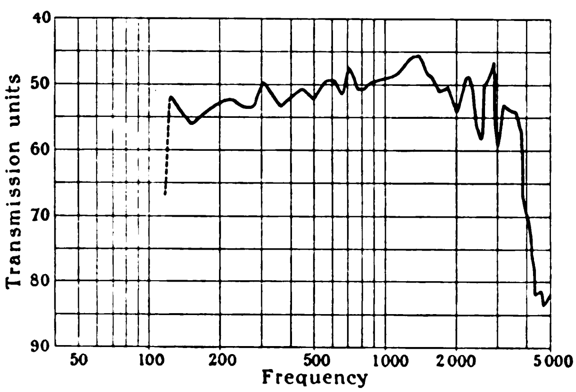

FIG. B.

harmonics are filtered out there is still a reasonable proportion of fundamental left. For several practicable purposes, routine tests of electrical equipments can satisfactorily be made with these calibrated records, without the use of a filter, by referring to a correction chart which gives the proportion of fundamental to total energy as indicated by the equipment under test. Fig. A shows the method used in calibrating the gramophone. At the top is the gramophone, and then there is the condenser transmitter—one of the Western Electric Co.'s condenser transmitters—then a preliminary amplifier and then the potentiometer which is used for bringing up the output at any frequency to a predetermined level. The voltmeter is at the bottom and at any frequency the potentiometer can be adjusted to give the same deflection on this voltmeter. It can thus be ascertained how much amplification has to be used for a particular frequency to bring it up to the standard, and a curve is plotted (see Fig. B). A filter is used to cut off all frequencies one octave higher than that being measured. The curve obtained is a good one and better than those given by the authors for the loud-speakers. I should point out, however, that whilst the curves in the paper are on a voltage scale, this curve is in transmission units plotted against a logarithmic frequency scale.

Mr. A. G. Warren: I suggest that the two curves in Figs. 26 and 27 would be greatly improved if the constants of the line per mile were included.* Towards the end of the portion of the paper dealing with the frequency characteristics of lines the authors say: "Electrical transmission lines, when their constants are known, are simple structures which lend themselves readily to calculation." Upon the usual assumptions this should be correct, but unfortunately a fair proportion of the literature upon telephony does not substantiate this statement. In the case of a continuous unloaded line the problem is quite simple, and if, say, the voltage is plotted against the length of the line, a continuous complex attenuation curve is obtained. In the case of a heavily loaded line the problem is quite simple also, because the line approximates to a filter, and the attenuation curve derives to a number of isolated points. The solution of a lightly loaded line is a more difficult matter, however, because there is a continuous attenuation variation between loading coils and then a sudden jump and this repeats over and over again. I am unaware of any published complete solution of the problem which is not open to considerable criticism from an analytical point of view. (Even the generally accepted theory of the simple unloaded line is not above question.) Admittedly calculations sufficiently accurate for existing practice are readily made, but I suggest that, in the present state of the theory, it would be unwise to rely upon calculations for cases departing widely from established practice. On page 1040 the authors describe a method of making direct tests on lines. In this connection I should like to ask them how they would make a test when the line is not sufficiently long for one to be certain that reflected waves are not reaching the measuring point. The termination of the line, of course, presents a difficulty. Any balanced circuit which is used is only an approximation, and calculations I have made suggest that any slight error in the balancing of the line may produce very considerable errors in a measurement of that type. The phasal relations of the direct and reflected waves do not lend themselves to accurate determination except at the receiving point. There they are easily determinable and it

* Since added for the *Journal*.

appears to me that a more reliable method would be to measure the current in the receiving section rather than to measure the voltage at some other point of the line. It might not give one the presumed accuracy of the other method, but one would be certain of it. It would be of assistance if the authors were to give the constants of the line for Fig. 29, and also the loading and the length of line.* In a paper accepted for publication in the *Journal*† I have shown that in a loaded line, even if there are no variations in the size of coils and so on, there must be as many dominant frequencies as there are sections. I should like to be assured that the variations which the authors show in Fig. 29 are really due to irregularities in the line, and that they are not partly due to reflections caused by imperfect balancing of the line at all frequencies. Fig. 30, again, is said to refer to a non-reactive line of line impedance of 1 000 ohms. It can, of course, if it is a real line, only have that impedance at one frequency. What was the frequency ? Then again, the authors point out that for reasons of economy it is desirable to reduce the number of loading coils to as low a value as possible. Of course, the objection to doing so is that the cut-off point is also lowered. Yet in Figs. 28 and 30 they refer to a line, which certainly does not cut off at 3 600 cycles, being used with a filter cutting off at 2 000 cycles. Had the line been designed with a small number of loading coils of greater value and wider spacing, would not line irregularities, attenuation, and cost, all have been reduced ? Fig. 31 shows an interesting case of the use of reflection in the determination of the position of a fault. For a loaded line there should be as many peaks on that curve as there are sections between the fault and the transmitting point, if the line is perfectly regular. I should like to know how far irregularities in the coils interfere with that determination. If one assumes a perfectly regular loaded, unrepeatered line with a bad value for the receiver impedance, one can get curves bearing some resemblance to Fig. 29 with most impressive irregularities, but do those irregularities mean very much ? They exist on the line up to the receiving point, but at the receiving point they almost disappear, because there the reflected wave bears a very definite relation to the transmitted wave: the relative magnitudes and phase are almost completely preserved throughout the whole frequency range. As one moves backwards from the receiving point the phase displacements become cumulative. There are, therefore, considerable current variations, with frequency, at the centre of the line, but these variations only exist in the receiver in a much smaller degree.

Mr. E. S. Ritter: Under the heading of " Apparatus for the production of electrical energy of constant value over the required range of frequency," the statement is made that " the Pollock alternator gives up to 6 000 cycles at 6 000 r.p.m." I have not worked at such a high frequency as this, and I have yet to see such high frequencies demonstrated at that speed. In Fig. 8 it is rather extraordinary that the voltage at zero frequency is apparently high, and then as the frequency increases the voltage falls and remains more or less constant. Is this really correct ? Under the heading " Frequency characteristics of lines " the authors quote a paper by Mr. G. A. Campbell which appeared in the *Philosophical Magazine* for 1903. I have looked up this reference, and I am under the impression that there is a slight error in their quotation.* They give the expression as $\frac{1}{2}\omega d\sqrt{(LC)}$, where $\omega = 2\pi \times$ frequency, $L =$ coil inductance and $d =$ distance between the coils. The term C is not explained, but it is presumably the capacity. Now, in the paper from which the authors quote, L and C are the inductance in henrys and the capacity in farads per mile of the circuit, where d is the spacing of the coils in miles. If that correction is made, the formula given in the present paper is correct. Another statement which requires qualification is with regard to four-wire repeaters, where the authors say: " With four-wire repeater circuits no repeater balances are required." That would rather imply that no balances are necessary with the four-wire repeater circuit, but as a matter of fact two balances are required at the ends of the circuit, and the gain in the circuit is to some extent limited by the accuracy of those balances. The authors say that Fig. 31 shows the input current for a 500-mile, 200-lb. aerial line, but I have not seen a 500-mile aerial line with such good characteristics. Is this a real line or an artificial one ? At the end of the Section dealing with impedance and power measurements the authors say: " It is obvious that the test made with the oscillator is very much quicker and less laborious than the corresponding tests of impedance made by means of a bridge," but I still remain to be convinced. In Fig. 26 it will be seen that the attenuation of the 20-lb. cable rises with frequency; in other words, the losses in the cable are higher as the frequency goes up. On the other hand, it will be seen from Fig. 32 (*a*) that the received voltage with the repeating coil in the cord circuit goes up with the frequency, and if the line is not too long these two effects will more or less compensate each other, and the received energy is more or less constant at different frequencies. In other words, the use of 20-lb. cable of not too great a length will tend to correct the distortion caused by the cord circuit. The same applies to Fig. 33 to some extent. Apparently if two instruments are joined up with a length of loaded cable, the frequency response levels up and the articulation is improved.

Captain F. Reid: I am chiefly interested in the application of this paper to the transmission of speech over a public telephone system. The transmission engineer has to meet three main requirements in the transmission of speech:—(1) Adequate volume; (2) elimination of distortion; and (3) transmission of a sufficiently wide frequency band. The authors, in emphasizing the importance of frequency characteristics, hitherto too much neglected, have somewhat overlooked the necessity for volume efficiency. On page 1023 they state " Articulation is a function of the perfection of reproduction of the originating wave-form." I suggest the addition of the words " but is also dependent on intensity." Figs. C and D are taken from an article by H. Fletcher in the *Bell System Technical Journal*, July 1925. Fig. C shows how articulation varies with

* Since added for the *Journal*.

† See p. 758.

* Since corrected for the *Journal*.

intensity. The ordinates show percentage articulation correctly received. The sensation level is measured in transmission units above the threshold of audibility, e.g. sensation level 40 indicates an intensity of sound which if attenuated 40 transmission units would be just inaudible. (10 transmission units are approximately equal to 11 standard miles at 800 cycles.) Fig. D shows how the sensitivity of the ear for a particular frequency varies with intensity. The lower curve,

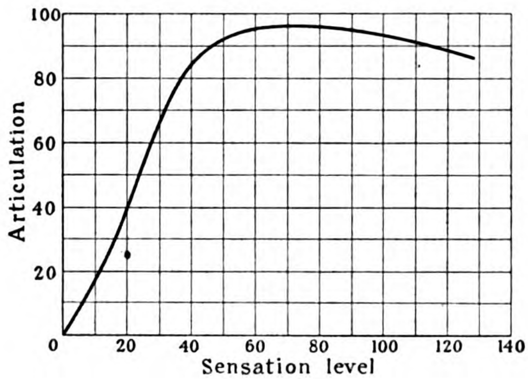

Fig. C.

which corresponds to Table 1 in the paper, represents the sensitivity to sounds which are barely audible. The ear at this intensity is most sensitive to frequencies of 1 000 to 2 000 cycles. At the other range of audition (sounds so loud as to cause discomfort) the conditions are reversed and the ear is most sensitive to very low or very high pitches. These curves show that if attention is not paid to maintaining adequate volume the

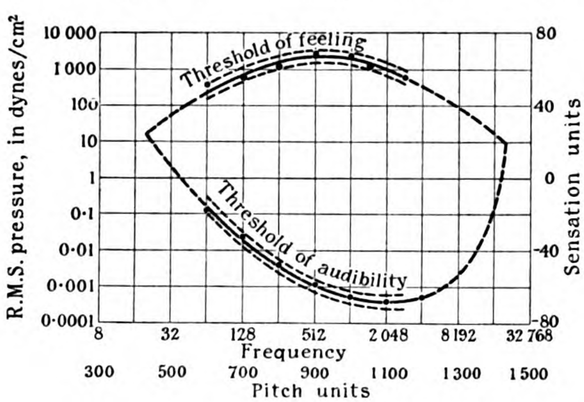

Fig. D.

ear will introduce distortion. The range of good articulation shown in Fig. C is only about 60 standard miles. This does not allow much margin for variation in lines, e.g. between a good local call and an indifferent long junction circuit, and for the difference in intensity between a man shouting close into the transmitter and a girl talking quietly away from the transmitter. One's experience of telephone testing does not seem to agree with Fig. C. The explanation lies in the elimination in commercial telephone circuits of all frequencies below 250 cycles. These low frequencies are hardly, if at all, necessary to articulation, and their presence would limit the extent to which the frequencies in the middle range, which are most essential to articulation, could be amplified in a transmitter. If all frequencies were amplified equally the low frequencies would mask those most necessary for articulation. By eliminating the low frequencies it should be possible to secure better articulation over a telephone circuit than with direct speech. I should like at this stage to comment on some of the features of the method of recording frequency characteristics adopted by the authors. (1) The record has to be taken so slowly that it represents only the steady state. All resonances have had time to build up to their full value. In transmitting speech, however, the transients are of great importance. A transmitter might give quite a flat resonance curve and yet fail to respond with sufficient rapidity to the rapid changes of wave-form occurring in speech. The authors point out on page 1024 the possibility of compensating for the frequency characteristic of one piece of apparatus by modifications in other apparatus or amplifiers. If no attention is paid to the time constant of a resonance the "correction" might conceivably be worse than useless. If, for example, a resonance in a receiver which took 0·005 sec. to build up were corrected for by a resonant shunt which had a time constant of 0·0002 sec., for very rapidly varying wave-forms the "corrected" receiver might be much worse than if no attempt had been made at compensation. (2) Although the authors are careful to employ pure sine-wave input into the apparatus under test, no test is made of the purity of output. For example, in Figs. 13 and 14 the characteristics appear to be much better than those of a receiver. What relation do the frequencies of the output bear to the frequency of the input? Is not the defect of most carbon transmitters due to "non-linear distortion," mentioned on page 1023, partly due to the restoring force on the diaphragm not being strictly proportional to displacement and partly to the variation of the resistance of the transmitter not being a linear function of the diaphragm displacement? (3) As only one frequency is applied to the apparatus at one time, any distortion due to combination tones will not be revealed. (4) The authors show the effect on a telephone receiver of holding it to the ear. What is the effect on the ear? Has not the resonating frequency of the auditory canal and eardrum been modified? If this canal and eardrum resonated normally to, say, a frequency of 2 500 should not a resonant frequency of 2 500 be introduced into the telephone system to compensate for this resonance being eliminated in the ear? In conclusion I would express the opinion that at the present stage of the telephone art it is necessary to employ the principle of resonance to obtain the necessary volume efficiency. The resonances should, of course, be made as flat as possible by damping, and any improvements which increase the volume efficiency of telephone plant will also permit increased damping. If this view is correct, then the question of the most suitable resonant frequencies should be determined. The solution lies in a study of the production and interpretation of articulate speech by the voice and ear.

Fig. E shows sections of a human ear. I would draw attention to the marked resemblance between the cochlea and the mouth. There are two main resonating cavities and the sound is introduced in each case at one end of the upper cavity. The basilar membrane (or the auditory nerve itself) corresponds to the tongue. I suggest that the interpretation of articulate speech by the ear is a signal system whereby the auditory nerves indicate the position of the tongue. In a way it is analogous to lip-reading as taught to the deaf. The sensor auditory nerves are no doubt linked to the motor nerves of the tongue, and motions of the basilar membrane are almost automatically copied by the tongue. A child learns to speak by listening to speech—not by watching the motion of a speaker's lips and tongue. Conversely the basilar membrane copies the movements of the speaker's tongue (but to a very different scale) when listening to articulate speech. This view is only a speculation, but, if correct, how would a telegraph engineer provide a signal system between the mouth of a speaker and an ear so that the motions of the membrane in the latter copy the motions of the tongue? Having only one medium he would utilize the resonant frequencies of the three chambers in the ear. We have evidence of a three-colour theory of vision, and Nature is very much inclined to solve similar problems in the same way. The resonances are probably very flat (the red sense covers almost the whole range of the visible spectrum). I am not therefore suggesting that transmitting three bands of frequencies will give as good articulation as if the whole range were transmitted. A three-colour print is not equal to natural colours, but if economy forces us to introduce resonances it is suggested that three of the resonances should be the peaks of the resonant curves for the three chambers in the cochlea.

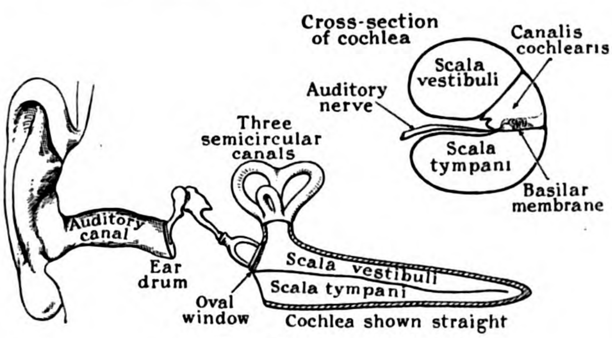

FIG. E.—The ear.

Mr. L. C. Pocock: The difficulties in the way of making such apparatus are very great. Prof. Mallett has indicated that it is not done by simply copying a circuit, and, whilst I congratulate the authors on having done it, I feel that they should have given more details of the difficulties encountered and the means by which they were overcome. Failing detailed design information, perhaps the authors would indicate whether they propose to put the apparatus on the market, and, if they do, perhaps they will consider the advisability of making the frequency scale logarithmic. It would also be more convenient if the amplitude or voltage scale were made to follow a linear instead of a square law. The peaks of the curves shown are much exaggerated, and it would be preferable if they were re-drawn on a logarithmic scale. I should be glad to know what results are obtained with the circuit shown in Fig. 2. As the authors probably know, several forms of this kind of circuit have been used on the Continent, especially in Germany.* I should like to have some further particulars of the special output transformer used. I do not quite understand from the description given in the paper how the transformer is made. Figs. 13 and 14 give some transmitter characteristics but do not really indicate what is happening over an extended frequency range, and of course the peaks are very much exaggerated by the scale; however, the curves show what is a well-known fact, namely that the telephone transmitter of to-day is far from being the best part of the apparatus in a telephone circuit. Although the solid-back transmitter used throughout this country has done extraordinarily good work I think we may reasonably expect a change and an improvement in transmitters before long. The improvement in line transmission and general line conditions has put upon telephone engineers a heavy obligation to bring the terminal instruments up to date. Under the heading "The Frequency Characteristics of Telephone Receivers" there is a short note in brackets referring to basic standard receivers. This note seems to suggest that telephone receiver standards should be used at a distance from the ear. I cannot think that a receiver standard used at a distance from the ear can have any real value. In the first place, although the resultant sound of the receiver can be affected by a variation of the position on the ear, it is also true that if the receiver is held away from the ear, another variable, namely the undefined, uncertain acoustic properties of the surrounding space, is introduced. In the second place, any fundamental receiver standard of performance is of value only under the conditions in which it really is intended to be used. Two complex sounds can be said to be equal only if the ear indicates they are equal, and the human ear is a variable factor so that equality only exists as a statistical average obtained with a large number of observers. I think it is only reasonable to include in that average the variations corresponding to variation of position of the receiver on the ear, just as much as we are bound to include the variation of the sensitivity of individual ears. Under the heading "Frequency Characteristics of Audio-Frequency Amplifiers" the authors say that intervalve transformers are tested between a resistance and a rectifying valve, and state that the plate circuit impedance may in some cases affect the result. As a matter of fact, in most cases the plate circuit impedance is the determining factor as regards the location of the point of resonance of the transformer. A number of performance tests have been made on transformers between valves loaded in different ways, and the results have been compared with calculated curves based on the transformer constants obtained by impedance analysis. It has been found that the

* See, for example, *Elektrotechnische Zeitschrift*, 1925, vol. 46, p. 915.

shape of the curves can be fully accounted for by a comparatively simple transformer theory when the load in the plate ciicuit is taken fully into consideration. I hope that the authors will now use this apparatus to produce a good deal of very necessary design data. I think there is a very real need for some sort of standardization of impedance data. There are a number of problems in which we need to know what is the average or representative terminal impedance of subscribers' lines at the subscribers' terminals, what is the average impedance of junction connecting lines or subscribers' sub-sets as measured from the exchange, and so on.

Mr. P. E. Erikson (*communicated*): In the introductory paragraph the authors refer to the two fundamental factors which are of first importance in determining the transmission efficiency of a telephone circuit, namely (1) volume and (2) articulation. If either of these factors is below a certain standard the intelligibility of the transmitted speech sounds is adversely affected. Intelligibility is here defined as the percentage of ideas correctly interpreted over a given circuit. The authors define articulation as a function of the perfection of reproduction of the originating wave-form. They also point out that badly distorted speech may be understood by an efficient co-operation of the ear and the brain of the listener. They rightly emphasize the fact that, when the context does not form an idea, such as in transmitting isolated words or sounds, the articulation requires to be at a much higher level for efficient reception. In this connection it would seem desirable to differentiate between at least two kinds of articulation—(1) "sound articulation," which may be expressed as the percentage of elemental meaningless sounds correctly received over a circuit, and (2) "syllable articulation," which is the percentage of whole syllables correctly received over a circuit. It is understood that the Post Office Research Section has done a considerable amount of work along these lines. Since quantitative articulation tests are rather laborious to carry out, it would be of interest to telephone engineers to learn the general conclusions which the authors have reached in regard to the relative value of tests carried out on the above bases. In this connection it may not be out of place to point out that articulation, as such, does not seem to be entirely adequate in rating the performance of a telephone circuit. A more satisfactory solution appears to be in terms of the time required to transmit ideas over the circuit. This conception is brought out in a recent paper * and there referred to as "traffic efficiency." The traffic efficiency of a reproducing system is there defined as being inversely proportional to the time taken to convey a single simple idea over the system. One of the authors, in discussing the paper referred to, suggests the term "transmission speed factor" for the same conception.† The latter term seems to convey the conception better, but whatever term is ultimately adopted is a matter of secondary importance. The main point is that a comprehensive rating of a circuit could be given by the ratio of the time required to transmit a set of ideas over an ideal circuit to the time required to transmit the same set of ideas over the circuit in question. Figs. 21–25 show frequency characteristics of loud-speakers—with and without horns. Presumably these characteristic curves are all based on the same volume-input level. It is noted that the curves for the horn-type loud-speakers show a lower cut-off point at, or near, 500 cycles per sec., whereas the hornless types cut off at about 250 cycles per sec. This difference in performance between horn-type and hornless loud-speakers is well known, but it may be of some interest to display it by a direct graphical comparison. For this purpose Fig. F has been prepared. This shows the frequency-response characteristics of a commercial horn loud-speaker and a hornless loud-speaker of a type described in British Patent Specifications Nos. 231556, 239245, and 240596. Apart from the more uniform response over the frequency range included, the hornless type extends down to frequencies of the order of 50 cycles per sec., whereas the horn type cuts off rather sharply at about 250 cycles per sec., the latter being due to the taper of the horn. In regard to the authors' method of portraying frequency characteristics, it is considered that for the purposes of serving as a criterion of performance, except in special cases, a frequency characteristic based on power ratios is generally more fundamental and more instructive than a frequency characteristic based on voltage ratios. Whilst, for purposes of measurement and calculation, voltage ratios are often more convenient, the conception of efficiency calls for the use of power ratios. It may be argued that the input to a valve is of so high an impedance that no power is supplied to it, but the power loss in the grid leak or in the input transformer is usually a finite quantity. The impedance of the human ear may be said to be purely reactive and to take no power, but the unavoidable coupling losses, the slip or leakage introduced between the contact of the receiver and the ear, are quantities of no small importance. In every practical case the production of alternating pressure

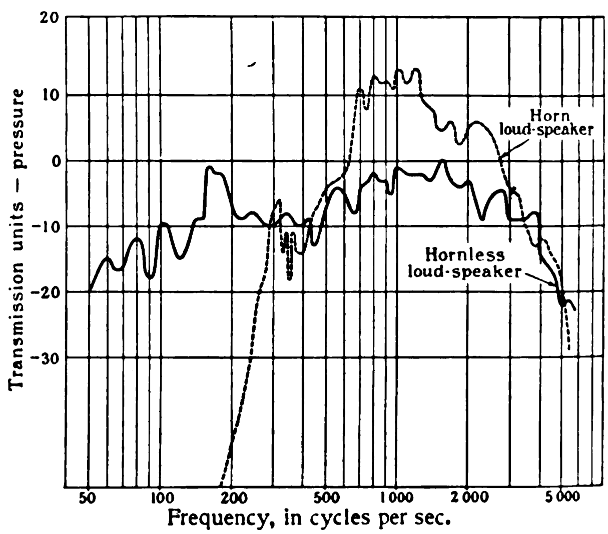

FIG. F.—Efficiencies of horn and hornless types of loud-speakers.

* L. C. Pocock: "Faithful Reproduction in Radio-Telephony," *Journal I.E.E.*, 1924, vol. 62, p. 791.
† Loc. cit., p. 808.

or voltage calls for the expenditure of power, and every problem therefore resolves itself into the question of producing this power at the required point with a minimum initial expenditure of power.

Mr. A. M. Hallawell (*communicated*): I was specially interested in that portion of the paper which deals with the employment of the Rayleigh disc, as I have recently been carrying out some experiments with the same apparatus in the research laboratories of His Master's Voice Gramophone Co. The apparatus is practically identical with that used by the authors except that I believe their disc is more sensitive than ours. I should like to suggest, first of all, that the 4 in. lining of cotton waste for the chamber is not quite as effective in reducing reflection effects as one would infer from Prof. Mallett's recent paper.* Exploring a short region about 8 cm long in front of the source at one or two frequencies is not calculated to show up standing waves very readily; if the whole of the region more remote from the source be explored, I think that the authors will find, if they have not already done so, that standing waves of quite considerable magnitude are evidenced at the higher frequencies. At lower frequencies it is difficult to detect the effects of reflection by looking for standing waves, because the box is too small to permit of their formation inside it. Nevertheless, reflection will still be disturbing the acoustic field, and I do not understand how the authors are able to gauge and allow for its effects at all frequencies. I should like to ask the authors if they were able to satisfy themselves that their telephone receiver with its resonator was producing a wave-form free from harmonics at the lower frequencies. If is of importance to be certain of this when calibrating transmitters, etc., otherwise a high response may be indicated at lower frequencies which in reality might largely be due to the transmitter's ready response to the harmonic. I have so far been unsuccessful in finding a telephone receiver which will fulfil the above conditions at reasonable outputs. Perhaps, however, the sensitivity of the authors' disc enabled them to work with very small outputs, and it would be interesting to know what was approximately the order of the sensitivity of their disc. Again, were they quite certain that the telephone-resonator combination was behaving as a source of spherical waves when radiating at low frequencies? If, as I suspect, this is not the case, it is not possible accurately to calculate the pressure or acoustic intensity from the particle velocity, since formulæ connecting these quantities are only available for the cases of plane, spherical and cylindrical waves. I cannot agree with the authors that a body such as an eddy-current transmitter placed 6 cm behind the Rayleigh disc is without important influence on the field around the latter, and I should like to know what steps they took to support such a conclusion experimentally. A question which is of importance in connection with all loud-speaker tests is: How can the characteristic of the speaker most usefully be expressed? The ideal method would be, of course, to give the overall characteristic of the speaker working in conjunction with the amplifier with which it is to be employed. Unfortunately loud-speakers are not usually supplied with their own amplifiers and hence it would seem desirable to express the frequency characteristic in such a way that it refers to the loud-speakers alone. The authors apparently interpose a high-resistance attenuator between the oscillator output transformer and the instrument under test, the voltage across the latter being measured. This procedure in itself would in many cases improve the characteristic of a loud-speaker amplifier combination, but it can hardly be said to be common practice. I think, therefore, that the acoustic output per unit current in the speaker over the whole frequency range should be given, together with its impedance-frequency characteristic. The overall performance of any given loud-speaker—amplifier assemblage can then be predicted from these curves, the performance of the amplifier being known. The authors have produced an effective and convenient form of oscillator. I am sure many are looking forward to receiving some practical hints as to how the many desirable features it possesses may be attained. The single-dial control over the whole frequency range, combined with the constant-voltage output, has made possible the autographic tracing of the frequency-characteristic curves. This is in itself an important feature, because it means that there is no possibility of the high but narrow peaks and narrow dips in the response curves being missed, as is frequently the case when a series of readings at definite frequencies are taken. It is these peaks and dips, however narrow, that play such an important part in determining the quality of reproduction.

* *Journal I.E.E.*, 1925, vol. 63, p. 502.

Mr. A. C. Timmis (*communicated*): The imperfections of the ordinary telephone transmitter and receiver are strikingly shown by the authors' curves, but the fact that the vertical scales are practically square-law scales gives a somewhat exaggerated impression. I would suggest that a really good rectifying valve, such as is now available with separately heated cathodes, would enable a fairly uniform scale to be obtained. With regard to the testing of intervalve transformers, although the method shown in Fig. 36 gives in a convenient manner a good idea of the behaviour of a transformer under various conditions, the results must be somewhat inaccurate. The impedance of the grid circuit connected to the secondary has considerable influence on the (primary) impedance of the transformer and therefore on the voltage produced across the primary. Under the usual conditions of audio-frequency amplifiers and telephone repeaters the grid impedance may be regarded as a practically pure capacity of the order of 50 $\mu\mu$F, which is of course much higher than the electrostatic capacity between the electrodes. The effect of adding a capacity of 50 $\mu\mu$F or so is shown by the curves of Fig. 37. For any ordinary valve this capacity may be calculated approximately from the formula

$$\text{Effective capacity} = C_1 + C_3 + \tfrac{1}{2}\mu C_2$$

where C_1 = grid-filament capacity,
C_3 = anode-grid capacity (both including the valve holder),
and μ = the amplification factor.

The most important quantities are μ and C_3, and it is evidently necessary, in specifying the performance of a

transformer, to state that it is tested between two valves of a particular type. In the arrangement shown in Fig. 36 a rectifying valve is used on the secondary of the transformer. Its amplification factor must vary under the conditions of test and this will give rise to errors. They are, no doubt, small, but can be eliminated by using an amplifier in front of the rectifier, so reproducing practical conditions. In the case of transformers having a turns ratio of 20 : 1 or 30 : 1, such as are used in telephone repeaters, the effect of the grid impedance (apparent capacity) is very much greater than in the case of intervalve transformers, with a turns ratio of, say, 4 : 1, and reduces the primary impedance seriously at high frequencies. For instance, a certain 25 : 1 transformer, with an L.S.5 valve connected to the secondary, had a primary impedance of 570 ohms at 2 000 cycles. Without the valve (secondary open) the primary impedance was 760 ohms at 2 000 cycles. The amplification factor of an L.S.5 valve is about 5. Another valve, with an amplification factor of 10 and about the same capacity between electrodes, reduced the impedance to 415 ohms at 2 000 cycles.

Dr. H. Salinger (*communicated*): The Rayleigh disc method has been used by the Telegraphentechnisches Reichsamt, Berlin (the work being carried out by Dr. E. Meyer), in the course of an investigation of the frequency characteristics of loud-speakers and has been found to be very convenient. The conditions were such that the sound waves were as nearly as possible plane. The calibration method was different from that described by the authors. According to a formula derived by König * and experimentally confirmed by Zernow †

$$P = a\sqrt{\left(\frac{3\rho D}{4r^3}\right)}$$

where P = R.M.S. pressure of sound in dynes per cm^2, ρ = density of air, a = velocity of sound, r = radius of the disc, and D = torque exerted on the disc by the acoustic forces. The formula assumes that the thickness of the disc is negligible in comparison with its diameter, and that the disc is located at an angle of 45° to the direction of the sound waves. In order to obtain P it is therefore sufficient to measure D. Now $D = 4\pi^2 K\alpha/T^2$, where α = observed angle of deflection, K = moment of inertia, and T = undamped oscillation period of the disc. K can be calculated, hence it is only necessary to determine T in order to convert the observed angles into sound pressures. With a disc of mica of radius 0·25 cm, hanging on a gold filament of 10 cm length and 5×10^{-4} cm diameter, T was found to be 7 seconds and $P = 0{\cdot}80\ \sqrt{n}$, where n = deflection in mm, the distance from the scale being 2 340 mm.

Messrs. E. Gerlach and **C. A. Hartmann** (*communicated*): The method suggested by the authors for the calibration of transmitters requires special means in order to eliminate sufficiently the action of stationary waves, which are produced by the reflection of the sound at the transmitter and the walls of the test-room, and, especially at the higher frequencies, give rise to annoying interferences. In the method employed in Messrs. Siemens and Halske's laboratory these precautions are not necessary. The sound impressed on the transmitter diaphragm is measured at so small a distance that the distribution of pressure between the diaphragm and the receiving portion may be regarded as uniform. The acoustic measurement itself follows closely the principles of sound-pressure compensation which have been outlined by one of us,* i.e. the receiving portion of the pressure gauge is placed in a magnetic or electric field and the sound intensities applied to the receiving portion are compensated for by electrodynamic or electrostatic forces, as may be ascertained by listening behind the receiving portion. The order of magnitude of the currents or voltages required for compensation immediately indicates the sound pressure per cm^2. Fig. G shows a pressure gauge designed for electrodynamic compensation. The transmitter (M) is applied to the sound capsule (K). At the other end of the boring (H) in the capsule, a thin strip-shaped aluminium foil (B), acting as receiving portion, is located in the homogeneous field of the magnet (Mn). The sound power is supplied at S. The soft rubber ring (G) prevents any sound from being conveyed to

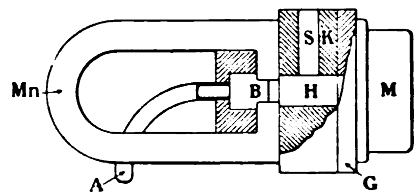

FIG. G.—Pressure gauge designed for electrodynamic compensation.

the transmitter except through the air. A current, originating in the same wave as that used for feeding the sound producer, is passed through the strip. By conveniently arranging its intensity and phase relatively to the sound phase, the strip can be brought to rest, which may be ascertained by listening at A. If B denotes the magnetic flux per cm^2, I the intensity of the strip current, and s the width of the strip, the pressure may be expressed by $p = BI/s$. Another advantage of this method, as against calibration by means of the thermophone, is that the properties of materials, excluding the dimensions of the acoustic chamber and the strip width, need not be considered in practice. The same method has also been utilized for the calibration of receivers. According to a suggestion by one of us,† the dimensions of the acoustic chamber H (see Fig. G) are made nearly equal to those of the ear-passage. By substituting for the transmitter (M) the telephone to be measured, and compensating again at B for the sound pressure, we obtain a measure for the acoustic output of the telephone applied to the ear.

Messrs. B. S. Cohen, A. J. Aldridge and **W. West** (*in reply*): In the interval between the writing of the paper and the reading before the Institution some

† E. GERLACH, loc. cit.

additional work was done on frequency characteristics; the results were mentioned at the meeting. In the first place, an attempt was made to obtain the frequency characteristic of a Bell receiver when acoustically loaded to correspond to working conditions, i.e. when the receiver is held to the ear. For this purpose an artificial ear was constructed which embodied an electrostatic transmitter suitable for use on the circuit shown in Fig. 2. Essentially, the transmitter comprises a disc of aluminium foil of about 1 in. effective diameter clamped to, and spaced a very small distance from, a solid back plate which comprised the back electrode. In front of the disc, and similarly spaced therefrom, was clamped a block of wood, $\frac{1}{2}$ in. thick, in the centre of which was bored a hole $\frac{3}{16}$ in. in diameter. The front of this block was covered with a layer of soft spongy rubber, about $\frac{1}{4}$ in. thick, having at its centre a piece of hard rubber about $\frac{3}{4}$ in. in diameter, in which a hole was cut tapering down to the diameter of the hole in the wood block. This design was intended to ensure that the frequency characteristic of the transmitter would not be appreciably affected by the presence of a receiver held over the aperture, with its cap in contact with the soft rubber. This artificial ear was then calibrated as a transmitter in the manner described on pages 1028 and 1029. Next, a Bell receiver was placed against the artificial ear and was actuated by the output from the heterodyne oscillator, a photographic record of the output from the electrostatic transmitter being taken. From this curve, and the calibration of the transmitter, the characteristic of the receiver was computed in terms of acoustic pressure output at the orifice of the artificial ear, per volt input to the receiver. This characteristic is reproduced in Fig. H. The receiver used was not the same as that referred to in Figs. 15 and 16, but in free air had resonances at about 750 cycles per sec. at the fundamental, and 3 300 cycles per sec. at the nodal circle mode. The degree of equivalence of conditions in the cases of a receiver being held to the artificial ear and to a real ear cannot easily be stated, especially as in the latter case the conditions vary considerably with different observers. It may be stated, however, that whereas the artificial ear alters the frequencies of resonance at the fundamental and nodal circle modes to a similar extent to a real ear, the impedance loop of a receiver at these resonances (where resistance is plotted against reactance) is smaller when the receiver is held to the artificial ear than has been found when the receiver is held to a real ear. The figures indicate, however, the very different performance of a receiver when tested in free air and when damped as in normal use.

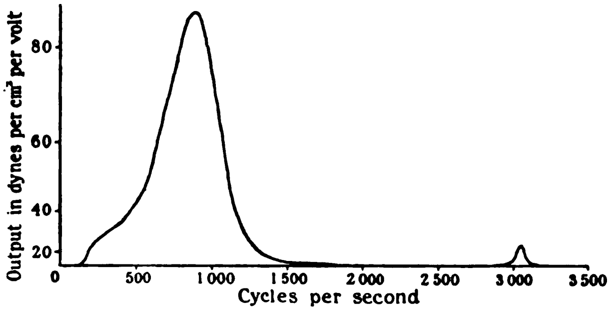

FIG. H.—Characteristic of Bell receiver held to the ear.

Another interesting characteristic is shown in Fig. J. This is the complete overall acoustic-electric-acoustic characteristic for a repeatered trunk connection with standard common-battery terminations. The lines used were artificial. As would be expected, the overall characteristic is practically a combination of the transmitter and receiver characteristics. This curve was taken with the receiver freely exposed to the air.

Several additions to the Bibliography have been suggested and this has been revised for the *Journal.*

Mr. Harrison has referred to the transmission unit and states that he believes in it. The authors are in agreement with him in this belief. This unit has, however, not been adopted by the C.C.I.,* which is the controlling organization for such questions so far as Europe is concerned, and, until this organization comes to a final decision on this matter, the Post Office must continue to use the older units.

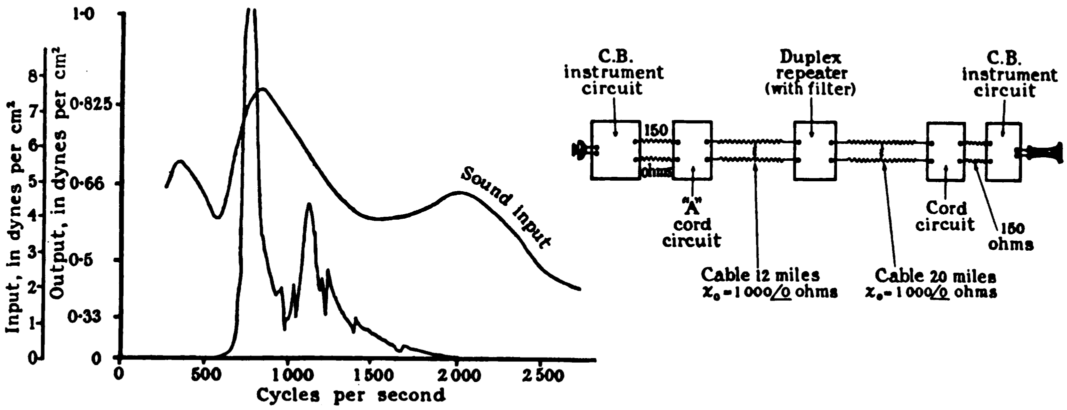

FIG. J.—Acoustic-electric-acoustic characteristic of trunk connection.

With regard to the behaviour of the telephone line

* Comité Consultativ Internationale des Communications Téléphoniques à Grande Distance.

as an electric filter, the late Mr. Shepherd, whose untimely demise we all deplore, was the first to point out that the inversion of an equivalent telephone line (i.e. series capacities and bridged inductances) gave an electric filter which had a cut-off at the lower end of the frequency scale, and he and two of the authors used such filters and combinations of upward and downward filters many years ago to investigate the relationship between articulation and frequency range.*

Prof. Mallett has suggested that all the necessary information for setting up the heterodyne oscillator is not given. It was thought that the diagram of connections and data would be sufficient, when applied with the precautions with which all users of medium- and audio-frequency apparatus are familiar, to enable satisfactory results to be obtained. There is, however, one omission: choke and condenser smoothing circuits are added in the high-tension circuits, and these, as

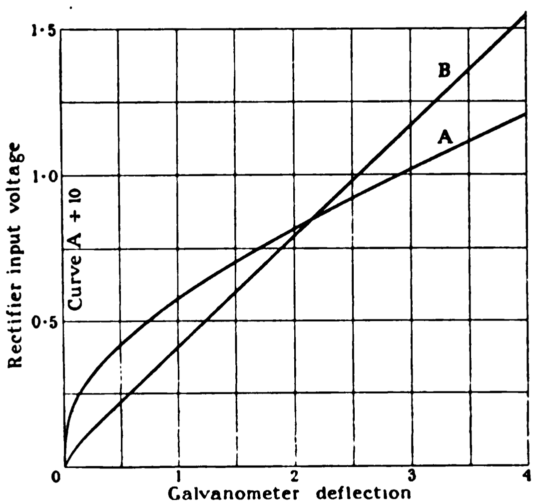

FIG. K.—Rectifier calibration curve.

A. Normal diode.
B. With 100 000 ohms in series with diode.

mentioned in the reply to Mr. Ritter, do have some effect on the output characteristic. The frequency, as required in a frequency characteristic, is given with sufficient accuracy from the readings of the variable condenser. The calibration (frequency : condenser-reading) is given in terms of the change of condenser setting from the setting corresponding to zero beat-frequency. If this zero beat-frequency is adjusted to occur at about the 10° point of the condenser, this calibration remains constant although the position of the zero beat-frequency may vary slightly with temperature and battery variations. The accuracy of the frequency value then obtained depends upon the fineness to which the condenser can be read. For individual measurements at any specified frequency the latter is measured at the time of test by means of one of the numerous types of frequency bridge available.

Prof. Mallett, and also Mr. Pocock and Mr. Timmis, refer to the false impression liable to be given in the frequency characteristics by the fact that a square-law rectifier is used. This was fully appreciated, but no other was available. Since then, however, practically a straight-line rectifier has been obtained. Fig. K shows the calibration of one of these. By using a low-impedance valve in series with a large non-inductive resistance the rectilinearity of the curve can be increased to any extent, though, of course, at the expense of sensitivity. For use with a galvanometer, however, this reduction in sensitivity need not be of great importance. The calibration curve is taken with a four-electrode valve, which type of valve lends itself well to this purpose, in series with a resistance of 100 000 ohms. Even with a straight-line rectifier the difference in amplitude between the resonance peaks and the rest of the characteristic will frequently be so great as to render advisable the taking of two records, one to show the resonance peaks and one the rest of the characteristic.

Mr. Sandeman refers to the weight of oscillators. A portable heterodyne oscillator weighing about 20 lb. (exclusive of batteries) has been designed, and it is anticipated that commercial apparatus of this type may shortly be available. He also shows that no great errors are to be expected in the frequency due to variations in temperature. This point is also referred to in the reply to Prof. Mallett. We are glad to have Mr. Sandeman's agreement with our contention that the distortion of the sound field due to the transmitter must be considered as part of the transmitter itself, but we do not agree that the effect of a man's head in distorting a sound field, when speaking to a transmitter, should be included in the transmitter characteristic. The effect requires investigation but does not appear to have the importance that the acoustic damping of the ear has on the receiver. A few characteristics have been taken with the source of sound close to the mouthpiece of the transmitter. No great difference was found in the characteristic except that the mouthpiece resonance is modified.

Mr. Mittell refers to the use of a gramophone as a source of sound. This is of interest, but appears to labour under very great disadvantages. The gramophone can only be a secondary source and requires some means of production for the original sound which produces the record. Again, elaborate electrical calibrating apparatus is required after the record is obtained. The instrument is bulky and cannot be considered as approximating to a point source, a very valuable feature. The records are made for separate single frequencies, and have not therefore the very valuable property of the heterodyne oscillator and associated apparatus in producing a continuously variable frequency. Incidentally, the instrument as demonstrated appeared to produce a noticeable hiss, and there also appeared to be a beat in the intensity.

Mr. Mittell states that no electrical frequency is pure, and that, in his experience, a filter is necessary in order to eliminate harmonics. We would point out that in no case has it been found necessary to use an electrical filter to purify the output from the heterodyne oscillator, but that, when a pure source of sound is required, use is made of an acoustic resonator from which, as pointed out by Messrs. Mallett and Dutton, a very pure note is obtainable. In obtaining the curve of Fig. B, pre-

* G. M. B. SHEPHERD: *Electrician*, 1913, vol. 71, p. 339.

sumably allowance is made for the condenser transmitter and amplifier characteristics. It is also necessary to know what percentage of the fundamental is attenuated by the filter at the different frequencies. Mr. Mittell does not state what precautions were taken to eliminate acoustic reflection effects.

In reply to Mr. Warren, particulars of the line constants for the different lines referred to in the paper have been included. We cannot agree with Mr. Warren's statements throwing doubt on the accuracy of the methods in general use by telephone engineers for calculating the transmission efficiency of lines and circuits. The statement that " Electrical transmission lines, when their constants are known, lend themselves readily to calculation " is correct, though this does not mean that the labour involved is necessarily small.

With regard to Mr. Warren's query as to the method of measurement for the case of an electrically short line, it is necessary, as explained in the paper, to make the line electrically long if it is the line attenuation only which is required to be measured. There is no difficulty in doing this for any particular frequency. It must be pointed out that there is no " attenuation constant " properly so called which can be given to a short piece of line with a few loading coils distributed in it, and this appears to be the case Mr. Warren has in mind.

With regard to the irregularities in Fig. 29, these are, as stated in the paper, due to irregularities in the cable, coils, etc. The figure gives the actual line impedances (due to whatever cause), and it is these impedances which must be sufficiently accurately balanced at the different frequencies to prevent " singing " of the repeater. No question of imperfect balancing of the artificial network can enter into the matter. The line used in Fig. 30 was an artificial line built up of non-inductive resistances to a line impedance of 1 000 ohms, and of course maintains this value at all frequencies. The reference to Figs. 28 and 30 is not clear. No line is mentioned in either case. Perhaps we may clear the matter up by explaining that Fig. 29 is given simply as an illustration of the kind of impedance variation which has to be balanced ; it has no specific relationship with Fig. 28 or Fig. 30. Fig. 30 simply shows the cut-off effect of the repeater filter. Fig. 31 is given to illustrate a method for the *location* of any fault or irregularity in an otherwise uniform line. In the case with the improper terminal impedance, quoted by Mr. Warren, the test would indicate the end of the line as the position of the irregularity. Loading coils are, of course, spaced in a line sufficiently closely to cause the irregularities in the wave transmission to be negligibly small. This test for fault location, made with a bridge, is in frequent use, and by its means the position of any irregularity in the line can be determined with considerable accuracy.

Mr. Ritter refers to the speed of the Pollock alternator. We can only say that the figure quoted was supplied by the designer. Fig. 8 is a reproduction of a photographic record. The curve actually rises steeply from zero to the peak shown and then falls. The effect is due to resonance in the high-tension battery smoothing circuit. Mr. Ritter has also pointed out that the G. A. Campbell formula is incorrectly quoted. This has been amended for the *Journal*. The line referred to in Fig. 31 was an artificial line. Mr. Ritter mentions an interesting point showing how the frequency characteristic of a cord circuit tends to neutralize the frequency characteristic of a 20-lb. cable, and this undoubtedly is of importance in improving the articulation of cable circuits.

Captain Reid quotes three desiderata for speech transmission ; of these, No. 3 is included in No. 2. He suggests an addition to the determining factor in articulation. The question of articulation is largely one of definition. Captain Reid is apparently confusing what may be considered to be an ideal definition of the articulateness of a system, with the practical testing of articulation by means of speech. Articulation *per se* is independent of volume, and it is only the intervention of the ear in commercial testing and use which causes the introduction of the volume effect. As mentioned later, we are concerned in this paper with telephonic apparatus only. We disagree entirely with Captain Reid's suggestion that articulation is improved by the elimination of the lower frequencies. It is surely obvious that a circuit which accurately transmits and reproduces the speech it receives will be perfect. Recent trials of a transmission system having an approximately flat frequency characteristic show that reproduction both as regards " naturalness " and articulation is practically perfect.

Captain Reid suggests that the method of taking records where " steady state " results only are obtained may give erroneous impressions due to the neglect of transient effects. It is agreed that a frequency characteristic will not necessarily indicate the exact performance under transient conditions. In practice, however, the acoustic transients appear to be of little importance, both for speech and for music. For example, both the eddy-current transmitter and moving-coil receiver described in the paper, being inertia-controlled instruments, would be expected to have a considerable time-lag, but they are found to give almost perfect reproduction of speech and music.

Captain Reid's suggestion that errors may be introduced if attempts are made to compensate one resonant portion by the addition of an inverse resonance, due to the fact that the time-constants of the two balancing resonances may be different, is hardly correct. It is not possible to balance out one resonance except by another of equal time-constant.

In testing transmitters the sound input was adjusted to approximate to that of speech, and any non-linear distortion produced by the transmitter must be considered a function of the transmitter. The question of the wave-form of the output therefore does not arise. As a matter of fact, unless the transmitter is overworked the non-linear distortion is small compared with the frequency distortion. The question of the effects of combination tones is answered under the reply on transients.

Captain Reid's remarks upon the ear and the effect upon this are very interesting and undoubtedly of great importance in transmission. They go, however, beyond the scope of this paper. We have attempted to show methods of measurement upon telephone

apparatus, and the behaviour of such apparatus under working conditions. If tests on the ear as well were to be included, the paper would need to have been very greatly extended. Captain Reid's "three resonance" speculation is very suggestive, and the recent production of a reliable transmission system with a flat frequency characteristic may enable this at some future time to be put to the proof.

Mr. Pocock's remarks regarding the heterodyne oscillator have been covered in the replies to Prof. Mallett and Mr. Sandeman. We consider the advantages of a logarithmic frequency scale negligible in comparison with the disadvantages. The advantage of a logarithmic scale in covering a wide range, by the crowding of the upper frequencies, is offset by the lower frequencies being unduly expanded. For example, if 50 cycles per sec. be taken as the lower limit of frequency the range, 50 to 200 cycles, a comparatively unimportant one, will occupy as much space as 500 to 2 000 cycles. For the comparatively small range of 5 000 cycles used, there seems no advantage in adopting any but a uniform scale. Further, with a logarithmic scale it is more difficult to interpolate the position of intermediate frequencies. As used with the present recording apparatus, to obtain automatically a logarithmic frequency scale would necessitate a condenser of specially shaped plates, in which case the valuable property of the constancy of calibration with small changes in the zero beat-frequency setting (see reply to Prof. Mallett) would be lost. The disadvantage of the square-law amplitude scale and the remedy have been referred to in replying to Prof. Mallett.

The condenser circuit shown in Fig. 2 has been found very useful as a receiving device for the measurement of sound. The pick-up condenser itself can be made quite small, can be used with a relatively long connecting lead, requires no polarizing battery, and, since it occurs in a high-frequency circuit, is much less liable to general induction than is the case with, for example, the eddy-current instrument. The transformer referred to by Mr. Pocock is presumably the output transformer of the heterodyne oscillator. This is constructed on a 1 in. square core of stalloy stampings. The windings consist of a number of slab coils about $\frac{1}{8}$ in. in thickness. Primary and secondary sections alternate. From 6 000 to 10 000 turns are used on the primary, and the number on the secondary is adjusted to the load. The number of turns per primary section is 2 000, and per secondary section is 500.

We do not agree with Mr. Pocock's objection to the use of standard receivers away from the ear. In the standard receiver suggested, an earcap similar to that used on commercial receivers is fitted, but instead of being screwed to the frame of the receiver it is bolted to it at some little distance by means of three distance-pieces. The earcap is thus held against the ear as usual, but the receiver diaphragm is open to the air, and the loading on it is independent of the exact position of the ear. Calibration can thus be made with the receiver open to the air, since this is the condition of use. With regard to the plate-circuit impedance in testing intervalve transformers, as stated in the paper this point has not been investigated, as the load on the transformer secondary includes in practice so many other variables in the secondary circuit, such as type of valve, primary and high-tension voltages, and wiring, for which no standard can be set. In the theory, therefore, the load on the secondary is taken to be a capacity load which is invariable over limited frequency ranges.

Mr. Erikson raises the question of articulation. It is not clear whether by "syllables" he means words or simply monosyllables forming parts of words. If the latter, there is little distinction between him and the authors. The Post Office Research Section has adopted the use of monosyllabic sounds for articulation testing, for the following reasons:—

(1) It is possible to prepare large numbers of equivalent lists of sounds without repetition.

(2) There is little risk of observers memorizing the sounds.

(3) The test of equivalent lists over the standard and non-standard circuits is considered to be the best method of obtaining the relative articulateness.

(4) The test is more easily carried out and gives a better quantitative result in a shorter time than a test involving whole sentences.

The relationship between articulation and intelligibility can be carried out once for all, though in this case, as pointed out by Captain Reid, the question of volume enters. While Mr. Erikson's "traffic efficiency" may be considered to be a very good ultimate test of a circuit, the difficulty of carrying out such a test must be enormous. With regard to the loud-speaker records, these are not necessarily at the same input level. The inputs were adjusted to give outputs within the capacity of the measuring set at the time. The characteristic given by Mr. Erikson for a hornless type of loud-speaker is of considerable interest and indicates an instrument which should give very high quality reproduction. We agree that a power ratio is the more fundamental ratio, but in the majority of cases a voltage ratio becomes practically the same thing. At the present moment the difficulties in obtaining power ratios preclude their use in many instances, for example in measurements upon the ear, or rather in obtaining acoustic power measurements which would be applicable when the measuring apparatus was replaced by the ear.

Mr. Hallawell is doubtful as to the effectiveness of cotton waste as an absorber. We have not experimented with other materials, but our tests agree with those of Messrs. Mallett and Dutton as to its effectiveness. Undoubtedly the kind of waste and method of packing affect the results. Standing waves, if present in the box, would be detected by taking readings over a range of distances, comparable with the wave-length, between source and transmitter. This cannot of course be done at lower frequencies, but for higher frequencies, above 2 000 cycles per sec. say, we have always employed this method. The values of the product r_2E have been found usually to lie within about 5 per cent of the mean figure for such tests, provided that the transmitter and its amplifier are not liable to amplitude distortion. This point is important and we have detected amplitude distortion in certain cases by observations on the product r_2E. It is also important to ensure that induction

on the transmitter, whether from the source of sound or otherwise, does not appreciably affect the readings. At lower frequencies, of course, this convenient means for detecting standing waves is not available, and it is suspected that at certain critical frequencies, dependent on the dimensions of the box, their effect is appreciable. A large number of points are usually taken at different frequencies at this end of the scale, and in all cases of tests on transmitters of the eddy-current or condenser type these have been found to lie reasonably closely on a smooth curve, such as would be expected from transmitters of this type.

We agree that the question of the wave-form of the source of sound is an important point, especially as the calculations involve frequency terms. We are, however, satisfied that the method of employing acoustic resonance to reinforce the fundamental note from a Bell receiver gives a sufficiently pure note. An exception occurs possibly at frequencies of half the fundamental and half the nodal circle frequencies of the receiver, at which the percentage of second harmonic is initially necessarily large. The sensitivity of the disc can be found from the formula on page 1029 when it is known that a unit of deflection, δ, on the scale measures 0·63 mm and that the distance from disc to scale is 80 cm.

We have not personally investigated fully the question of the equivalent point-source at low frequencies, but we were able to obtain readings on the disc at distances of 8 and 10 cm, whilst the investigations of Messrs. Mallett and Dutton show that the wave-front from a similar resonator tube is substantially spherical at a distance of 5 cm at 400 cycles per second. Further, we have observed that at distances of 6, 8 and 10 cm, at frequencies down to 200 cycles per sec., the quantity $V\Big/\sqrt{\left[\left(\frac{\omega}{rc}\right)^2+\left(\frac{1}{r}\right)^4\right]}$ is constant to within 5 per cent of the mean.

We regret that the distance between disc and eddy-current transmitter was incorrectly stated to be 6 cm in the advance copies of the paper.* The transmitter is placed at such a distance behind the disc as not to interfere with the beam of light from the galvanometer, and, as seen from Table 2, the mean distance from the source is about 25 cm, whilst the mean distance from source to disc is about 8 cm, so that the transmitter is situated about 17 or 18 cm behind the disc. Now if it be assumed that the eddy-current transmitter is a perfect reflector of sound, and if S_0 be the strength of the source of sound and S_1 the strength of the reflected sound from the eddy-current transmitter, the value of S_1/S_0 will be of the order of the ratio of the area of the eddy-current transmitter to the surface of the sphere with its centre at the source and its radius 25 cm. This is numerically about 0·025 and the distance of the disc from the eddy-current transmitter is about twice that of the disc from the source.

It is agreed that the method of test of a loud-speaker, in common with other apparatus, requires careful consideration and that the best method would be to test it in association with an amplifier. The tests which we made on loud-speakers were provisional, made chiefly to try out the use of the heterodyne oscillator and recording apparatus; but they were considered to be of sufficient interest for publication, pending more accurate and quantitative tests. It may be remarked, however, that where a loud-speaker is intended to be used in the plate circuit of a valve, an approximate equivalent circuit is available by replacing the valve by an ohmic resistance of, say, about 6 000 ohms to represent valve impedance, to which an E.M.F. may be applied.

* Since corrected for the *Journal*.

Mr. Timmis refers to the use of square-law rectifiers. This has been dealt with in the reply to Prof. Mallett. The rectifier calibration shown in Fig. K is considerably more rectilinear than that obtained with the separately-heated cathode valve, though this could of course be improved in the same way by means of an added resistance. Mr. Timmis's remarks on the grid impedance of a valve are of great interest. The difficulty of defining constants used in valve amplifiers, as commercially supplied, is considerable, since the wiring, valve constants and supply voltages all introduce variations in the load on the transformer secondary. In any case, however, where this load is more or less fixed and known, as in telephone repeaters, the circuit of Fig. 36 may still, it is considered, be used, since the rectifying-valve constants and voltages can be so chosen as to give the desired load, or an external capacity may be added across the grid to bring the total up to the required amount; and, moreover, a suitable impedance may also be inserted in the plate circuit to represent working conditions more closely. It may be added that the circuit of Fig. 36 may prove useful in obtaining approximately the impedance characteristic of the transformer primary, since, with a constant applied voltage, the voltages across R_1 and the transformer primary can be taken and the impedance computed therefrom.

Dr. Salinger's remarks on the calibration of the Rayleigh disc are very interesting, and particulars of further work carried out in the Post Office Research Laboratories, partly as a result of Dr. Salinger's suggestion, may be of interest. The use of a continuous flow of air for the calibration of the Rayleigh disc has been abandoned in favour of two other methods. The continuous-flow method can be made to give good results, as indicated by those obtained by Mallett and Dutton and ourselves. It is, however, rather cumbersome, and it is very difficult to ensure that there are no eddies in the stream, and that the velocity is uniform over the cross-section of the tube. The errors increase as the sensitivity of the suspended system is increased. Tests have been made, in the manner described by Dr. Salinger, using König's formula and calibrating the suspended system by measurements of the time of oscillation and moment of inertia. This method of obtaining the relation between deflection and velocity has been checked against another method, suggested by Mr. E. J. Barnes, in which the disc is exposed to a known particle velocity and the corresponding deflection measured. The disc and strip are enclosed in a sealed tube with windows at the lower end to admit the lantern beam, and the tube is oscillated with simple harmonic motion over a range of amplitude and velocity. The

effect is to cause the air in the tube to oscillate bodily at a known frequency and amplitude past the disc. It is found that, provided the frequencies are not such as to cause irregular motion such as resonance of the suspended system or part of it, the agreement between the two methods is within experimental error, say 1 per cent. Frequencies up to 30 cycles per sec. have been tested, and amplitudes from 0·2 mm to 2·0 mm.

Messrs. Gerlach and Hartmann have given particulars of what is evidently a very valuable method of sound measurement used in the Siemens and Halske laboratories. This method, which is a null one where the effects of a sound pressure are balanced out by means of a current adjustable in magnitude and phase, has the great advantage that no part of the apparatus is in motion at the time of balance. Work has been done in the Post Office Laboratories with this method for directly compensating the sound pressures, somewhat on the lines of the Gerlach compensation method. A moving-coil instrument similar to those referred to in the paper is used; that is to say a few turns of wire are wound on a mica cylinder and arranged to be in position in a strong annular magnetic field. The outer end of the mica cylinder is flush with the face of the magnet and closed with a wooden disc. Into the centre of the end of the magnetic core is screwed the stem of a standard-pattern common-battery transmitter button. The front electrode of this button is attached to the inside of the wooden disc closing the mica cylinder. The cylinder and coil are thus held in position by the microphone button only. When any sound falls upon the wooden disc the coil is moved, and an indication of this is obtained by listening on a circuit connected with the microphone button. Current of adjustable amplitude and phase is now passed through the moving-coil winding and adjusted until no sound is heard in the microphone circuit. Calibration is carried out very simply by hanging the coil, without the microphone button, in the annular magnetic field, and weighing, by means of a chemical balance, the effect of various currents in the moving coil.

LOW-FREQUENCY INTERVALVE TRANSFORMERS.

By P. W. WILLANS, M.A.

(*Paper first received* 1*st February, and in final form* 19*th July*, 1926 ; *read before the* WIRELESS SECTION 2*nd June*, 1926.)

SUMMARY.

The theoretical expression for the voltage amplification of a valve followed by a transformer is developed in its simplest possible terms, and various particular cases are considered. The importance of low leakage inductance for the uniform amplification of the higher frequencies is emphasized.

A practical verification of the theory is provided by actual measurements of the vector amplification ratio and comparisons with the theoretical equations, and graphical methods are given whereby the constants of a transformer can be deduced from these measurements and the amplification ratio extrapolated to frequencies beyond the range of convenient measurement.

A practical design of transformer is described in which low leakage inductance and self-capacity are ensured by a sectionalized and spaced construction, and a curve of amplification of this transformer is given.

Various questions relating to intervalve transformers are briefly considered, and circuits are described for increasing the amplification of low frequencies and the effective step-up ratio of the transformer.

The use of low-frequency reaction for correcting distortion is described and is illustrated by measurements.

INTRODUCTION.

The subject of low-frequency intervalve transformers is one which has excited considerable interest among radio engineers since the inception of broadcasting. The general principles on which voltage amplifiers operate have been known for a considerable length of time, but the special problem of designing a transformer to operate in conjunction with a valve so as to constitute a uniform voltage amplifier over the important range of audio frequencies has not until recently been adequately dealt with in any published work.

The paper by Mr. D. W. Dye * published in the autumn of 1924 represents a comprehensive survey of the whole problem. The author's only reasons for presenting the present paper are first that the method of measurement employed by him throughout the work is possibly novel, and, secondly, that there are some aspects of the problem of designing an intervalve transformer which it is thought might be of some interest to bring forward. If the present paper to some extent has a tendency to traverse old ground, the author can only say in extenuation that his work was carried out in 1923 for the Marconiphone Co. and, had it not been for commercial reasons, publication would have taken place some considerable time ago.

Apart from Mr. Dye's paper, the author can lay claim to no very thorough knowledge of the bibliography of the subject. A paper † by Mr. N. L. Casper summarized the intervalve transformer problem very fairly, but did not deal with it thoroughly from the mathematical point of view. The present author made a brief reference to the effect of magnetic leakage in intervalve transformers in the course of the discussion * on Mr. L. C. Pocock's paper in 1924, and also described and demonstrated a testing set for intervalve transformer measurements at the discussion † on Mr. H. A. Thomas's paper.

* *Experimental Wireless*, 1924, vol. 1, p. 691.
† *Journal of the American Institute of Electrical Engineers*, 1924, vol 43, p. 196.

The object of the present paper is to set out briefly the important theoretical aspects of the problem, to give an experimental verification of the theory and, finally, to discuss questions of design and to describe a particular form of transformer which has been patented.

The author would like to place on record at this juncture his great indebtedness to his assistant and co-patentee, Mr. M. Ward, B.Sc., who took most of the original measurements of amplification and to whose painstaking efforts in this respect any success that may have been achieved in respect of transformer design is largely due.

THEORETICAL CONSIDERATIONS.

It is not proposed to go deeply into transformer theory in this paper, but rather to develop the simplest

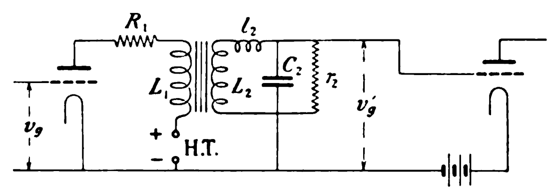

FIG. 1.

l_2 = secondary leakage inductance.
r_2 = secondary effective resistance (shunt).
C_2 = secondary effective capacity.
m = valve magnification factor.
r_a = valve internal resistance.

possible mathematical expressions that will account for those facts which are relevant to the practical problems of design. The simplifications that have been introduced are mainly justified by experiment, though the latter was in some cases insufficient to separate out all the variables.

In Fig. 1 is shown the representation of an intervalve transformer which has been adopted as the most practical for interpreting the experimental results. The arrangement of the transformer in association with its valve also brings out clearly what is meant by a stage of voltage amplification.

Referring to the figure, a sinusoidal voltage v_g is

* *Journal I.E.E.*, 1924, vol. 62, p. 809.
† *Ibid.*, 1926, vol. 64, p. 269.

applied between the grid and filament of a valve in the anode circuit of which is connected the primary winding of the transformer. The secondary winding is connected at one end to the filament of this valve and at the other to the grid of a second valve; in the actual measurements the grid-bias battery was connected as shown, though from the theoretical point of view its exact position is of course unimportant, the filaments of the valves being in effect connected together. The voltage across the secondary winding is denoted by v_g', and the ratio v_g'/v_g, in general a complex quantity, may be termed the "amplification factor" of the stage.

The performance of the transformer may be judged in terms of v_g'/v_g, which is a function of the constants of the transformer and the angular frequency of the applied voltage. This ratio can be both calculated and measured, and a comparison between theory and experiment in this respect has formed the basis of the work here described.

The secondary inductance of the transformer is shown as consisting of two parts L_2 and l_2, the former being supposed tightly coupled to the primary and the latter completely independent of it. It can be readily shown that, so far as magnetic leakage is concerned, there is no more general way of representing an intervalve transformer, and that the location of the leakage inductance entirely in the secondary comes to the same thing as distributing it between the two windings in any proportion. In fact, in most of the transformers which were tested the greater part of the leakage inductance was located in the secondary, so the diagram is in any case in close agreement with facts.

The main assumptions are the representation of the self-capacity by a condenser across the secondary and the representation of the transformer losses by a shunt resistance across this condenser.

The former assumption is not strictly in accordance with the experimental facts, as a reversal of one or other of the transformer windings produces a change in the value of C_2. This shows that the mutual capacity between primary and secondary constitutes an appreciable part of the transformer capacity. However, if the effect of mutual capacity be strictly taken into account we have to consider a system having two natural frequencies, and, in view of the fact that the second of these is well above the limit of practical audibility, the complexity is not warranted from the point of view of interpreting the results.

In respect of the resistance it will be noted from the figure that the ohmic resistance of the primary winding is simply in series with the valve internal resistance. Apart from this the experimental evidence is that there is a loss which can be represented as a shunt across one or other winding; the reason for choosing the secondary is simply that the loads due to the valve and transformer losses respectively are indicated as being on opposite sides of the leakage inductance. It does not appear to be of importance to inquire more closely where these losses are located, as in actual practice the damping of a transformer by the associated valve when a reasonably flat characteristic is attained is very much greater than the damping due to losses in the transformer itself; it is only when additional damping resistances are applied to a transformer that an effect of any importance is obtained.

For convenience of calculation we may still further simplify Fig. 1 as shown in Fig. 2. Here we make use of the fact that the voltage across L_1 must be in a constant ratio to that across L_2, and consequently we can transfer the whole load from the secondary to the primary in accordance with well-known transformer theory. Further, the primary ohmic resistance can be absorbed into the valve resistance and counted as part of it, and thus when the symbol r_a is used it will be understood to denote $r_a + R_1$.

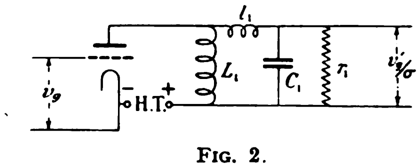

FIG. 2.

If σ = step-up ratio:—

$$l_1 = \frac{1}{\sigma^2} l_2$$
$$C_1 = \sigma^2 C_2$$
$$r_1 = \frac{1}{\sigma^2} r_2$$

voltage across $r_1 = \dfrac{v_g'}{\sigma}$

Referring, then, to Fig. 2, if we denote the anode circuit impedance by Z and the alternating voltage across it by v_a we have, from well-known theory,

$$-\frac{v_a}{v_g} = \frac{m}{1+(r_a/Z)}$$

and, from the figure,

$$\frac{\dfrac{1}{j\omega C_1 + (1/r_1)}}{j\omega l_1 + \dfrac{1}{j\omega C_1 + (1/r_1)}} = \frac{\dfrac{1}{\sigma} v_g'}{v_a}$$

Hence

$$-\frac{v_g'}{v_g} = \frac{m\sigma}{[1 + (r_a/Z)][1 + j\omega l_1\{j\omega C_1 + (1/r_1)\}]}$$

Further,

$$\frac{1}{Z} = \frac{1}{j\omega L_1} + \frac{j\omega C_1 + (1/r_1)}{1 + j\omega l_1[j\omega C_1 + (1/r_1)]}$$

This gives

$$-\frac{v_g'}{v_g} = \frac{m\sigma}{1+j\omega l_1\left(j\omega C_1+\dfrac{1}{r_1}\right) + r_a\left[\left(j\omega C_1+\dfrac{1}{r_1}\right)\left(1+\dfrac{l_1}{L_1}\right)+\dfrac{1}{j\omega L_1}\right]}$$

If we neglect l_1/L_1 in comparison with unity and substitute for C_1, L_1, l_1, and r_1 in terms of C_2, etc., this reduces to

$$-\frac{v_g'}{v_g} = \frac{m\sigma}{1+\dfrac{r_a\sigma^2}{r_2}-\omega^2 l_2 C_2+jr_a\sigma^2\left[\omega\left(C_2+\dfrac{l_2}{r_2 r_a\sigma^2}\right)-\dfrac{1}{\omega L_2}\right]} \quad (1)$$

This equation gives a sufficiently general expression for v_g'/v_g to account for the results obtained in the case of practical transformers. It will be noted that the denominator consists of a real term having the form $A - B\omega^2$ and an imaginary term $j[C\omega - D/\omega)]$; that this is in close agreement with the experimental results will be shown later in the paper.

Special cases. Close-coupled transformers.—Assuming for the moment that equation (1) gives a tolerably good account of the properties of an intervalve transformer, it is now worth while to consider what should be aimed at in the matter of design. For this purpose we will consider the simplest cases first and then go on to the general result.

Case (1). *Loss-free close-coupled transformer.*—If we write $l_2 = 1/r_2 = 0$ in equation (1) we have the ideal case of the loss-free close-coupled transformer. The equation may then be re-written in the form

$$-\frac{v_g'}{v_g} = \frac{m\sigma}{1 + jr_a\sigma^2[\omega C_2 - (1/\omega L_2)]} \quad . \quad . \quad (2)$$

An inspection of this equation shows at once that the maximum amplification occurs, as would be expected, at the frequency for which $L_2C_2\omega^2 = 1$ and that its value is then equal to $m\sigma$. The degree of sharpness of this maximum may be best considered on the following basis. The imaginary term is numerically less than $r_a\sigma^2/(L_2\omega)$ at frequencies below resonance, but approximates to this value the lower the frequency; similarly the imaginary term is less than, but tends to reach, the value $r_a\sigma^2C_2\omega$ at frequencies above resonance. Hence, if we can make $r_a\sigma^2/(L_2)$ and $r_a\sigma^2C_2$ sufficiently small we can attain any degree of constancy desired.

Now L_2 and C_2 are characteristics of the secondary of the transformer (if we neglect the dependence of C_2 on mutual capacity as an approximation). Consequently, when once we have built a transformer of the highest possible L_2 and the lowest possible C_2, we have done our best as far as the design of the secondary winding is concerned, and it only remains to adjust the value of σ to give the required degree of constancy. It thus appears at once that if we consider a valve of given internal resistance, an n-fold increase in L_2 and $1/C_2$ will enable us to effect a $\sqrt{n}$-fold increase in σ (and consequently in the amplification) without loss of uniformity.

We may look at this problem from another angle. Supposing r_a, L_2 and C_2 are all fixed, then by a variation of σ we can obtain families of different resonance curves. If we write $\omega_0 = 1/(\sqrt{L_2C_2})$ and $b_2 = \sqrt{(L_2/C_2)}$ equation (2) may be re-written in the form

$$-\frac{v_g'}{v_g} = \frac{m\sigma}{1 + j\dfrac{r_a\sigma^2}{b_2}\left(\dfrac{\omega}{\omega_0} - \dfrac{\omega_0}{\omega}\right)}$$

or, writing ψ for $\dfrac{\omega}{\omega_0} - \dfrac{\omega_0}{\omega}$

$$-\frac{v_g'}{v_g} = \frac{mr_a}{1 + j\dfrac{r_a\sigma^2}{b_2}\psi} \quad . \quad . \quad . \quad . \quad (3)$$

The function ψ vanishes when $\omega = \omega_0$ and has numerically equal values when $\omega = \omega_0 n$ and ω_0/n, n having any value. Hence, if a resonance curve (v_g'/v_g against ω) be plotted in which the frequency scale is logarithmic, it will be symmetrical about the $\omega = \omega_0$ axis.

If a family of such resonance curves be drawn they will intersect each other, and for every value of ψ there is a value of σ giving optimum amplification. For values of ψ near $\omega = \omega_0$ the value of σ becomes increasingly large, though actually the losses of the transformer would prove a limiting factor. If σ be adjusted to give optimum amplification for a certain value of ω remote from ω_0, a reduction of σ will decrease the amplification within these limits and increase it outside them.

Hence a reduction in the value of σ flattens the resonance curve both by increasing the amplification on the extreme frequencies and decreasing it on the middle frequencies.

It thus appears (cf. Dye's paper) that the simple resonance of inductance and capacity in the secondary circuit is accompanied by no sudden changes in the amplification ratio of the combination of transformer and valve, and, in the absence of magnetic leakage, the resonance curve can be flattened to any desired extent by a sufficient reduction of σ.

Case (2). *Effect of damping on close-coupled transformers.*—Let us next consider the effect of a damping resistance r_2, magnetic leakage being still supposed absent. Instead of equation (3) we then have

$$-\frac{v_g'}{v_g} = \frac{m\sigma}{1 + (r_a\sigma^2/r_2) + j(r_a\sigma^2/b_2)\psi} \quad . \quad . \quad (4)$$

It thus appears that a symmetrical curve of the same type as before is obtained, but that the maximum amplification is reduced by the presence of the damping resistance.

To form an estimate of the extent of this reduction and the consequent change in shape of the resonance curve, let us suppose a loss-free transformer of ratio σ' to be constructed so as to have the same shape of curve as the above; then by comparison with (3) we should have

$$\frac{r_a(\sigma')^2}{b_2} = \frac{r_a\sigma/b_2}{1 + (r_a\sigma^2/r_2)} \quad . \quad . \quad . \quad . \quad (5)$$

Also since the maximum amplifications are respectively $m\sigma'$ and $\dfrac{m\sigma}{1 + (r_a\sigma^2/r_2)}$ their ratio is

$$\frac{\sigma'/\sigma}{1 + (r_a\sigma^2/r_2)} = \frac{\sigma}{\sigma'}, \text{ from (5)}$$

Hence the maximum amplification in the transformer of ratio σ' is σ/σ' times that of the transformer of higher ratio σ when the latter is damped down by a resistance across the secondary so as to give the same curve as the former.

Effect of magnetic leakage.—Let us now consider the effect of leakage. We see on reference to equation (1) that the presence of l_2 has two distinct effects: (a) a change in the real term in the denominator which is

now no longer constant but has the form $A - B\omega^2$, and (*b*) a change in the imaginary term amounting to a virtual increase in the self-capacity of the transformer. The former effect is manifested whether the transformer has appreciable losses or not; the latter only occurs when there are losses as well as magnetic leakage.

Case (3). *Transformer with magnetic leakage but no losses.*—In practical cases the effect of r_2 is not very great except when damping resistances are applied to the secondary of the transformer. Considering r_2 as infinite, in the first place the equation becomes

$$-\frac{v_g'}{v_g} = \frac{m\sigma}{1 - \omega^2 l_2 C_2 + j r_a \sigma^2\left(\omega C_2 - \dfrac{1}{\omega L_2}\right)} \quad . \quad (6)$$

If we denote $1 - \omega^2 L_2 C_2$ by X and $r_a\sigma^2[\omega C_2 - (1/\omega L_2)]$ by Y it is clear that as ω increases from ω_0 to higher values X decreases and Y increases. Since

$$\frac{V_g'}{V_g} = \frac{m\sigma}{\sqrt{(X^2 + Y^2)}}$$

the result at first sight may either be an increase of V_g'/V_g or a decrease according to circumstances. Both effects are found under practical conditions.

In order to discriminate between the two cases we may evaluate the denominator. We have

$$\sqrt{(X^2 + Y^2)} = \sqrt{\left\{\begin{matrix} 1 - 2r_a^2\sigma^4(C_2/L_2) + \omega^2(r_a^2 C_2^2\sigma^4 - 2l_2C_2) \\ + \omega^4 l_2^2 C_2^2 + r_a^2\sigma^4/(\omega^2 L_2^2) \end{matrix}\right\}} \quad . \quad (7)$$

The first two terms are constant and, provided l_2 is sufficiently small and L_2 sufficiently large, the last two may be neglected over a considerable range of frequencies above ω_0. The criterion for discriminating between a rising or falling characteristic is thus whether $2l_2/C_2 >$ or $< r_a^2\sigma^4$.

We have, therefore, as an approximate result for low values of leakage, that if $r_a^2\sigma^4 < 2l_2/C_2$ the characteristic will rise for frequencies above ω_0 and that if $r_a^2\sigma^4 > 2l_2/C_2$ it will fall.

The result of this effect is that we can no longer flatten our characteristic indefinitely by reducing the value of σ, because otherwise it will rise at the higher frequencies. There is thus a limit to the uniformity of amplification obtainable in any transformer unless damping resistances be employed in the secondary circuit.

Case (4). *Transformer with both losses and leakage.*—Returning again to equation (1) we see that in the general case

$$X = 1 + \frac{r_a\sigma^2}{r_2} - \omega^2 l_2 C_2$$

and $$Y = r_a\sigma^2\left[\omega\left(C_2 + \frac{l_2}{r_2 r_a \sigma^2}\right) - \frac{1}{\omega L_2}\right]$$

and the criterion for a rising characteristic is

$$2l_2C_2\left(1 + \frac{r_a\sigma^2}{r_2}\right) > r_a^2\sigma^4\left(C_2 + \frac{l_2}{r_2 r_a\sigma^2}\right)^2$$

which reduces to

$$2\frac{l_2}{C_2} > r_a^2\sigma^4 + \frac{l_2^2}{r_2^2 C_2^2}$$

Thus it is evident that in all cases the tendency of the characteristic to rise at high frequencies is diminished by the presence of the damping resistance. At the same time the proportionate amplification on the low frequencies is improved.

The objections to this method (which is in general use) of correcting the effects of magnetic leakage are two-fold. First, as has already been pointed out, the use of a damping resistance impairs the efficiency of the transformer, that is to say the flattening of the curve is only effected at the expense of a considerable sacrifice of amplification. Secondly, the effective increase in C_2 by the amount $l_2/(r_2 r_a\sigma^2)$ produces a diminution in amplification at high frequencies, so that the advantages of a damping resistance are not fully obtained, even though a sacrifice of efficiency has been made.

Referring to equation (7), if the condition for a flat characteristic is satisfied the coefficient of ω^2 vanishes and the efficiency at high frequencies is governed by the coefficient of ω^4, namely $l_2^2C_2^2$. Accordingly, in order to attain uniformity of amplification up to the highest possible frequency, we must keep l_2C_2 as small as possible. In other words, whereas by a suitable choice of step-up ratio we can ensure a flat characteristic to a transformer over a limited range, the upper limit of this range is determined by the degree of constancy of X.

If a damping resistance is employed we enable X to be kept constant to a greater degree, but at the expense of efficiency. If, on the other hand, we reduce the leakage inductance we attain this constancy with only the small sacrifice of efficiency necessitated in order to preserve the flat characteristic.

It is interesting to work out how much loss of amplification is involved in producing, by means of a damping resistance applied to the secondary of a transformer, the same constancy of X as results from a specified reduction of l_2, say to one-quarter of its original value.

Referring to equation (6), if we reduce l_2 to $\frac{1}{4}l_2$ we have

$$-\frac{v_g'}{v_g} = \frac{m\sigma}{1 - \frac{1}{4}\omega^2 l_2 C_2 + j r_a\sigma^2\left(\omega C_2 - \dfrac{1}{\omega L_2}\right)}$$

whereas if we apply a damping resistance r_2 to the secondary and increase the step-up ratio to σ' (the value to be settled by a comparison with the above) we get

$$-\frac{v_g'}{v_g} = \frac{m\sigma'}{1 + \dfrac{r_a(\sigma')^2}{r_2} - \omega^2 l_2 C_2 + j r_a \sigma'^2\left(\omega C_2' - \dfrac{1}{\omega L_2}\right)}$$

[C_2' being greater than C_2, cf. equation (1)]

Now if the real terms in the denominators of the above have the same degree of constancy we must have $1 + [r_a(\sigma')^2/r_2] = 4$. Hence the real term in the damped transformer has four times the value of that in the undamped one; consequently, to keep the two curves the same shape at low frequencies we can increase the imaginary term to the same extent. Thus $\sigma' = 2\sigma$ and the maximum amplification of the second transformer

is half that of the first. If we aim at keeping the shape of the curves the same at high frequencies, σ' must be less than 2σ and the efficiency of the damped transformer is still lower.

Summary of Theoretical Considerations.

The conclusions to be drawn from the foregoing theoretical discussion of the problem may be summarized as follows :—

(i) The performance of a single-stage transformer amplifier may be expressed as a vector voltage amplification ratio consisting of a fraction having a numerator independent of the frequency and a denominator consisting of a real part X and an imaginary part Y, both in general varying with the frequency.

(ii) The imaginary term Y vanishes for a certain frequency (the resonant frequency) which is determined mainly by the inductance L_2 and capacity C_2 of the secondary winding. The extent of the variation on either side of this frequency is determined by the ratio C_2/L_2, the step-up ratio σ and the valve resistance r_a, the constancy being greater the smaller the values of these quantities. The values of Y are identical for any two frequencies bearing inverse ratios to the resonant frequency. As far as the design of the transformer is concerned it is of importance that C_2 and $1/L_2$ should be separately made as small as possible. The value of σ can then be adjusted in conformity with r_a so that the required degree of constancy of Y is attained.

(iii) The real term X vanishes for a certain frequency which is dependent upon the secondary leakage inductance l_2, capacity C_2 and resistance r_2. The variation of X at frequencies higher than this critical frequency is very steep, but its value tends to constancy at low frequency. The lower the values of l_2, C_2 and r_2 the higher is the frequency for which X vanishes, but a low value of r_2 impairs the efficiency of the transformer.

(iv) Since the constancy of X is not governed by σ we cannot ensure constant amplification by a reduction in ratio. The best that can be achieved is the adjustment of σ until $(X^2 + Y^2)$ is constant over a band of frequencies, but the width of this band is determined by the degree of constancy which has been achieved for X.

(v) Setting aside the alternative of applying a damping resistance to the transformer windings, the problem of intervalve transformer design therefore resolves itself into increasing the secondary inductance to the utmost extent and at the same time reducing to the lowest limits the secondary capacity and the secondary leakage inductance. This will necessitate a determination of the winding space occupied by the primary winding but not of the number of turns with which this space is filled.

We are then left with the value of the step-up ratio at our disposal and we are enabled to adjust this so that in conjunction with any given valve, and, within limits, operating into any given impedance, a voltage-amplification characteristic will be obtained of the greatest possible constancy.

Experimental Results.

(1) *Method of measurement.*—The method adopted for measuring the ratio v_g/v_i for an intervalve transformer connected to a valve has already been described in the *Journal*,* but a diagram of the apparatus employed is here reproduced for the sake of convenience (Fig. 3). During the earlier part of the work a slightly different arrangement was used in respect of the Wagner connection and for frequency measurement, but as these points do not affect the essential features of the device it is sufficient to refer briefly to the main characteristics of the apparatus previously described.

The principle of the bridge was given in the description referred to. In order to make the various operations

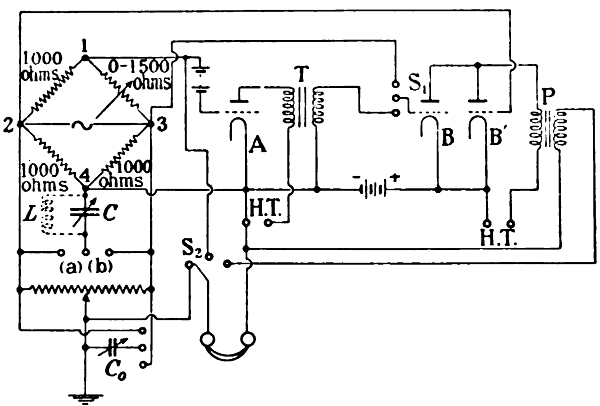

Fig. 3.

clear, simplified diagrams are given in Figs. 4, 5 and 6 which show the successive operations required to effect a measurement of amplification.

In Fig. 4 is shown the bridge set up as a frequency meter. In this case the valves A, B and B_1 are not in use and the instrument operates as an ordinary a.c. bridge. It will be seen from the diagram that a rejector

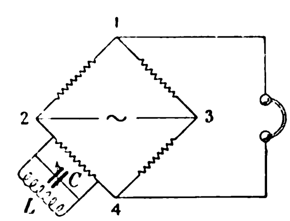

Fig. 4.—Bridge set for frequency measurement.

circuit LC is shunted across one arm of the bridge, which therefore balances at the frequency for which the reactance of this circuit is zero.

No attempt was made to determine the value of the frequency from the settings of L and C, but the apparatus was calibrated from an oscillator having a large number of harmonics, the fundamental of which was adjusted by means of a tuning fork.

In effecting the measurement of frequency the switch S_2 (see Fig. 3) is set in the central position first and a rough balance obtained. It is then set in the left-hand position, giving the arrangement shown in Fig. 4 *a*, the condenser C_0 being connected either as shown or in the position indicated by the dotted lines.

* *Journal I.E.E.*, 1926, vol. 64, p. 270.

The earth balance according to the Wagner principle is then obtained, after which the adjustment is completed according to Fig. 4.

In view of the somewhat complicated operation of setting up the source for any given frequency, it is easier to employ standard tuning forks when an arbitrary known frequency is all that is required. This has been done in most of the more recent measurements, since the agreement between theory and experiment is close enough to permit of satisfactory interpolation.

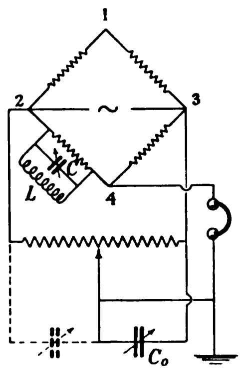

FIG. 4 *a*.—Wagner adjustment of frequency bridge.

Having set up the source of alternating current to any required frequency, the next step is to balance the two valves B and B_1. The arrangement for this is put into operation by setting the switches S_1 and S_2 of Fig. 3 in the upper and right-hand positions respectively. The resulting circuit arrangement is shown in simplified form in Fig. 5.

The bridge is balanced exactly, the variable condenser being disconnected, and the filament brightness of one

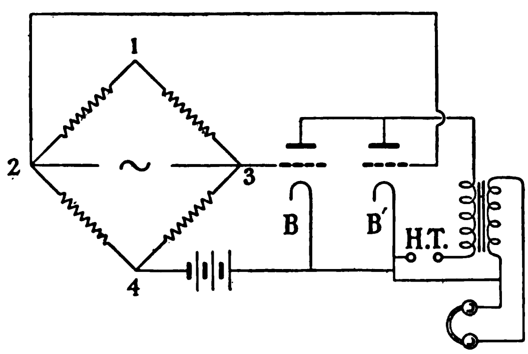

FIG. 5.—Balancing of valves B and B′.

or other of the valves B and B_1 varied until an extinction is obtained. The Wagner balance is then effected and the measurement completed as before.

The last operation, which is the actual measurement of amplification, is carried out as shown in Fig. 6, the switches S_1 and S_2 being in the lower and right-hand positions respectively. In this case we have to displace the balance of the bridge, by means of the variable resistance R_1 and the condenser C connected across one or other of the two ratio arms, in order that the output voltage across the secondary of the transformer T may be equal and opposite to the voltage across 2, 4. This point is of course indicated by an extinction of the sound in the telephones. The measurement is completed as before by first adjusting the earth bridge and then re-balancing the arrangement shown in the figure.

The voltage amplification factor is equal and opposite to the ratio of the voltage across the arm 2, 4 to that across 1, 4, this ratio being readily calculable. The values of this factor are respectively given by

$$-\frac{v_g'}{v_g} = \frac{R' + R}{R' - R - j\omega R^2 C}$$

and
$$-\frac{v_g'}{v_g} = \frac{R' + R}{R' - R + \omega^2 R^3 C^2 + j\omega R^2 C}$$

according as to whether the condenser switch is in position (*a*) or position (*b*).

It is thus apparent that the measurement of amplification can be effected in a way which makes a comparison with the theoretical expression given in equation (1) a very simple matter.

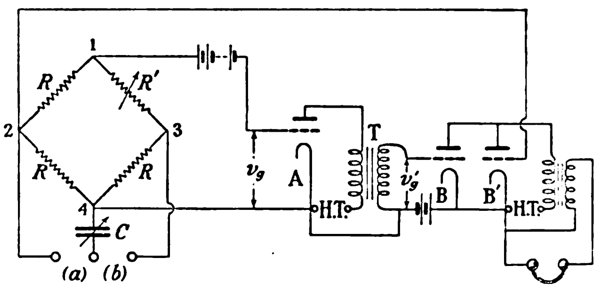

FIG. 6.—Measurement of amplification.

For this purpose it is convenient to reduce the calculated results to the form

$$-\frac{v_g'}{v_g} = \frac{1}{P + jQ}$$

and we thus have

$$Q = \pm \frac{\omega R^2 C}{R' + R}$$

and
$$P = \frac{R' - R + \omega^2 R^3 C^2}{R' + R} \quad \text{or} \quad \frac{R' - R}{R' + R}$$

according to the position of the switch.

P and Q are thus readily calculable from the settings of the bridge when a balance is obtained in the manner already described.

If it is desired to calculate the scalar amplification factor and phase angle, we have at once from the above

$$\frac{V_g'}{V_g} = \frac{1}{\sqrt{(P^2 + Q^2)}} \quad \text{and} \quad \tan\phi = \frac{Q}{P}$$

V_g and V_g' being the moduli of the corresponding voltages and ϕ the phase angle between them.

(2) *Verification of theory.*—During the course of the work a large number of transformers were tested, some of which were practical audio-frequency intervalve transformers actually on the market, others tentative designs and others again actual samples drawn from production of the final design of transformer which was adopted by the author's firm. As would naturally be expected, the measurements yielded an enormous

diversity of response characteristics, but in all cases the same general results were obtained and confirmed the theory set out in the first part of this paper.

For the purpose of this verification, and as a routine check on the accuracy of the measurements, a graphical method has been adopted which has many convenient features.

Referring to equation (1), it was noted that the expressions denoted by X and Y are functions of the frequency, having the forms $A - B\omega^2$ and $(C/\omega) - D\omega$ respectively. In other words, X and $Y\omega$ are linear functions of the square of the frequency.

If, therefore, the theory is substantially correct the expressions P and $Q\omega$ should similarly be linear functions of ω^2, and this fact can easily be checked by plotting the values of these expressions in such a manner that they should lie in a straight line.

In practice it has been found most convenient to employ squared paper in which the abscissæ are plotted according to a quadratic law and designated as frequencies, the latter being expressed, for purposes of arithmetical convenience, as kilocycles. In this case, if f is the frequency in kilocycles corresponding to any observations, all that is necessary is to plot the values of P and Qf as ordinates against the corresponding frequencies, and the results should, and in fact very largely do, lie on a straight line.

In cases where the results conform closely to theory it is readily possible to obtain empirical formulæ for P and Qf, and by means of these to obtain a general formula for the voltage amplification of the stage, which will enable extrapolation to be carried out to frequencies beyond the range of convenient measurement.

As an example of this method a series of readings is shown in full in the above table, the results being tabulated in a convenient manner for working out. For this series the values of P and Qf are plotted as above described, empirical formulæ are obtained for v_g'/v_g and $\tan \phi$, and a curve of amplification is plotted from this formula covering frequencies from 0·1 to 10 kilocycles. The phase angle is marked along the curve at intervals of 10°. Amplification curves are similarly plotted for a number of other transformers.

The greatest divergencies from the straight-line law are found in the case of the values of P for transformers having comparatively small inductance. In these cases the value of P is found to be less at low frequencies than would correspond to a straight-line plot. The reason for this would appear to be bound up with the variation of magnetic leakage due to varying flux density in the iron. As it was not readily possible to work at constant flux density this question was not followed up; it did not appear to be of practical importance as it did not occur to any material extent in the case of transformers having sufficient inductance.

The values of Qf showed satisfactory conformity with the above law in practically all cases.

It is clear from these results that both the real and imaginary terms in the denominator of v_g'/v_g vanish for a certain frequency. In the case of the Q term this frequency is well within the audible limit, and easily ascertainable by direct measurement. In the case of the P term, the vanishing frequency is considerably higher and, as a rule, outside the range of convenient measurement.

The frequency for which Q vanishes has been denoted as the "resonant frequency," because it is in practice very largely determined by the inductance and effective capacity of the transformer. Other factors have an influence on its value, notably the secondary resistance in a transformer having appreciable magnetic leakage, but even in this case the effect is precisely that of a virtual added capacity, so that the analogy to resonance is quantitative.

In the above,

$$\left.\begin{aligned} y &\equiv -\omega R^2 C \\ x &\equiv R' - R \end{aligned}\right\}\text{switch in position } (a)$$

or

$$\left.\begin{aligned} y &\equiv +\omega R^2 C \\ x &\equiv R' - R + \omega^2 R^3 C^2 \end{aligned}\right\}\text{switch in position } (b)$$

$$\text{Figures in last column} = \frac{1\,000 + R}{\sqrt{(x^2 + y^2)}}$$

The values of P and Qf are plotted in Fig. 7 *a*.

The frequency for which P vanishes (termed by Dye the "second resonance") marks in a general way the upper limit of effective amplification of a transformer, inasmuch as beyond this point both P and Q increase with the frequency, the former very steeply. The variation in the value of P has been shown in the foregoing to be due to the joint effects of magnetic leakage and self-capacity. In this connection the properties of iron at very low flux densities have to be borne in mind, the permeability of stalloy iron for the small alternating currents experienced under working conditions being of the order of 200–300. The consequence of this is that the coefficient of coupling between the two windings is very much less than would be the case if the flux density were of the value commonly experienced in power-transformer work.

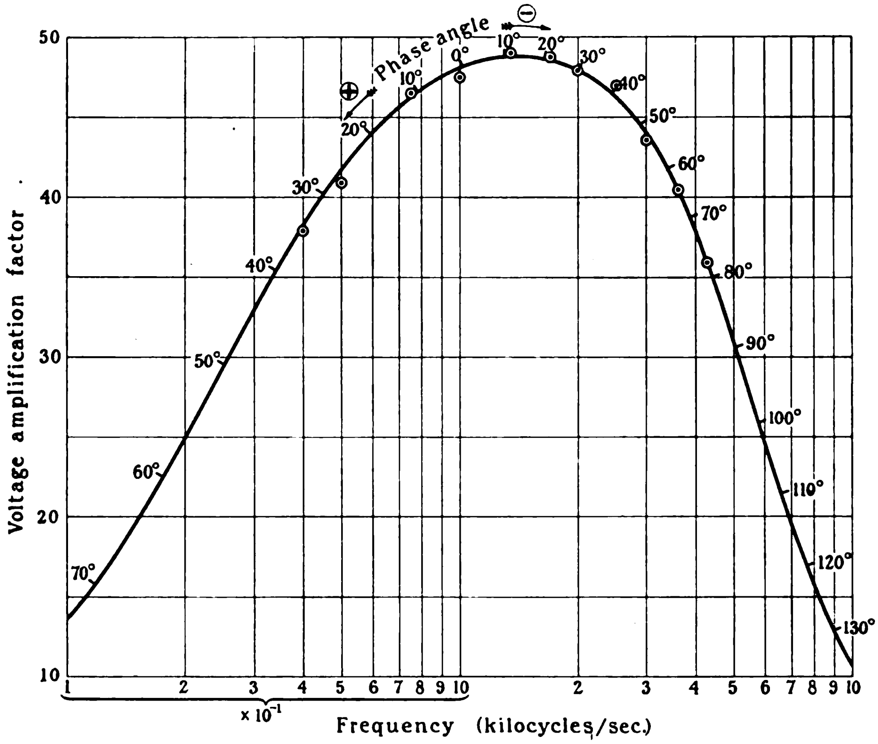

Fig. 7.—Transformer No. 1.

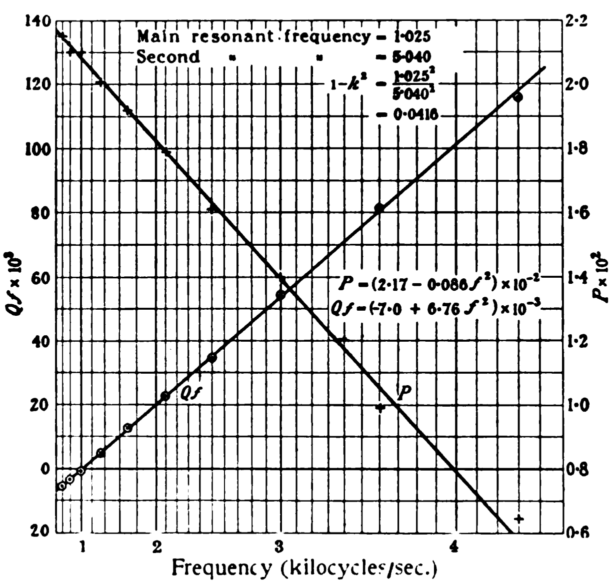

Fig. 7 *a*.—Transformer No. 1.

Between the two frequencies corresponding to $Q = 0$ and $P = 0$ respectively we invariably have a state of affairs in which P decreases while Q increases, and it is readily possible to design a transformer in which, over an appreciable band of frequencies, the one effect counteracts the other so far as the scalar response characteristic is concerned.

On the other hand, even with measurements extending up to 4 kilocycles only, the difference in performance between two such transformers can be readily estimated, inasmuch as in some cases the individual variations in P and Q are far less acute than in others. This is clearly shown in the series of curves to which reference has been made.

Description of Low-Leakage Transformer.

The transformer finally developed by the author and Mr. Ward was the result of an attempt to obtain the utmost constancy of P without the employment of a damping resistance. It is clear from the theory that in order to achieve this object we must reduce both l_2 and C_2 to the utmost possible extent and, whilst the importance of low self-capacity had been stressed in published work and in manufacturers' advertisements, the question of leakage inductance did not appear at

the date of the specification (Dec. 17, 1923) to have received the attention it deserved.

The reason for this seemed to be two-fold: first, that on the analogy of power transformers one would suppose that the leakage could be reduced well below 1 per cent simply by attention to the iron circuit, and, secondly, that in cases where it was clearly realized that a considerable percentage of leakage existed, it was actually considered a desirable characteristic inasmuch as it counteracted the effects of self-capacity.

The exacting requirements of faithful reproduction in broadcast reception indicated, however, that something further was required than merely the limited range of straight characteristic obtainable with a transformer constructed on normal lines, and the quality of reproduction in the upper register which was obtained as a result of the modified design appeared to justify this view.

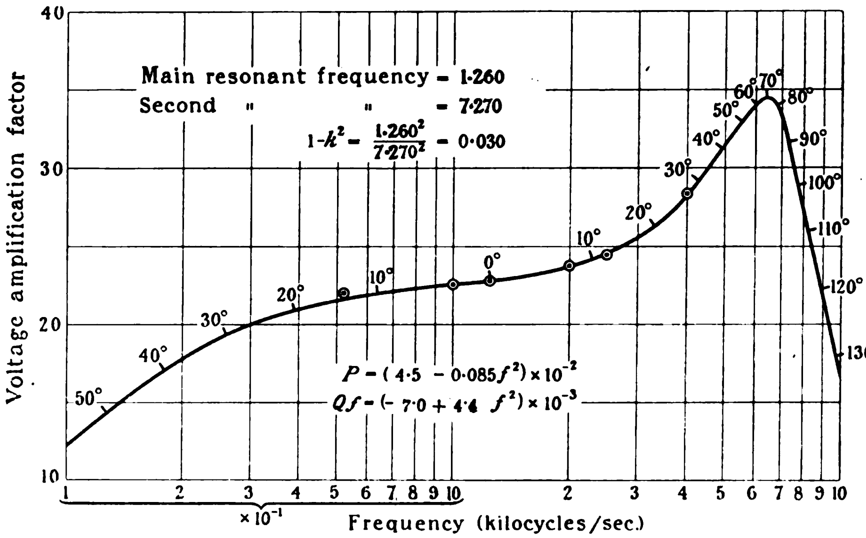

FIG. 8.—Transformer No. 2.

In order to reduce the value of leakage inductance the customary method was adopted of dividing the primary and secondary windings into sections and interleaving them. This was first attempted without any special precautions, but it was immediately found that the mutual capacity between primary and secondary gave a very heavy drop in the value of Y at high frequencies. Accordingly the sections were spaced apart from each other until no appreciable gain in respect of capacity was obtained by spacing them any further,

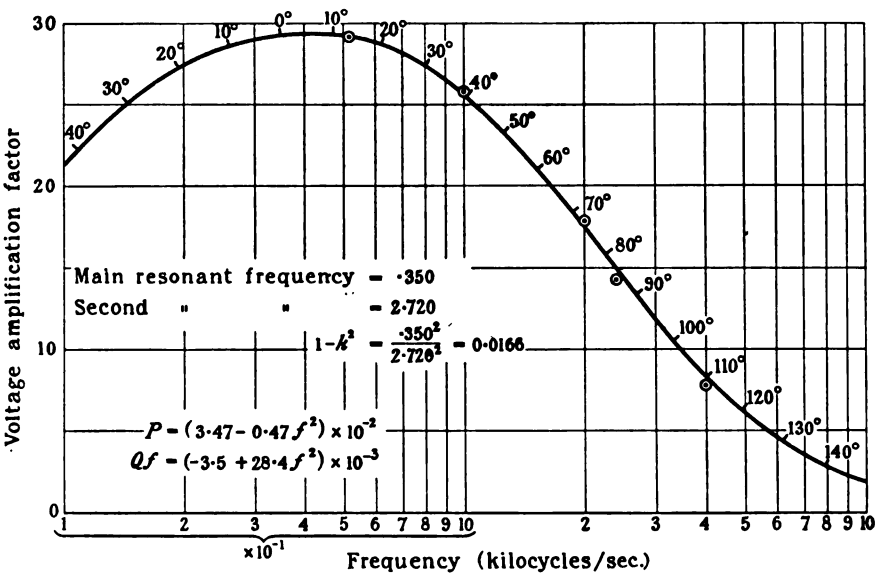

FIG. 9.—Transformer No. 3.

and the result was a transformer having the characteristics shown in Fig. 10.

A sectional view of the transformer is shown in Fig. 11, which is extracted from the patent specification. The sections C consisted in all cases of about 5 000 turns of 44 S.W.G. enamelled wire, but the gauge and number of turns of the sections B varied according to the ratio of the transformer.

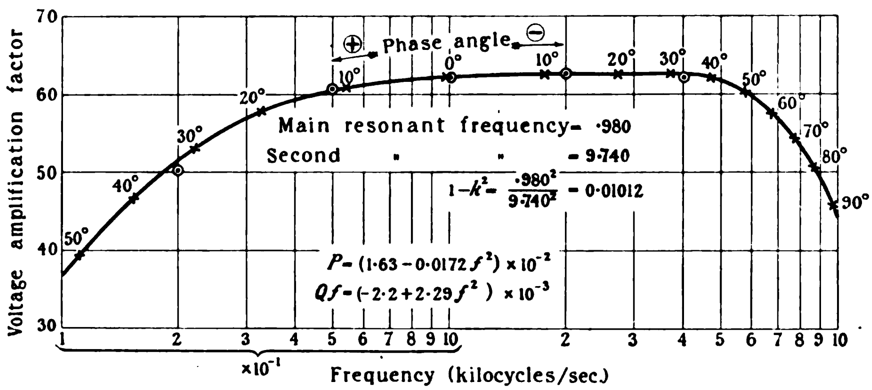

FIG. 10.—Transformer No. 4.

In order to space the sections apart from each other, star-shaped spacing-pieces of the kind shown in the figure (reference D) were used. These were made of strips of thin millboard situated edgewise on. Other methods have also been adopted to give an equivalent effect.

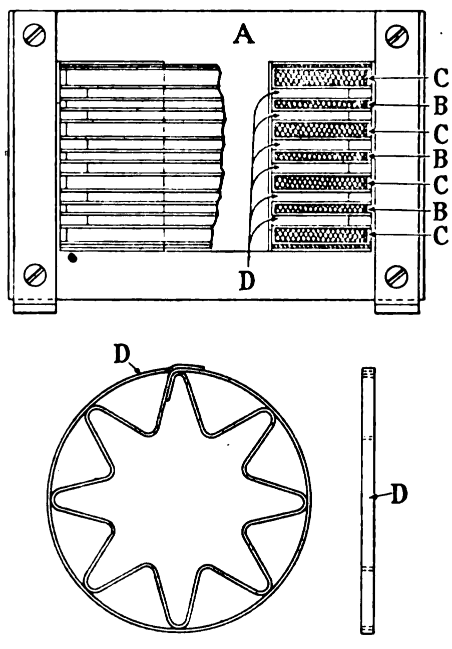

FIG. 11.

As will be seen from the figure, a shell-type iron core was employed consisting of T-shaped and U-shaped stalloy laminations lapped in the usual manner. These were secured by bolts passing through the corners, and it is worth noting in passing that there was no perceptible advantage of any kind to be obtained by not punching the laminations in this manner, nor did it appear to make any difference whether the bolts were insulated or not.

The cross-section of the iron core was about 5·5 cm² and the length of the iron circuit 18 cm. The average effective shunt resistance across the secondary winding has been worked out from a set of circle diagrams of primary impedance furnished to the author by Mr. E. C. Cork; its value was approximately 8 megohms, though it varied somewhat with different transformers. In view of the fact that it was necessary that the resistance thrown into the secondary winding from the anode circuit of the valve should have a value of the order of 0·25 megohm it will readily be seen that no very great gain was to be expected by improving the transformer in respect of losses, and this would appear to account for the point mentioned above regarding the bolting of the laminations.

The secondary inductance of these transformers was of the order of 300–350 H and the effective leakage was about 1 per cent. The latter varied slightly with different ratios of transformer, an improvement being found in the case of the lower ratios where the density of primary winding was greater. The variation was probably due to the different gauges of wire used and the different manner in which the winding space was filled up.

Four different ratios of transformer were specified. The lowest of 2·7 : 1 was suitable for use in conjunction with valves having an impedance of about 40 000 ohms, such as the ordinary R type. The transformer of ratio 4 : 1 operated very satisfactorily in conjunction with a valve of about 16 000 to 18 000 ohms impedance; the 6 : 1 ratio with a 7 000-ohm valve, and the 8 : 1 with a valve of 4 000 to 5 000 ohms impedance. This last transformer is also useful after a crystal rectifier, though it is doubtful whether it has a sufficiently high step-up ratio for some of the very low-resistance crystals.

All of the above transformers appear in general use to offer one very definite advantage, namely a comparative immunity from reaction effects tending to self-oscillation or distortion. It has been the belief of the author for some time that a transformer of low leakage

inductance is inherently more stable in cascade amplification, and measurements on the effect of the impedance of the windings of one transformer on the amplification of another, due to the grid-filament capacity of the valves appeared to support this contention.

There appears also to be some justification for the view that actually better reproduction is given with a low-leakage transformer amplifier on the frequencies, say, up to 5 000 cycles than with transformers of the ordinary type which are carefully adjusted to give a uniform amplification curve up to this frequency and no further. At any rate it appears desirable, for really good-quality reproduction, to place the second resonance of the transformer at the very highest possible frequency, and a value of 8 000 to 10 000 cycles does not appear by any means to be excessive. The transformer shown in Fig. 10 has a second resonance of 9 740 cycles.

The defect of the transformer characteristic under consideration is undoubtedly the inefficient reproduction of the lower frequencies, and it is of interest to note that, in a transformer embodying the same principles of design which has been recently developed and put on the market, this deficiency has been made good with very little sacrifice on the upper register.

Notes on Transformer Characteristics.

In order to carry out a practical analysis of a transformer we can make use of the vector response-characteristics plotted in the manner already described, and this method has the advantage that we obtain the constants of the transformer under actual working conditions.

An approximate method, which is quite satisfactory in nearly all cases, is to neglect the transformer resistance. We then take the main and second resonant frequencies given by equating Q and P respectively to zero. Denoting these by ω_0 and ω_0' (in radians per sec.) we have

$$L_1C_1\omega_0^2 = 1$$

and

$$(1 - k^2)L_1C_1(\omega_0')^2 = 1$$

Hence

$$1 - k^2 = \frac{(\omega_0')^2}{\omega_0^2} = \frac{(f_0')^2}{f_0^2}$$

(f_0' and f_0 being the corresponding frequencies).

To find L_1 and C_1 separately we require to know the valve resistance r_a.

Since $-\frac{v_g'}{v_g} = \frac{1}{P + jQ}$ we have by comparison with equation (6)

$$-\frac{P}{Qf} = \frac{(1 - \omega^2 l_2 C_2)}{(r_a\sigma^2/6\,280L_2) + \text{terms containing } \omega} = \frac{(1 - \omega^2 l_2 C_2)6\,280L_1}{r_a + \ldots \text{etc.}}$$

If we equate f to zero we thus have

$$\left(-\frac{P}{Qf}\right)_{f=0} = \frac{6\,280L_1}{r_a}$$

Hence

$$L_1 = \frac{r_a}{6\,280}\left(-\frac{P}{Qf}\right)_{f=0}$$

Taking the transformer shown in Fig. 10, it was found that $r_a = 19\,100$ ohms.

Hence $$L_1 = \frac{19\,100}{6\,280} \times \frac{1\cdot 63}{2\cdot 20} = 22\cdot 6 \text{ H}$$

On measurement the value of L_1 was found to be 21·6 H, and the resonant resistance of the primary came out to 0·6 megohm.

In order to obtain a more accurate estimate of L_1 from the curve, we may employ the figure of 0·6 megohm to apply a correction. We have, by comparison with equation (1) instead of (6) :—

$$-\frac{P}{Qf} = \frac{\left(1 + \frac{r_a\sigma^2}{r^2} - \omega^2 l_2 C_2\right)6\,280L_1}{r_a + \text{terms containing } \omega}$$

Hence $$\left(-\frac{P}{Qf}\right)_{f=0} = \frac{[1 + (r_a/r_1)]6\,280L_1}{r_a}$$

and thus $$L_1 = \frac{r_a}{6\,280[1 + (r_a/_1r)]} \times \left(-\frac{P}{Qf}\right)_{f=0}$$

The corrected value of L_1 is thus reduced in the ratio

$$\frac{1}{1 + (19\cdot 1/600)} = \frac{1}{1\cdot 031}$$

i.e. instead of 22·6 H we have a figure of 21·9 H, which is in good agreement with the measured value.

Referring to Fig. 10 it will be seen that $1 - k^2 = 0\cdot 0101$. Taking this as an approximate value we can calculate C_1, taking the values of l_1 and r_1 correctly into account. It will readily be seen from equation (1) that at the frequency for which $Q = 0$ we have

$$L_1\left(C_1 + \frac{l_1}{r_1 r_a}\right)\omega^2 = 1$$

Hence

$$C_1 + \frac{0\cdot 22}{0\cdot 6 \times 0\cdot 019} \times 10^{-12} = \frac{10^{-6}}{21\cdot 9 \times 6\cdot 28 \times 0\cdot 980}$$

i.e.

$$\begin{aligned} C_1 &= 0\cdot 00121 - 0\cdot 000019 \\ &= 0\cdot 00119\ \mu\text{F} \end{aligned}$$

Hence the virtual capacity due to leakage and losses is only of the order of 2 per cent of the actual capacity, and, in consequence, there is no material error in the calculation of $1 - k^2$.

The values of L_2 and C_2 can be obtained from the known value of σ and work out to 350 H and 0·000074 μF. The latter includes the capacity of the valve to which the transformer is connected. The value of l_2 is of course 3·5 H.

The method of measuring m and r_a for the above purposes may be of interest. To obtain m, two high-quality choke coils of very low resistance were constructed having an inductance of the order of 100 H and a resonant impedance of the order of 20 megohms or more. These were arranged as an intervalve coupling unit and connected to the bridge in the same manner as an intervalve transformer (cf. Fig. 12).

The amplification of the stage was thus equal to the value of m for the valve, and the conditions under which any transformer was tested could thus be immediately reproduced.

In view of the high impedance of the chokes no correction was necessary in practice, and it may further

be noted that it is not essential actually to make the measurement at the resonant frequency of the chokes since, provided the coupling condenser is large enough, the amplification factor is simply $1/P$.

In order to measure r_a an arrangement similar to that shown in Fig. 13 was employed. Here it will be noted that the high-tension supply is fed to the valve through a choke (which in the actual experiments was one of those used for the previous test) and the anode resistance

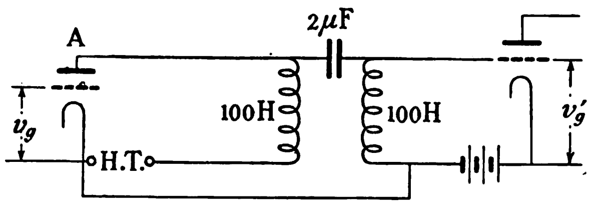

Fig. 12.—Measurement of m.

$-v_g'/v_g$ = magnification factor of valve A.

is coupled by a condenser so as to be in effect a shunt across one of the 1 000-ohm arms of the bridge. Assuming this to be the arm adjacent to R_1 we have at once

$$\frac{1}{R_1} = \frac{1}{1\ 000} + \frac{1}{r_a}$$

from which r_a can be calculated.

The impedance of the coupling condenser makes it necessary to employ a capacity across one of the other ratio arms in order to balance the bridge, but the error as far as the measurement of resistance is concerned

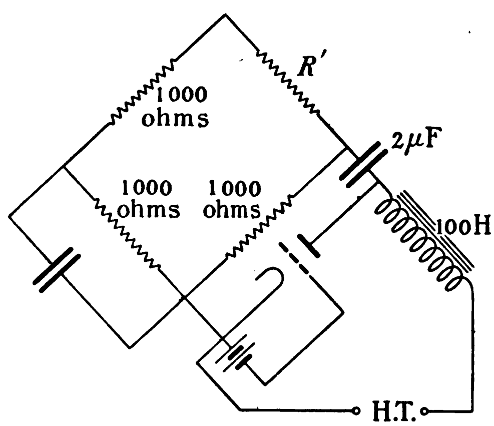

Fig. 13.—Measurement of r_a.

can easily be made insignificant by choosing a large enough condenser and working on a high enough frequency. A capacity of 2 μF at a frequency of 1 000 cycles is good enough for all practical values of r_a.

The Choice of a Valve.

No consideration has so far been given to the question of a valve for use in conjunction with an intervalve transformer, and it is of importance to review certain factors in this connection.

Referring to the simplest case as exemplified in equation (8), it is evident that the shape of the response characteristic is determined by the product $r_a\sigma^2$, whereas the peak value is determined by $m\sigma$.

Suppose that we consider a series of valves and transformers for which $r_a\sigma^2$ is constant, and endeavour to work out the peak value of amplification from them.

Then we may write $\quad r_a\sigma^2 = K$

and thus $\quad \sigma = \sqrt{\frac{K}{r_a}}$

Hence the peak amplification is equal to $m\sqrt{(K/r_a)}$ and is thus proportional to $m/\sqrt{r_a}$.

Now if we take a range of valves in which the electrodes occupy the same geometrical positions and the emissions are the same but the density of the grid windings are different, we find in practice that the value of m/r_a is approximately constant.

It is thus evident that the peak amplification is proportional to the square root of the amplification factor of the valve. As evidence of this effect it is worth while to compare the curves in Figs. 7 and 10. In the former case the valve had an impedance of 7 000 ohms and a magnification factor of 5·5. In the latter case the corresponding values were 19 100 ohms and a magnification of 15·6. The ratios are thus substantially the same, but even with the very steep curve shown on the transformer in Fig. 7 it fails to attain the maximum amplification of the transformer in Fig. 10. Had the characteristic in the former case been of a 6 : 1 transformer of the same type as that shown in Fig. 10, the characteristic would have been of substantially the same shape and the maximum amplification about 33 (these figures are taken from published characteristics of the transformer in question).

It thus appears that a very considerable gain is to be expected from the employment of a valve of high magnification factor and a transformer of conservative step-up ratio, and there seems to be little doubt that, if a valve could be produced having an impedance of the order of 0·25 megohm and a proportionate amplification factor, the best form of intervalve coupling would be of the choke type. This, however, neglects practical difficulties such as questions of battery supply, which must of necessity enter into any consideration of this kind.

As an offset to the advantages gained by the employment of a valve of high magnification factor it is further worth while remarking that it is a matter of great difficulty to produce such a valve with a sufficiently straight characteristic to avoid asymmetric distortion on the high and low frequencies respectively. The use of such valves is thus of greater advantage in the earlier stages of an amplifier where the voltage amplitude is small.

A further question must also be considered, namely, the greater effect of inter-electrode capacity in a valve of this kind, since the capacity is at least as great if not greater than with open-mesh valves, and the voltage developed across this capacity is of course considerably greater.

The Effect of Inter-electrode Capacity.

No attempt can be made to deal thoroughly in this paper with this very intricate question, but a few general considerations may be briefly outlined.

It is well known that the effect of an impedance in the anode circuit of a valve on a preceding stage of amplification can be represented by an input impedance across the grid and filament, and it is possible to calculate this on the basis of the theory previously given.

Referring to Fig. 14, C_0 is the anode-grid capacity of a thermionic valve and i_0 the current flowing through it in response to an E.M.F. v_g across the grid and filament. Z_a is the impedance in the anode circuit and Z_g the effective input impedance due to C_0.

Then $$i_0 = j\omega C_0(v_g - v_a)$$

Now $$\frac{v_a}{v_g} = -\frac{m}{1 + (r_a/Z_a)}$$

Hence $$i_0 = j\omega C_0 v_g\left[1 + \frac{m}{1 + (r_a/Z_a)}\right]$$

and we have

$$\frac{1}{Z_g} = j\omega C_0\left[1 + \frac{m}{1 + r_a(/Z_a)}\right]$$

The input impedance thus consists of two parallel

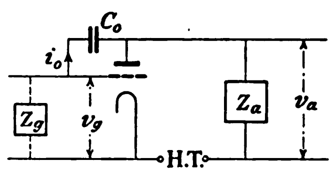

FIG. 14.

branches, a capacity equal to C_0 and an impedance equal to

$$\frac{1 + (r_a/Z_a)}{j\omega m C_0}$$

We need only concern ourselves with the latter, since the former can be counted as a part of the transformer capacity.

If we neglect the resistance of the transformer we may write

$$\frac{1}{Z_a} = \frac{1}{j\omega L_1} + \frac{1}{j\omega l_1 + (1/j\omega C_1)}$$

in accordance with the simplifications of Fig. 2.

We shall then obtain the result

$$Z_g = \frac{1}{j\omega m C_0} - \frac{r_a}{mL_1 C_0 \omega^2} + \frac{r_a C_1/(mC_0)}{1 - l_1 C_1 \omega^2}$$

It thus appears that the input impedance can be represented by a condenser of value mC_0 in series with a resistance the value of which varies with the frequency and may be either positive or negative.

The feature of interest in this connection is the effect of leakage inductance. If we write $l_1 = 0$, the equation reduces to

$$Z_g = \frac{1}{j\omega m C_0} - \frac{r_a}{mL_1 C_0 \omega^2}(1 - L_1 C_1 \omega^2)$$

Hence the resistance has zero value at the resonant frequency of the transformer, is negative below this frequency and positive above it, remaining positive however high the frequency is raised.

Now for values of ω below the main resonant frequency of a transformer the effect of the negative resistance is not enough to cause any serious disturbance of the resonance curve of a preceding stage, inasmuch as the reactance of the effective capacity mC_0 is so high. This can easily be verified by actual measurements. Hence, in the absence of magnetic leakage, the only effect of any consequence is at high frequencies and manifests itself as a capacity in series with a positive resistance across the secondary of the transformer.

If we consider the case where l_1 is finite it is at once apparent that if $l_1 C_1 \omega^2 > 1$ the resistance is again negative. Hence we may expect a regenerative effect

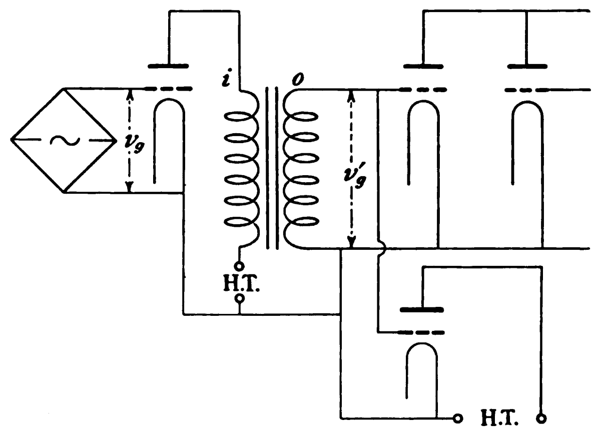

FIG. 15.

above the second resonance, and this will be far more serious owing to the lessened reactance of mC_0. This appears to be the cause of whistling and distortion on the upper frequencies, which are so often encountered in the case of transformers having the second resonant frequency not high enough. Transformers which have a high second resonance will occasionally go into oscillation on an inaudibly high frequency, but this is not generally difficult to suppress without impairing the amplification characteristic over the important frequency range.

Within the normal audio-frequency range the input load takes the form of an addition to the self-capacity of the transformer. This can usually be allowed for by a slightly conservative step-up ratio. On the other hand, with a transformer of low leakage inductance the use of the neutrodyne circuit becomes practicable.*

In order to form an estimate of the possibilities in this direction, and also to investigate the nature of the reaction effect in a stage of audio-frequency amplification, a series of tests was carried out with the circuit arrangements shown in Figs. 15, 16, 17 and 18, the results being given in Tables 2 to 5.

Referring to Fig. 15, it will be seen that the valve is inserted with its grid and filament shunted across a transformer in a normal manner for bridge measurement, but with its windings in opposite senses. The arrangement with Fig. 15 shows no impedance in the anode circuit of its additional valve, so that only the normal capacities between grid and filament and grid and plate are added to the secondary capacity of the transformer.

* Cf. *Proceedings of the Institute of Radio Engineers*, 1926, vol. 14, p. 231.

In Fig. 16 the same arrangement is employed except that a transformer is connected in the anode circuit of the additional valve, this being the same transformer as was used for the plotting of the characteristic shown in Fig. 8.

In Fig. 17 a small neutralizing condenser is connected on the plate of the additional valve to the plate of the amplifying valve; otherwise the arrangement is as in Fig. 16.

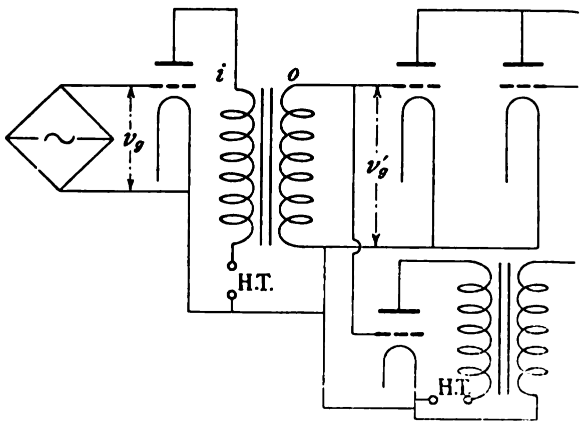

Fig. 16.

In Fig. 18 a 0·0003 μF condenser is shunted across the secondary of the transformer connected to the additional valve. This has the effect of lowering the second resonance very considerably and bringing it within the range of practical measurement, in fact to about 2·7 kilocycles.

The measurements with these various arrangements are given in Tables 2 to 5. Table 2 shows that the

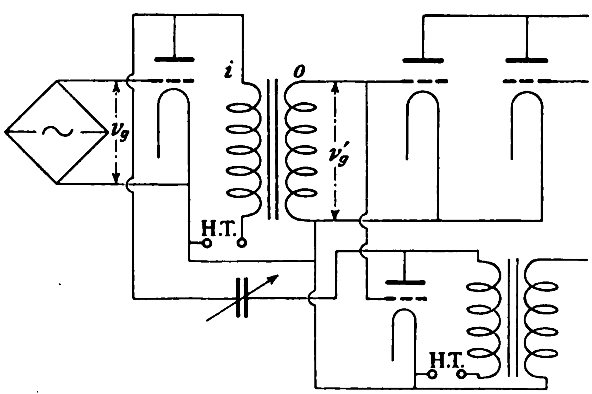

Fig. 17.

amplification characteristic of the transformer is quite normal, the curve being that corresponding approximately to the characteristic shown in Fig. 10 but measured on a different occasion.

Table 3 shows a small change in the value of P_2 as a result of reaction from the second stage, but a very steep rise in the value of Q_2. This is what would be expected, since within the range of frequencies measured the reactance of the transformer primary is capacitative and very high.

In Table 4 it will be seen that the values of Q_3 are substantially the same as those of Q_1. This was deliberately arranged by a suitable adjustment of the neutralizing condenser. Under these conditions the

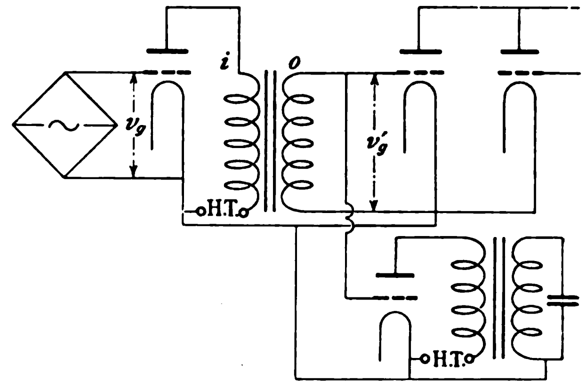

Fig. 18.

values of P_3 drop more steeply than those of P_1 and a rising characteristic is obtained. If, however, the neutralizing condenser had been so adjusted as to permit

Table 2.

Effect of Inter-electrode Capacity.

Second stage inoperative (see Fig. 15).

1·00	1·63	0·07	61·3
1·50	1·59	0·25	62·1
2·00	1·55	0·42	62·1
3·00	1·42	0·71	63·1
4·00	1·24	0·98	63·1

Table 3.

Effect of Inter-electrode Capacity.

Second stage operative; second transformer unloaded (see Fig. 16).

f (kilocycles)	$P_2 \times 10^2$	$Q_2 \times 10^2$	$\frac{1}{\sqrt{(P_2^2 + Q_2^2)}}$
1·00	1·57	0·42	61·5
1·50	1·52	0·84	57·6
2·00	1·46	1·12	54·4
3·00	1·28	1·75	46·1
4·00	1·03	2·32	38·3

of a small additional increase in the value of P_3, a flat characteristic could have been obtained but the extent would not have been as great as that of a transformer operating under the conditions of normal measurement.

The imperfect neutralization is due to the magnetic leakage of the first transformer.

In Table 5 we see the effect of reaction from a subsequent stage both below and above the second resonant frequency, the first three figures for P_4 being definitely greater than the corresponding figures in Table 2, showing the positive resistance thrown into the amplifying circuit, and the last two figures being less, in the second case very considerably so. As far as the values of Q_4 are concerned these are always increased, as would be expected, but the increase is a minimum in the neighbourhood of the second resonance, viz. at 3·00 kilocycles.

TABLE 4.

Effect of Inter-electrode Capacity.

Second stage operative but neutralized; second transformer unloaded (see Fig. 17).

f (kilocycles)	$P_3 \times 10^2$	$Q_3 \times 10^2$	$\dfrac{1}{\sqrt{(P_3^2 + Q_3^2)}}$
1·00	1·60	0·07	62·5
1·50	1·53	0·25	64·5
2·00	1·43	0·42	67·0
3·00	1·14	0·71	74·5
4·00	0·76	1·02	79·5

The most interesting feature of these measurements appears to be the successful manner in which audio-frequency neutralization can be carried out, and it would seem that this aspect of the problem of designing audio-frequency transformer amplifiers has been undeservedly neglected.

VARIOUS INTERVALVE TRANSFORMER CONNECTIONS.

(*a*) *Primary series-condenser circuit.*—If a condenser of suitable value is placed in series with the primary winding of a low-frequency transformer, an increase of amplification may be obtained at frequencies below the main resonance of the transformer, the effect being exactly analogous to that of magnetic leakage at high frequencies. Circuits embodying this principle have been published by various workers.

In order to carry out this scheme, it is necessary to provide means for feeding the anode of the associated valve with high-tension voltage, and this can best be effected by means of a parallel choke arrangement as shown in Fig. 19.

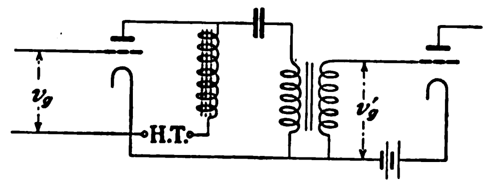

FIG. 19.

For the sake of simplicity we may neglect magnetic leakage and resistance in the transformer, and the figure may be redrawn, on the analogy of Fig. 2, as shown in Fig. 20.

With the notation of this figure we can readily obtain the result

$$-\frac{v'_g}{v_g} = \frac{m\sigma}{1 - \dfrac{1}{L_1 C\omega^2} + jr_a\left(C_1\omega - \dfrac{1}{L_1\omega}\right)}$$

(C_1/C being neglected in comparison with unity, which is legitimate under practical conditions).

The scalar amplification factor is given by

$$\frac{V'_g}{V_g} = \frac{m\sigma}{\sqrt{\left[1 + r_a{}^2\dfrac{C_1}{L_1} + \left(\dfrac{r_a{}^2}{L_1^2} - \dfrac{2}{L_1 C}\right)\dfrac{1}{\omega^2} + \dfrac{1}{L_1^2 C^2\omega^4} + r_a{}^2 C_1^2\omega^2\right]}}$$

Now at low frequencies $r_a{}^2 C_1^2\omega^2$ can be neglected in comparison with unity. If at such frequencies $1/(L_1^2 C^2\omega^4)$ can also be neglected, the constancy of amplification is governed by the coefficient of $1/\omega^2$, and the characteristic rises or falls according as $2L_1/C >$ or $< r_a{}^2$, a flat characteristic being given by $2L_1/C = r_a$.

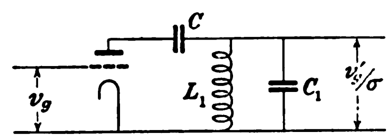

FIG. 20.

At very low frequencies the term $1/(L_1^2 C^2\omega^4)$ begins to have weight, and below a certain frequency the amplification is reduced by the presence of the series condenser.

The disadvantage of this arrangement would appear to be an increased tendency towards asymmetric distortion at low frequencies. There is no doubt that the inductance of the windings of an intervalve transformer carrying no polarizing current increases with increasing flux density, but, however much it increases, the magnification cannot exceed the value $m\sigma$ when it is normally connected. With the series-condenser arrangement there is a possibility of a large resonance

hump at high amplitudes, since in this case $2L_1/C$ may be greater than r_a^2.

As an illustration of this method, a resonance curve was taken for transformer No. 4, with a condenser of 0·07 μF capacity in series with the primary and a feed-choke of 100 H. The results are given in Table 6, P_1 and Q_1 being the values of P and Q with the condenser short-circuited, and P_2 and Q_2 with the condenser in circuit.

TABLE 6.

f (kilocycles)	$P_1\times 10^2$	$Q_1\times 10^2$	$\left(\frac{V_g'}{V_g}\right)_1$	$P_2\times 10^2$	$Q_2\times 10^2$	$\left(\frac{V_g'}{V_g}\right)_2$
0·20	1·64	1·28	48·1	1·02	1·22	62·9
0·30	1·64	0·81	54·6	1·37	0·81	62·9
0·40	1·63	0·62	57·5	1·50	0·57	62·5
0·50	1·63	0·41	59·5	1·60	0·41	60·5
1·00	1·62	—	61·7	1·62	—	61·7

It will be noted that with the condenser in circuit a progressive decrease of P_2 is obtained with decreasing frequency which off-sets with a good measure of accuracy the increase of Q_2, giving uniform amplification.

(b) *Low-frequency reaction circuits.*—It is possible to compensate for the loss of amplification in an intervalve transformer circuit at both high and low frequencies by means of reaction. In order to consider the possibilities in this direction, it is convenient to take the case of low frequencies and to compare the effect obtained with that given by the condenser circuit above described.

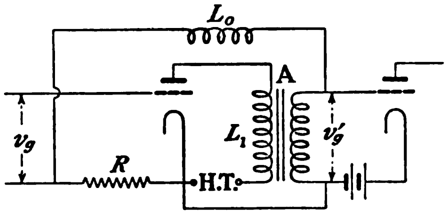

FIG. 21.

Referring to Fig. 21, A is a transformer the windings of which are oppositely connected so that σ is negative. The grid terminal of the secondary is connected through an inductance L_0 to a resistance R which is situated in the grid circuit of the input valve. The impedance of L_0 is arranged to be large in comparison with R at practical low audio frequencies.

Under these conditions we have two effects to consider :—(a) the loss of primary inductance due to L_0 being shunted across the secondary of the transformer, and (b) the effect of the reaction potential developed across R.

Considering (a), if L_1' be the effective primary inductance and L_1 its normal value, we have

$$\frac{1}{L_1'} = \frac{1}{L} + \frac{\sigma^2}{L_0} \text{ (} R \text{ being neglected)}$$

Now if the potential across R be denoted by v_r we have

$$\frac{v_g'}{v_g + v_r} = \frac{m\sigma}{1 + (r_a/Z)} \text{ (where } Z = \text{anode impedance)}$$

$$= \frac{m\sigma}{1 + \frac{r_a}{j\omega}\left(\frac{1}{L_1} + \frac{\sigma^2}{L_0}\right)} \text{ (at low frequencies)}$$

and $$v_r = \frac{R}{j\omega L_0} v_g', \text{ since } \omega L_0 >> R$$

Hence

$$v_g'\left[1 + \frac{r_a}{j\omega}\left(\frac{1}{L_1} + \frac{\sigma^2}{L_0}\right)\right] = m\sigma v_g + \frac{m\sigma R}{j\omega L_0} v_g'$$

If then we make

$$\frac{m\sigma R}{L_0} = r_a\left(\frac{1}{L_1} + \frac{\sigma^2}{L_0}\right)$$

we have

$$\frac{v_g'}{v_g} = m\sigma \text{ at low frequencies,}$$

i.e. constancy of amplification is attained.

A more detailed consideration of this case shows that the amplification at high frequencies is substantially unaltered by the inductance L_0, the only effect being as if the inductance of the transformer were made infinite within the limits of effective operation of the reaction circuit.

The contrast between the method of working and that considered under heading (a) is noteworthy. In the latter case the increase in Q is compensated by a drop in P; according to the present method this increase is itself annulled.

In practice this circuit is quite readily workable, L_0 being a fixed inductance and R a variable resistance of the graphite-leak type. It is found that if R be increased, a setting is reached where oscillations occur on a very low frequency. On setting R to a value close to but definitely below this point, a stable arrangement is obtained and a great increase results in the low-frequency amplification.

The effective limit of this circuit is found when the value of R starts to be comparable with the impedance of L_0. The immediate effect is a drop in the value of P, which gives a still further increase in amplification and is apparently the cause of self-oscillation when R is increased, a frequency being found where $P = 0$ and $Q = 0$ simultaneously. The effect at very low frequencies must necessarily be a decrease in amplification as in the case considered under (a), but a very much greater range of constant amplification may be attained by the present method.

Table 7 gives the results of a series of measurements on a small transformer with and without the correcting device. As before, P_1 and Q_1 correspond to the normal circuit arrangement and P_2 and Q_2 to the circuit shown in Fig. 21.

The asymmetric distortion in an arrangement of this sort would appear to be definitely diminished as far as the iron is concerned, though undoubtedly there is a

danger of introducing valve distortion in its place. How far this latter effect would be troublesome is a matter for further experiment.

Other low-frequency reaction effects may be obtained by shunting L_0 with a small condenser (which annuls the increase in Q at high frequencies) or a high resistance (which increases the amplification at middle frequencies). The condenser circuit has the disadvantage that high-frequency oscillations are very readily set up owing to magnetic leakage, and also that inter-electrode capacity couplings appear to upset the circuit when it is used as part of an amplifier, even though it

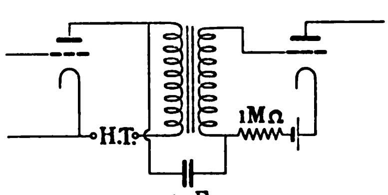

FIG. 22.

operates in accordance with theory when connected to the bridge. The resistance connection produces a very great increase of amplification at some sacrifice of quality.

(c) *Auto-transformer circuit.*—An arrangement due to Messrs. Graham and Rickets is illustrated in Fig. 22 and is well worth consideration.

Here the transformer is connected so that σ is positive, and the plate end of the primary winding is coupled through a condenser to the filament end of the secondary, the latter being connected to the grid battery through a high resistance. The values of 1 μF and 1 megohm were arbitrarily chosen but appeared to give satisfactory results.

It is obvious from the circuit that the effect of the arrangement is roughly to increase σ to $(\sigma + 1)$. This is achieved at the expense of some slight increase in the self-capacity of the transformer, due apparently to the increased mean alternating potential between the windings. The figures are given in Table 8.

CONCLUSION.

The author would like to express his thanks to Mr. E. C. Cork for the information referred to on page 1074, to Mr. L. E. Currah, Associate Member, for reading the proofs of the paper, and to Messrs. A. J. Franklin and A. D. Hodgson for assistance in taking some of the measurements.

APPENDIX.

(A) THE EFFECT OF PRIMARY CAPACITY.

If a condenser is connected across the primary winding of a transformer a modification is required to the previous equations, which become slightly more complex. This case is of interest, both on account of the use of condensers in this manner to by-pass high-frequency currents and as representing a certain tendency in

transformer design, the only object of which is to improve the response characteristic.

Supposing that in Fig. 2 there is a condenser C_1' across L_1, we may evaluate v_g'/v_g by substituting $1/L - \omega^2 C_1'$ for $1/L_1$. This gives

$$\frac{v_g'}{v_g} = \frac{m\sigma}{1-\omega^2 l_1 C_1 + jr_a\left[\omega\left(C_1 + C_1' + \frac{l_1}{r_1 r_a}\right) - \frac{1}{\omega L} - \omega^3 l_1 C_1 C_1'\right]}$$

l_1/L_1 being neglected in comparison with unity.

If we neglect transformer losses, we may express the condition for a flat characteristic as in the case of equation (7), only in this case we have another disposable constant, i.e. C_1', and can thus make the coefficient of ω^4 zero as well as that of ω^2. We have

$$\sqrt{(X^2+Y^2)} = \sqrt{\left[1 - 2\omega^2 l_1 C_1 + \omega^4 l_1^2 C_1^2 - 2r_a^2\frac{(C_1 + C_1')}{L_1} + \omega^2 r_a^2 (C_1 + C_1')^2 - 2\omega^4 r_a^2 l_1 C_1 C_1'(C_1 + C_1') + 2\omega^2 r_a^2 \frac{l_1}{L_1} C_1 C_1' + \frac{r_a^2}{\omega^2 L_1^2} + \omega^6 r_a^2 l_1^2 C_1^2 C_1'^2\right]}$$

For the optimum characteristic we have therefore

$$2l_1 C_1 = r_a^2 (C_1 + C_1')^2 + 2r_a^2 \frac{l_1}{L_1} C_1 C_1'$$
$$l_1^2 C_1^2 = 2r_a^2 l_1 C_1 C_1'(C_1 + C_1')$$

Neglecting l_1/L_1 in comparison with unity (i.e. omitting the second term on the right-hand side of the first equation), this reduces to

$$C_1' = \frac{1}{3}C_1 \quad \text{and} \quad \frac{l_1}{C_1} = \frac{8}{9}r_a^2$$

If these conditions are satisfied we shall have only the term containing ω^6 remaining in the denominator, and thus a greater extent of straight characteristic is obtainable. On the other hand, it is necessary for C_1 to be less, i.e. a smaller step-up ratio must be employed, with a consequent sacrifice in amplification.

The analogy of this system to a low-pass filter is interesting. What we have in effect at the high frequencies is shown in Fig. 23. And we find that v_g'/v_g can be reduced to an expression of the form $m\sigma/\sqrt{(A + B\omega^6)}$ by satisfying two equations among the four quantities l_1, C_1, C_1' and r_a. Assuming r_a to be given, we can satisfy one more equation which will determine the frequency for which the "cut-off" becomes effective.

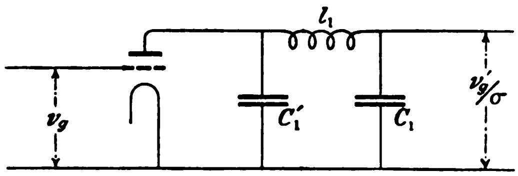

FIG. 23.

If we add a further inductance and condenser as in Fig. 24, we now have two more disposable constants with which we can satisfy two more equations (i.e. equating the coefficients of ω^6 and ω^8 to zero). The expression for v_g'/v_g then takes the form $m\sigma/\sqrt{(A+B\omega^{10})}$.

Similarly, if we employ a network containing n elements we can arrange that v_g'/v_g takes the form $m\sigma/\sqrt{(A+B\omega^{2n})}$ and can also satisfy one further condition which will determine the cut-off frequency. The solution is unique, i.e. there is one and only one value for each of the elements. No general solution has been obtained, but it would appear to be real in all cases.

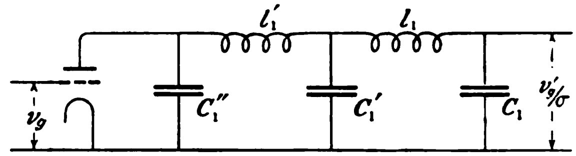

FIG 24.

The arrangement is not a true filter but a device for producing a constant terminal voltage for an input of given magnitude, within certain limits of frequency. It thus fulfils the function of a filter and might be conveniently embodied for this purpose as part of a voltage amplifier. Band and high-pass arrangements are of course as readily devised. No practical work has been carried out on this problem apart from measurements on intervalve transformers having primary capacity.

(B) MEASUREMENTS ON LEAKAGE INDUCTANCE.

The figures for $1 - k^2$ which were calculated from the characteristics shown in Figs. 8, 9 and 10 are uniformly lower than those corresponding to independent measurements made on the transformers. The values of the primary inductances of the transformers were measured in circuit, and those of the leakage inductances were measured by short-circuiting the secondary windings and making a simple bridge measurement of the residual primary inductance. As a result the following figures were obtained :—

Transformer	$1 - k^2$ from characteristic	$1 - k^2$ from measurement
No. 2	0·030	0·053
No. 3	0·017	0·031
No. 4	0·010	0·013

The discrepancy is thus very large, though at the same time the straight-line plots for the values of P gave a strong indication that the theory was basically sound.

With a view to investigating the matter further, some measurements were made on transformer No. 2 with a condenser of value approximately $0 \cdot 0003\ \mu F$ across its

secondary winding, so that the external capacity was large in comparison with the internal capacity. The following results were obtained on a measurement of amplification :—

First resonant frequency = $0 \cdot 615$ kilocycles
Second resonant frequency = $2 \cdot 690$ kilocycles

and from this $1 - k^2 = 0 \cdot 0520$, which is in good agreement with the directly measured value.

It thus appears that the distribution of the capacity of the transformer through the winding controls the effective value of $1 - k^2$. At first it was thought that the discrepancy might be due to the presence of mutual capacity, but this would require a variation of $1 - k^2$ in the opposite sense. The interpretation would seem to be that the effective capacity of the transformer does not embrace the whole of the leakage inductance, so that the representation of the transformer is as shown in Fig. 25.

The effective secondary capacity is here shown as being connected to an intermediate point on the secondary leakage inductance. The addition of a large condenser to this arrangement shunts the whole of the

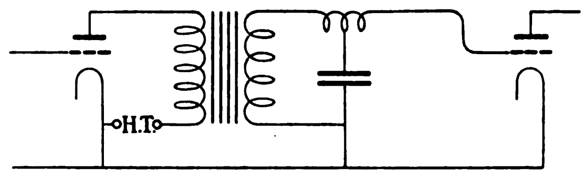

FIG. 25.

secondary leakage inductance by capacity and the normal figures are obtained.

It may further be remarked that measurements on line transformers having a resistance load on the secondary winding give normal results for the values of $1 - k^2$.

DISCUSSION BEFORE THE WIRELESS SECTION, 2 JUNE, 1926.

Mr. P. K. Turner: There is in my opinion a fundamental objection to the bridge method described by the author. A few months ago, when the author described this bridge in connection with another paper, he claimed as one of its great advantages that the transformer was measured under normal working conditions. But I perceive that under the usual conditions of use of this bridge there is no alternating current in the anode circuit of the valve following the transformer being measured. Hence there is no throw-back across that valve. From this it follows that there is no possibility of negative resistance in the input circuit of that valve, and hence the transformer has quite definitely a positive load on its secondary winding. If there were an inductive load in the anode circuit of the valve following the transformer, it is practically certain that the effective load on the transformer would be considerably reduced, with perhaps quite different results on measurement. In everyday use, the valve following the transformer will have in its anode circuit either another transformer or a telephone (or loud-speaker); in fact, there will be in this circuit a complex impedance. Therefore at different frequencies there will be a varying load on the transformer, which will affect its anode impedance and almost certainly its performance. Thus it seems to me that the bridge does not, in fact, fulfil the stated conditions of measuring the transformer under conditions of use. Now that we have received so much information about what one might call the preliminary design of a transformer, I am anxious for even more information. Supposing that by the use of the author's principles of design one has arrived at the point that the primary of the transformer which one proposes to design must be of such and such an inductance, that the magnetic leakage must not be more than a certain small percentage, and that the stray capacities must be below a certain small amount, how does one proceed to design the transformer? What is the permeability of an iron core with laminations of normal thickness under conditions of use in a transformer? I can think of three possible permeabilities, owing to the fact that there is a steady polarizing current in the core. There is the ordinary permeability, B/H, measured at the value of H given by the pure alternating current; there is the same B/H measured at the H given by the polarizing current; and there is the differential permeability, dB/dH, measured about the H given by the polarizing current. With most types of iron these will be widely different from one another. Then, again, what is the effective cross-section of the iron with laminations of normal thickness, i.e. to what extent does the field penetrate into the iron itself at various frequencies? Again, in view of the fact that the transformer works with a high resistance in its primary circuit, what is the comparative importance of transformer losses? I am sure that information on some of these puzzling points would be much appreciated by all of us, and I should like to make it clear that any criticisms which I have made on details of the author's methods do not in any way indicate a lack of appreciation of the very valuable work that he has done.

(*Communicated*): Although it may seem only a minor detail, I should like to comment upon some of the symbols used in the advance copies of the paper, especially the use of ρ* for the internal resistance of the anode circuit. There is a general tendency in physical work nowadays to use small Greek letters to indicate entities which are essentially in the nature of absolute quantities, while using English letters for actual physical quantities: typical of this is the author's own choice of σ for the step-up ratio of the transformer, which is a pure number; and of L and R for inductance and resistance, which are physical quantities. Apart, however, from this general objection, I should like to call the author's attention to the fact that ρ has been officially standardized as the symbol for resistivity, and should therefore not be used for a resistance. The symbol R_a is almost universally used as the symbol for internal differential resistance between anode and filament of a valve. There are other points of termin-

* Corrected for the *Journal*.

ology in the paper to which I should like to refer. For example, immediately under Fig. 2 the author indicates by Z what he calls the "anode impedance," but judging by the analysis which follows, what he really means by Z is the *external* impedance of the anode circuit. Again, in the same sentence he denotes by v_a the "anode voltage", and again the analysis shows that what he means is the voltage developed in the external anode circuit, which is a quite different thing, for "anode voltage" should surely mean the total E.M.F. induced in the anode circuit. Again, on page 1074, and I believe elsewhere, he refers to the "coefficient of coupling," and gives it as 1 per cent.* It seems fairly obvious from the context that he really intends to say that the coefficient of coupling is 99 per cent and that the *leakage* coefficient is 1 per cent.

Mr. H. A. Thomas : I wish to confine my remarks entirely to the method of measurement. My objection to the method is that the output valve is not fulfilling its normal functions. It is not giving the load on the transformer secondary; and, as is well known, the effect of very small impedence shunts across the secondary is very serious. The backing-off valve which is used acts virtually as a shunt to the normal output valve, and the grid of this valve is connected by a large amount of apparatus forming a large input capacity to the other output grid. I have recently tried the effect of this shunting valve as shown in the author's diagram. A Marconi transformer was used with a D.E.R. valve and 100 volts high tension, and a negative grid bias of 4 volts, the frequency being 2 000. The stage amplification with a weak output under normal conditions was found to be 33. A similar valve was connected across the original output valve in the same way as shown in the diagram, and the amplification fell to 28. The connecting grid lead was lengthened to about 1 ft., which I should estimate would be about the length that would be used with the bridge. The amplification fell from 28 to 26·5, showing very clearly that even a small amount of wire will have a very great effect on the amplification. The effect of the capacities of the bridge taken as a whole, not to earth, would increase this fall. Therefore, it seems that the presence of the backing-off valve may produce an error of at least 25 per cent in the determination of the amplification. I should be interested to know what differences the author has obtained with his method when compared with other methods which give normal output conditions.

Mr. H. L. Kirke : The work I have done on transformers has been concerned with input and output transformers for amplifiers used in broadcasting transmission chains rather than intervalve transformers; but some points do actually come into the question in connection with intervalve transformers. The author discusses the series-condenser method of increasing the low-frequency component of amplification in any intervalve transformer system. I have used that method, and I believe that other wireless engineers have used it in various connections, particularly in the case of output transformers, where the output is connected to a line. I have found it very satisfactory indeed, and I have taken care to see, by the use of cathode-ray oscillographs and the like, that there is no distortion whatever. With regard to the question of iron distortion, the point did arise, as I was using transformers at very high flux densities, and the cathode-ray oscillograph showed that there was no appreciable distortion in the iron, provided that a value of B of 5000 per cm^2 was not exceeded. In this connection it is interesting to know that the value of inductance of a transformer, i.e. the effective value of permeability, can vary about 15 to 1, according to the value of flux density in the iron over the range; but, nevertheless, the minimum permeability appears never to decrease below the value of between 200 and 300. Those tests were made with the ordinary inductance bridge, amplifying the output of the bridge in a carefully screened amplifier, and putting various known values of the current into the bridge so that the actual value of H could be calculated. One point brought out in the paper, in connection with the series-condenser method of bringing up the low frequency, is the variation of output impedance due to the condenser and transformer primary forming a series resonant circuit, lowering its impedance about the resonant frequency. That question is of importance, particularly if the input to the valve is large; the dynamic characteristic will vary considerably and so cause distortion. Although it is not actually a point in connection with this paper, the distortion due to the use of reactive output impedance in a rectifier is very interesting. In some forms of rectifiers, particularly the crystal, the effect of input impedance on rectification is dependent very largely upon the low-frequency back E.M.F. If that back E.M.F. is out of phase with the low-frequency current, some curious effects will be noticed. I have noted them on the cathode-ray oscillograph: in one particular case I had a rectifier which should have been perfect, but the oscillograph showed that the results were very far from being perfect. That is due to having a reactive impedance. On making the reactance completely non-reactive, the distortion disappeared completely. The author has pointed out that, by placing a condenser across the primary of the intervalve transformer, he effectively turned it into a low-pass filter. He stated that the value of the condenser should be one-third of the effective capacity of the secondary winding, as shown on the primary. In the ordinary design of electric filter circuits, the capacity of the end condensers, if we use the mid-shunt termination, should be one-half of that of the condensers in the centre. If there is only a single stage with the condenser at each end and one inductance in the middle, the two condensers should be equal. I should be very interested to know why he used the value of one-third, or whether it is merely empirical. With regard to Mr. Turner's point about the value of permeability and how to calculate it, I have done a certain amount of work on that subject, and particularly in regard to the change of inductance due to varying flux through the transformer. I attempted to calculate the inductance which would result by using a static iron characteristic, and I found that the a.c. inductance bore no relation to the position on the static iron characteristic due to d.c. flux. In

* Corrected for the *Journal*.

general the d.c. flux tended to decrease the inductance rather than to increase it. The d.c. permeability of iron often varies from about 200 to 2 000. One would expect a.c. permeability to do the same, if one sets the d.c. flux to that point, but actually in practice it does not do so. I was particularly interested in the author's remarks about inter-electrode feed-back effects, as I have had considerable trouble in this direction in high-power modulation systems, where a number of valves are used in parallel and the inter-valve capacity is relatively large (of the order of 0·0001 to 0·0003 μF). In this case the feed-back effect is to produce a decrease in amplification at high frequencies; in some cases the amplification was reduced to 10 per cent of the maximum. With regard to the curves of transformers published in the paper, I should like to point out that, for good reproduction, frequencies as low as 50 cycles require amplification; and, no doubt, development in efficient transformer design has been considerably delayed by the fact that the average loud-speaker does not reproduce the low frequencies at all (i.e. the frequencies below 200 cycles). I think that future development should be on the lines of an essentially flat characteristic from 50 to 10 000 cycles, which, to my knowledge, cannot be obtained without considerable loss of efficiency.

Mr. C. G. Garton: I think that it is important to obtain as low values as possible in the leakage inductance and self-capacity, but it seems to be quite possible to get a very good design of transformer which has both large leakage inductance and large self-capacity. The curve can certainly be obtained flat to over 5 kilocycles. Can the author say whether he considers there is any great disadvantage in that design? I think that the second resonance point is probably about 6 to 7 kilocycles, rather than 9 to 10 kilocycles, which makes for a larger and more expensive design. But these figures are on the limits of the audio-frequency range, and I do not think the increased cost is justified by the better quality obtained by the author's design. With regard to the question of permeability of iron and the losses therein, so long as the a.c. amplitude is small compared with the d.c. polarizing current, there is no question that the differential permeability is the correct permeability to use. It is practically constant for the whole range of the curve until the saturation point is reached, and, for ordinary iron, ranges between 200 and 400. It is possible to obtain nickel-iron alloys in which the differential permeability reaches values as high as 1 200; but they are prohibitively expensive, unless it is required to make a special transformer for a particular purpose. There is very little difference between the permeability curves for 400 cycles and 50 cycles. I have not gone above 400, but I have found that the permeability is of very little importance above that frequency, because the reactance at 400 cycles is so large that one is not concerned with it but only with the question of iron permeability at lower frequencies. So far as the losses in iron are concerned, they seem to be negligible. As has been mentioned already, the inductance is the determining factor. I was interested also in the question of whether the bridge which is used for obtaining these frequency characteristics should or should not take account of the reaction due to the load in the second valve. My own bridge, an account of which was given in the *Journal*,* received precisely the same criticism. I wish to maintain strongly that these bridges ought to be worked with a second valve and no reaction. It is a sound principle in any investigation to reduce the number of variables as much as possible. If the load, i.e. the measuring valve of any bridge, is to be allowed to vary with the conditions, the characteristic curve obtained is not one for a particular transformer and its associated valve, but for a two-valve amplifier, in effect. Therefore, I think it is a sound principle to use a bridge which eliminates that effect and, if it does not give a practical curve, gives a curve from which something can be deduced, instead of one which is compounded of several different effects.

Mr. C. F. Phillips: Ingenious as the author's bridge arrangement undoubtedly is, from my own point of view it has certain disadvantages. Perhaps the most serious are the elaboration of the apparatus, the time taken in conducting a test, and the amount of arithmetic involved. I should like to indicate a method by which part of the information—the degree of effective amplification per stage—can be measured in a considerably simpler manner. This method has, however, one defect; it gives no information as to the comparative phase of the input and output voltages. It is in essence a variation of the old "slide-back" method, in which an a.c. voltage on the grid of a valve was measured by seeing how much bias was required to reduce anode current to zero. The serious disadvantage was the difficulty of determining just when the anode current became zero. Further, it cannot be used in this case, for the valves would be working under freak conditions. By watching, instead, the grid current, this method becomes quite practical. A galvanometer and potentiometer are inserted in the grid circuit of the valve before and the valve after the transformer, and each grid is biased until the grid current vanishes. Knowing the grid potential for zero grid current with *no* input E.M.F., one has only to observe the "drop" to give zero grid current in each valve under signals, and their ratio is the value of the stage amplification. It is obvious that the measurement is taken under precisely the right conditions for satisfactory amplification, and is therefore a true working test. In conclusion I should like to ask the author what, in his opinion, are the causes of transformer breakdowns.

Dr. R. L. Smith-Rose: It has been very noticeable during the last few years that new-comers to the intervalve transformer industry have, in nearly every case, repeated all the mistakes made by those who preceded them in the manufacture of such transformers. At the present time the available transformers can be divided into two classes, those which are moderately good and those which are bad. The author has gone about the matter scientifically, and has been studying the problem theoretically as well as from a practical point of view, and has thereby arrived at some quite successful results. One point which I should like to raise in connection with his method of testing, or in connection with the results obtained by testing, is the

* *Journal I.E.E.*, 1926, vol. 64, p. 270.

question of the lowest frequency at which he is able to carry out those tests. I understood previously that this frequency was in the neighbourhood of 250 cycles per sec., whereas in every case the curves in the author's diagrams continue down to 100 cycles per sec. Were those results obtained by extrapolation, or were they actual measurements with the bridge in question? Also, with reference to the question raised by Mr. Garton of studying the behaviour of an isolated transformer with no valve or its equivalent load attached, it should be remembered that at the present time the only practical application of intervalve transformers is as the coupling portion of a valve-amplifying stage. A perfect transformer may be produced, but in practice a valve must be connected to it with its associated load; and it is that combination which we desire to give uniform amplification at all frequencies. In the method of measurement described by Mr. Phillips, the only pitfall is the question of the limiting accuracy. The measurement depends upon the detection of the start of the grid current. Since the grid-current/grid-voltage curve meets the axis at a small angle, although not necessarily tangentially, it may be very difficult to determine the exact point at which the grid current commences, and that would place a limiting accuracy on the method. Considering that the transformer employs a closed iron circuit, I was surprised to find on pages 1073 and 1074 that the coefficient of coupling* is stated to be about 1 per cent. Is there not a slip in nomenclature here? The question of the future of the intervalve transformer to be used for reproduction of music appears to require concentrated attention in the direction of lower frequencies. If, instead of employing uniform frequency curves, the results are plotted on the pitch scale, one immediately realizes that the frequency of 250 cycles comes almost in the centre of the important part of the scale of audible frequencies. With frequencies above that limit we are able to obtain transformers with reasonably straight characteristics; but all those transformers show a tendency to fall off at a frequency below 250; and I think they must inevitably pass through zero at zero frequency. It is at the range of frequency between say 16 and 250 cycles that attention is now required, and I should like to obtain opinions as to whether we shall ever get a satisfactory coupling unit as a simple transformer or whether the final solution will not rather lie in the direction of a coupling component, using actual chokes and condensers the equivalent of which we are at present trying to concentrate into the windings of the transformer itself. I think it is possible that the development of such a coupling unit—it does not matter how complicated it is, provided it is put together in a box with just the input and output terminals accessible—will be necessary and more expedient in the very near future. In common with Mr. Phillips, I should like to hear the author's views on the subject of the breakdown of transformers. In this connection Fig. 19 shows one useful way out of the transformer breakdown difficulty by shifting the responsibility on to the choke, which is less expensive to replace; and in the case of a breakdown of the choke one can always use the transformer in its more usual circuit arrangement.

* Corrected for the *Journal*.

Mr. P. W. Willans (*in reply*): I should like to thank the members of the Wireless Section for the kind reception which they have given to the paper and for the remarks of appreciation of the work carried out. The main criticism which has been directed against the work as a whole is that the bridge method does not give a true estimate of the performance of an intervalve transformer under the conditions of operation, and I propose therefore to deal with this point first of all, in reply particularly to the criticisms of Mr. Turner and Mr. Thomas. Here I am very considerably helped by the remarks of Mr. Garton who has been working on a similar method. First of all as far as the measurement of the performance of transformers is concerned we must necessarily employ some standardized conditions, and there is no doubt that if we allow the use of a subsequent valve with an arbitrary impedance in its anode circuit the conditions are the reverse of standardized. We are then concerned not only with the capacity of this valve, which may be regarded as of small account in determining the characteristic (apart from the Miller effect), but we must also consider the magnification factor and resistance of the valve and the nature of the impedance included in its anode circuit. I much regret that the measurements which have been given in illustration of the Miller effect were not available in the advance copies of the paper, but I hope that they give a sufficiently good indication that the bridge method of measurement is quite equal to taking this into account should it be desired to do so; and the fact that the main part of the paper has been written without reference to this effect, and only in connection with the performance of transformers under conditions where it is suppressed, is merely due to the very reasonable desire to make comparisons of transformer characteristics and constants under unvarying conditions. I cannot put this point better than it has been put by Mr. Garton in the latter part of his remarks.

With regard to Mr. Turner's further comments, some of the points he raises have been dealt with in the text of the paper, in particular the question of the permeability of the iron under the conditions of operation. This I estimated as having a value between 200 and 300 (cf. page 1072, col. 2), and I note that Mr. Kirke and Mr. Garton both give values which substantially confirm my own. This permeability is of course the differential permeability at the points on the *B-H* characteristic corresponding to the value of the polarizing current under working conditions. For normal voltage-amplitudes this may be regarded as constant, though for high amplitudes at low frequencies there may be a deviation from this value, in general an increase. Mr. Garton has mentioned other types of iron, in particular nickel-iron alloys, and I can confirm the values of differential permeability which he gives, as also the question of expense.

With regard to the effective cross-section of iron, the work carried out does not give full information on this point, but it does give the practical information that the transformer can be regarded, between certain limits of frequency, as having a substantially constant

inductance at low flux densities. I would estimate these limits as between 250 and 1 000 cycles per second; at the higher frequencies the inductance may quite well fall off in value without this change being apparent from the transformer characteristics, since the inductive impedance is so very much higher than the capacitative impedance. For values below 250 cycles I have no measurements which are sufficiently reliable to give any indication. The leakage inductance of a transformer appears to rise slightly at the lower frequencies, but here its effect is not very great. From 1 000 cycles upwards it may be considered to have a constant value; but this is only natural, since one would expect the flux through the core to thread both windings and, in consequence, the leakage inductance to depend only upon the geometrical arrangement of the coils.

Mr. Turner's point regarding transformer losses has been dealt with on page 1074 of the paper. These are negligible in any transformer of good construction unless there are short-circuited turns in the windings.

In reply to Mr. Turner's criticisms regarding the symbols used, I have only apologies to offer. I assure him that I will endeavour to "think internationally" in future. I have modified the text of the paper so as to meet his criticisms as regards the definition of Z and any lack of clarity there may have been as to what was meant by "anode voltage." The leakage of the transformer is of course 1 per cent and not the "coefficient of coupling," although I should like to mention, in passing, that if $1 - k^2 = 0 \cdot 01$ the value of k will be $0 \cdot 995$.

In reply to Mr. Thomas's criticisms, I have already dealt with the use of the bridge in relation to the Miller effect. With regard to his criticism of the method of measurement, I cannot agree that the "backing-off" valve, which I assume is the valve B′ in Fig. 3, acts virtually as a shunt to the normal output valve. It is quite clear from the manner in which the bridge is used that at the point of balance the plates of the valves B and B′ are at steady potential in relation to their filaments and also, by virtue of the Wagner balance, in relation to earth. It would seem that, provided the Wagner principle is properly applied, there is no possibility whatever of induction from one grid to the other through the plates of the valves. The effect of the large amount of apparatus, e.g. batteries and the like, is admittedly very serious unless a proper Wagner balance is employed; I have tried to use the bridge without the Wagner arrangement and obtained extremely inconsistent results, which resemble those described by Mr. Thomas. I admit that if an impedance be inserted in the anode circuit of the output valve and no trouble be taken to balance the bridge in the manner described, the load on the transformer may vary enormously and all sorts of discordant results be obtained. Without further knowledge of the exact conditions of Mr. Thomas's measurements I cannot suggest any explanation for his results, but I can assure him that the amplification of transformers is so closely in agreement with theory that there is not the slightest chance of an error as serious as 25 per cent. I have made no actual comparisons with other methods but have placed reliance on this agreement with theory, and I suggest that, if a comparison between any two methods is being made, the bridge be set up in exactly the manner described and an attempt be made to measure the input and output voltages of the stage of amplification at the same time. I regret that my resources have not been sufficient to make a really good comparative test on this point, and it would be of interest if Mr. Thomas or any other worker who has similar resources at his disposal could make a really satisfactory comparison. At the same time I feel that there must certainly be something wrong in the tests which he has so far carried out, and I venture to suggest that some consideration of the points above outlined may result in an explanation of the discrepancies experienced.

Mr. Kirke's remarks regarding the work which he has carried out on line transformers are of the greatest interest. These transformers are employed in circuits which are characterized by the presence of a load on each winding, and under practical conditions their self-capacity is so low as to be negligible. The result is a great predominance of the virtual capacity term due to losses and leakage and, in consequence, a state of affairs where it is difficult to get adequate reproduction of the lower frequencies without a cut-off at the higher frequencies. Mr. Kirke's success in this respect is of course well known. There seems to be some slight confusion regarding the question of amplitude distortion in the series condenser circuit, as Mr. Kirke alludes to the variation of output impedance due to the condenser and transformer primary forming a series resonant circuit, which of course is the principle underlying the method whereby an accentuation of the lower frequencies is obtained. My contention was that if the input to the valve varied, the effective inductance also varied, and the anode circuit impedance in consequence became a function of the amplitude. Mr. Kirke appears to put this in other words by saying that the dynamic characteristic will vary considerably and so cause distortion. Such distortion would appear to me to be inevitable at some low frequency and, in view of the amplification rising to a high peak value in the series condenser circuit, I consider the latter is more prone to give variations in the dynamic characteristic than a simple transformer. This defect is not found in the reaction circuit described in the paper. Mr. Kirke's notes on the subject of rectifiers are of great interest; I have noticed that a condenser and leak in series with the grid of an amplifying valve produce quite a definite change in the amplification of the transformer following it. With regard to the filter-circuit question, I am afraid that this was dealt with in a very inadequate manner when the paper was read and I have therefore elaborated it somewhat in the Appendix. The point really is that the arrangement is strictly not a filter at all but only analogous to one, in that it is a device for producing a constant voltage across a given terminal impedance when the input impedance is a resistance of given value. The value of one-third is based entirely on theoretical considerations, as appears from the analysis given in the Appendix. Mr. Kirke notes the necessity for the adequate reproduction of really low frequency, and this point is also mentioned in Dr. Smith-Rose's criticisms. I have dealt with this question later in my reply.

In reply to Mr. Garton I am bound to say that I consider it advisable to have the high value of second resonance which was specified, as I believe that under these circumstances the transformers work better in combination with each other whether the neutrodyne method be used or not. If a neutrodyne connection is employed, low leakage inductance is essential in order to get adequate neutralization with valves of high magnification factor, and it is definitely possible to employ such valves without loss of quality. If no neutralization be used it is necessary to reduce the step-up ratio of the transformer, and in this case the effect of the reaction from a subsequent stage of amplification will be to reduce the extent of possible straight characteristic by steepening the drop of P. I feel very strongly that there is a necessity for a margin of straight characteristic over and above what might be regarded as the upper limit of practical audio frequency in order that there may be something in hand when the transformers are worked in association with each other. With the remainder of Mr. Garton's remarks I am in entire agreement, and the points he raises have already been dealt with.

Mr. Phillips's criticisms of the bridge method on the grounds of the difficulty of working it are, I think, unjustified. I admit that the arrangement looks somewhat terrifying in the form of a circuit diagram, but in practice it is readily possible to take, say, six observations of a transformer amplification curve in the space of 20 minutes or so, and the reduction of these results when reduced by a rule-of-thumb process is very speedy indeed. Furthermore, the possibility of extrapolating the results and of deducing what is going on in the circuits under consideration, to my mind far outweighs any preliminary difficulties in getting acquainted with the routine of working the apparatus. With regard to Mr. Phillips's suggested method, I share Dr. Smith-Rose's mistrust of the slide-back principle, particularly in view of the possible damping effect of grid current. I have used slide-back methods in the past and have found the observation of the " end point " an extremely difficult and nerve-racking matter, and it would seem barely worth while to place reliance on such a method now that the thermionic voltmeter has reached such a satisfactory state of development. A possible source of error in all methods of this kind may be worth mentioning, namely, that due either to bad wave-form of the input frequency or to the generation of harmonics in the circuit under test. The bridge method has the advantage of isolating one frequency in what is possibly the simplest of all manners. With regard to Mr. Phillips's question on the subject of transformer breakdowns, which are also alluded to by Dr. Smith-Rose, I fear that I have no useful information to give, though I believe that with the transformer under discussion a satisfactory method of impregnating the windings has been arrived at and breakdowns now no longer occur. Unfortunately, as I was no longer connected with this work when the trouble of breakdowns arose, I have not had any experience in this respect and can therefore make no useful contribution to the question.

In reply to Dr. Smith-Rose, the measurements down to 100 cycles per second are extrapolated, though I see no reason why the bridge method should not be applied to such frequencies if a vibration galvanometer is substituted for the telephones. I appreciate that we have to consider the effect of a loaded transformer, but I submit that the use of the neutrodyne renders the associated load practically negligible at the important audio frequencies, and that we may consider this combination just as well as any other in dealing with the transformer problem. Apart from the question of neutralizing, there is no question to my mind that a transformer which is good when unloaded is also good when loaded. The nomenclature as regards the coefficient of coupling was of course a slip and has been rectified for the *Journal*. Dr. Smith-Rose's remarks on the importance of low frequencies are of great interest, though as a result of comparisons between resistance and transformer amplifiers I would not agree that the frequencies below 250 cycles are of as great importance as the frequencies above this limit. I am considering now purely the æsthetic aspect of broadcast reproduction, and I can only explain this by the fact (for so it appears to me) that if we are enabled to reproduce all the harmonics of a given tone in an adequate manner we get psychologically a large measure of the effect of the fundamental note. I believe that experiments have established this to a remarkable degree. However, there is no doubt that the lower frequencies have great importance as far as naturalness of certain tones is concerned, and I quite admit that the transformer in question, in common with nearly all others, leaves a considerable amount to be desired in this respect. I believe, all the same, that there is great hope in the correct application of the low-frequency reaction principle to supplement the lower frequencies, on the lines of the circuit which has been described in the paper.

THEORY OF OVERLAPPING JOINTS.*

By Raymond M. Wilmotte, B.A.

[From the National Physical Laboratory.]

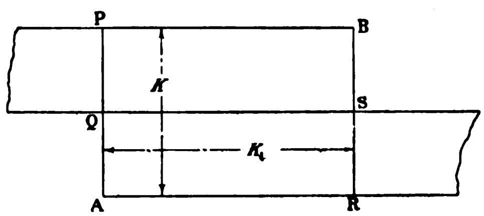
(*Paper received 4th March, 1926.*)

Summary.

Melsom and Booth have investigated experimentally the theory of overlapping joints, dividing the resistance of the joint into two parts: one representing the resistance due to the contact, and the other that due to the stream lines of the current at the joint. In the present paper the latter part is obtained theoretically in terms of elliptic functions. The result is expanded and leads to a very simple formula, with which the experimental results of Melsom and Booth are found to agree.

In a paper presented in 1920 to the Institution † S. W. Melsom and H. C. Booth described an experimental investigation of the efficiency of overlapping joints. They divided the resistance of a joint into two parts, one representing the resistance due to the stream lines of current at the joint and the other that due to the contact, and assumed that the two could be added arithmetically.

The second part cannot be estimated mathematically, but the first can be readily obtained and is reducible,



in practical cases, to a very simple formula. Melsom and Booth estimated the first part by cutting a piece of tinfoil to the shape of the joint and measuring the potential difference across the joint when a known current was flowing. They expressed the efficiency of the joint as the ratio of the potential difference across the joint to the potential difference across an equal length of one straight conductor. This they called σ. When the joint is infinitely long, σ obviously tends to the value $0 \cdot 5$.

The resistance of a rectangular conductor with any electrodes along the edge is readily obtained by Schwarz's transformation ‡ of conformal representation.

In the case of an overlapping joint, we shall obtain a lower limit to the resistance if we assume that PQ and RS (see diagram) are equipotentials. When the overlap is long compared with the thickness, as it invariably is in practice, this lower limit will be very nearly the true resistance required. Let $\frac{1}{2}K$ be the thickness of each conductor and K_1 be the length of the overlap; then it can be shown that the resistance of the joint is given by

$$2\sigma = \frac{KL_1}{K_1 L} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where L_1, L, are the complete elliptic functions of the second kind of modulus $\sqrt{(1-l^2)}$, l respectively, given by

$$l^2 = \tfrac{1}{2}[1 - \sqrt{(1-k^2)}]$$

and the complete elliptic functions of the second kind of modulus k, $\sqrt{(1-k^2)}$ are K, K_1 respectively.

In practice, $K_1 > K$, so that k and l will be small, and we can write

$$K = \tfrac{1}{2}\pi(1 + \tfrac{1}{4}k^2 + \ldots)$$

$$K_1 = (1 + \tfrac{1}{4}k^2 + \ldots)\log_e\left(\frac{4}{k}\right) - \frac{k^2}{4} + \ldots$$

These two equations give

$$k = 4x\,(1 - 4x^2 + \ldots)$$

where $x = e^{-\frac{1}{2}\pi\rho}$ and $K_1/K = \rho$

Therefore $l^2 = 4x^2(1 - 4x^2 + \ldots)$

and finally, expanding L and L_1 in terms of l, we have

$$2\sigma = 1 + \frac{2}{\pi\rho}\log_e 2 + \frac{2}{\pi}e^{-\pi\rho}$$

$$= 1 + \frac{0 \cdot 441}{\rho} + 0 \cdot 636e^{-\pi\rho} \quad . \quad . \quad . \quad (2)$$

The last term in this equation is small and can be neglected in practical cases.

In the following table the values of σ are given for various values of ρ, and are compared with the experimental values of Melsom and Booth.

2ρ	σ calculated	σ observed
1	1·01	1·10
2	0·72	0·74
3	0·65	0·63
4	0·61	0·59
5	0·58	0·56

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† *Journal I.E.E.*, 1922, vol. 60, p. 889.

‡ H. F. Moulton: *Proceedings of the Mathematical Society*, 1905, vol. 31, p. 104.

These values are obtained from equation (2), which is only approximate. Thus the true value of σ, calculated from Legendre's table for $2\rho = 1$, is $1 \cdot 12$, which is very close to the observed value. When $\rho > 1$, equation (2) will give a very close approximation.

When there is a contact resistance between the two conductors the lines of flow will be altered at the junction. This alteration increases with increasing contact resistance. The percentage error in assuming, as Melsom and Booth did, that the lines of flow were unaltered, will therefore not be large, for the effect of σ on the efficiency of the joint decreases as the contact resistance increases.

THE PRODUCTION OF FLICKER IN ELECTRIC LAMPS BY CYCLIC IRREGULARITY IN THE VOLTAGE.*

[REPORT (REF. Z/T22) RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.]

INTRODUCTION.

This investigation was undertaken at the Faraday House Testing Laboratory to ascertain the limits observable by the human eye of cyclic irregularity in the voltage of the supply to electric incandescent lamps.

An investigation has been carried out by K. Simons † which tends to show that the eye is most sensitive to flicker occurring with a periodicity of about 6 cycles per second. It is also shown that the percentage variation of light which can be detected by the eye decreases with large increase of intensity of illumination.

SCOPE OF RESEARCH.

The following was the scope of the proposed investigation :—

(*a*) Tests to be made with cyclic irregularity having a frequency of 0 to 15 cycles per second, and therefore covering the most sensitive region, as shown by previous investigators.

(*b*) It was suggested that the test be made with a d.c. supply, the voltage pulsation being superimposed either by means of an a.c. transformer or a crank-driven sliding-contact rheostat.

(*c*) A test to be made in the first place with an ordinary 50-watt 200-volt metal-filament lamp.

(*d*) It would be necessary to establish provisionally a limit of flicker. The limit may vary with the investigator, and it would be desirable to test two or three observers to ascertain what extent of agreement there would be as to the point at which the flicker disappeared. If there were no clear limit, it would be necessary to adopt an arbitrary limit, as, for example, a negligible (though observable) amount of flicker produced by a certain percentage voltage fluctuation at a given frequency with, say, the above lamp, and to make a direct comparison of this degree of flicker with that obtained under other conditions.

(*e*) As the observable flicker varies with the illumination, it was suggested that flicker be observed on a white surface with clear black print illuminated by bringing the lamp within, say, 18 in. of the surface, as might be done by a draughtsman.

(*f*) The same investigation should be repeated in sufficient detail for purposes of comparison with :—

(i) a low-voltage thick-filament lamp,
(ii) a high-voltage gas-filled lamp.

METHOD OF SUPERIMPOSING VOLTAGE PULSATIONS.

The lamp under test was run from a steady d.c. supply, and the voltage pulsations were superimposed by two methods in turn, namely :—

(i) by means of an a.c. transformer, and
(ii) by means of a crank-driven sliding-contact resistance.

Owing to the great difficulty of measuring accurately at very low frequencies the small a.c. voltages required, the first method was discarded after a considerable amount of unsuccessful experimenting.

The second method, using a crank-driven rheostat, was more successful and was finally adopted as being the more practical. All the results given were obtained by this method.

DESCRIPTION OF APPARATUS.

An ordinary sliding-contact resistance was so arranged that the slider could be oscillated backwards and forwords at any frequency between 0 and 15 complete oscillations per second by means of a connecting rod and crank on the end of a motor shaft. In order to make the

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† *Elektrotechnische Zeitschrift*, 1917 vol. 38, pp. 453, 465 and 474.

motion of the slides approximately simple harmonic, the length of the connecting rod was made about 6 times the length of the stroke. The rubbing-contact springs or brushes were very stiff laterally (i.e. in the direction of motion of the slides) so that distortion due to large accelerations at the higher frequencies was reduced to a minimum.

The Circuit.

It was desirable to be able to vary the superimposed fluctuating voltage continuously without causing any appreciable change in the average voltage applied to the lamp under test, and for this purpose the circuit shown in Fig. 1 was used. The crank-driven resistance

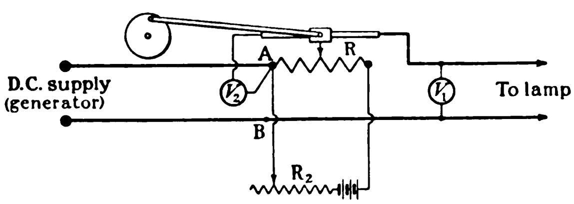


Fig. 1.—Diagram of connections.

R was connected through the slides in series with the lamp in the ordinary way. Across the ends of the resistance R was shunted an auxiliary circuit as shown, thus giving a potentiometer effect. The current through the auxiliary circuit could be varied at will, thus giving any desired voltage pulsation at R. The whole of the apparatus except the lamp and the regulating resistance R_2 was placed outside the dark room.

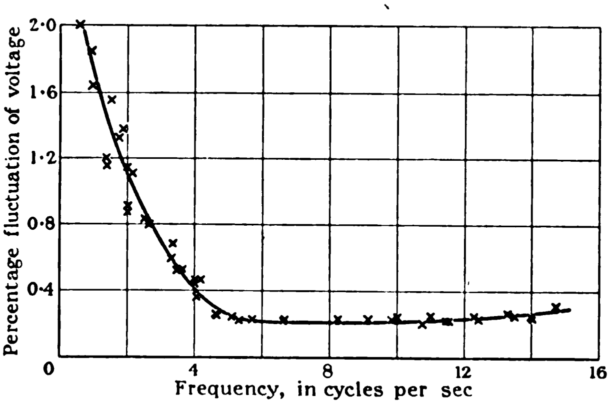

Fig. 2.—Relation between frequency and percentage fluctuation of voltage for negligible amount of flicker. 30-watt, 200-volt vacuum lamp.

While an observation was being made an assistant kept the average voltage V_1 constant and determined the speed of the motor. The frequency was kept constant and the voltage pulsations were varied in amplitude by the observer himself, and when he had found the position on R_2 which gave a limit of visible flicker the motor was stopped and the two values of V_2 read, with the slider of R at each end of the stroke respectively. The total voltage pulsation is given by the difference of these two readings. The main supply to the lamps was taken from a d.c. generator, and the voltage was varied by operating on the field so that the resistance of the circuit could be kept low. No voltage variation could be detected across A B on moving the slider of R.

The lamp under test was in each case placed 18 in. from a sheet of white paper 20 in. × 26 in. containing black print. The eye seemed more sensitive to flicker and the limit was more definite when the illuminated

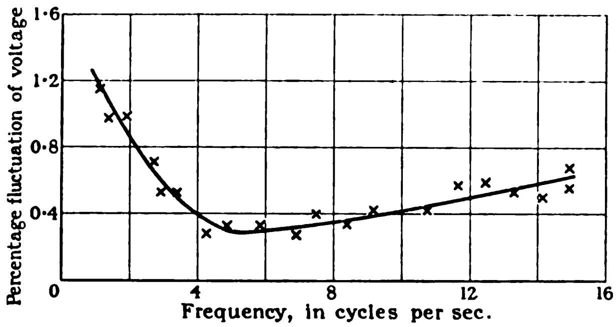

Fig. 3.—Relation between frequency and percentage fluctuation of voltage for negligible amount of flicker. 30-watt, 50-volt vacuum lamp.

surface was viewed from a little distance. In all cases the screen was observed from a distance of 6 ft. The direct rays of the light from the lamps were shaded from the face of the observer.

As would be expected, it was noticed that when the observer looked at the middle of the screen the flicker disappeared there some time before it disappeared at the corners; then, again, on looking at one corner of the screen, although no flicker was noticeable there, it could be easily discerned, by indirect vision, on the centre

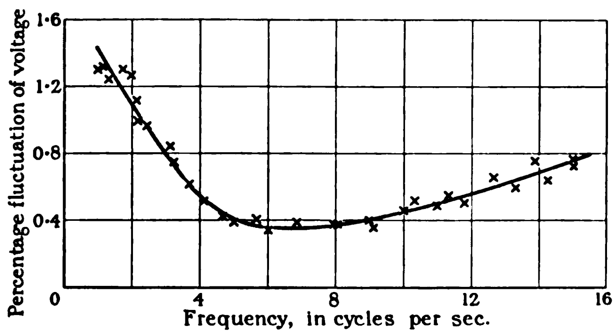

Fig. 4.—Relation between frequency and percentage fluctuation of voltage for negligible amount of flicker. 100-watt, 200-volt gas-filled lamp

and other parts of the screen. In these observations the screen was viewed in the middle, and the amplitude of the voltage pulsations was gradually reduced until the flicker was only just noticeable on the edges and corners of the screen. In determining this limit the degree of uncertainty seemed to vary considerably with the frequency and the type of lamp. In some cases the limit was quite sharply defined and two observers agreed remarkably closely and consistently. On the other hand, especially at frequencies below 3 cycles per second, it

was found most difficult to establish a limit; in the curves of Figs. 2, 3 and 4 all the points have been shown and the degree of uncertainty can be judged.

Tests were first carried out on an ordinary vacuum

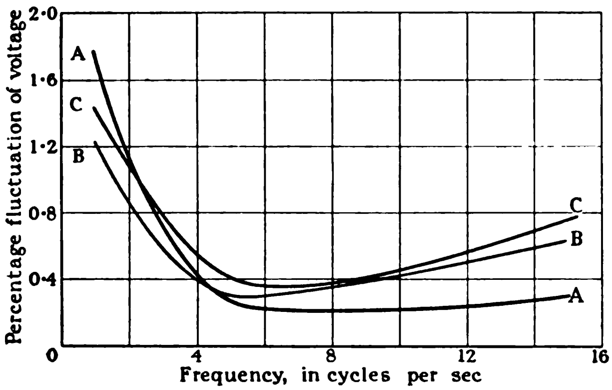

FIG. 5.—Relation between frequency and percentage fluctuation of voltage for negligible amount of flicker.

Curve A.—30-watt, 200-volt vacuum lamp.
Curve B.—30-watt, 50-volt vacuum lamp.
Curve C.—100-watt, 200-volt gas-filled lamp.

lamp rated at 30 watts and 200 volts, and in Fig. 2 a curve is given showing the relation between the frequency and total percentage voltage fluctuation for a negligible amount of flicker. Figs. 3 and 4 give the same relations for a 30-watt 50-volt vacuum lamp and a 100-watt 200-volt gas-filled lamp respectively.

In all cases the total fluctuation is given as a percentage of the average pressure applied to the lamp, viz. :—

$$\text{Percentage fluctuation} = \frac{\text{Max. volts} - \text{Min. volts}}{\text{Average volts}} \times 100$$

In order to facilitate comparison the three curves of Figs. 2, 3, and 4 have been redrawn to the same scale on one sheet (Fig. 5), but in this case the points have been omitted.

CONCLUSIONS.

The investigation, as far as it goes, confirms Simon's conclusion that the eye is most sensitive to flicker at a periodicity of about 6 cycles per second.

Between the limits of frequency of 6 to 10 cycles per second, which is within the limits of speed of gas engines, it will be observed that the percentage fluctuation of voltage should not be more than 0·2 per cent, equivalent to a cyclic irregularity of 1/500.

It has been contended in some quarters that the limit laid down in the present B.E.A.M.A. Standardization Rules of 1/150 for such engines is unnecessarily exacting, but this Report furnishes no support to the contention. In the light of previous work which showed a logarithmic relationship between the percentage variation of light which can be detected by the eye and the intensity of illumination, it is seen that the result obtained would not have been different in character with any reasonable reduction of the illumination of the observed surface, and, whilst the investigators have deliberately taken an unfavourable case for test, the conditions are nevertheless not abnormal.

THE JUBILEE OF THE TELEPHONE.

The Institution celebrated the Jubilee of the Telephone on Thursday, the 24th June, 1926, the nearest convenient date to the anniversary of its submission to the International Jury by its inventor, Alexander Graham Bell, at the Centennial Exhibition at Philadelphia, U.S.A., on the 25th June, 1876.

Luncheon.

The proceedings were inaugurated by a luncheon at the Hotel Cecil, London, which was attended by, among others :—Mr. R. A. Chattock (*President*) in the chair, The Rt. Hon. Sir William Mitchell-Thomson, Bt., K.B.E., M.P. (*Postmaster-General*), The Rt. Hon. Lord Gainford, P.C., D.L., Sir Ernest Rutherford, O.M., F.R.S. (*President, Royal Society*), Sir Oliver Lodge, D.Sc., F.R.S. (*Hon. Member*), Sir William Henry Ellis, G.B.E. (*President, Institution of Civil Engineers*), Sir James Devonshire, K.B.E. (*Vice-President*), Sir E. Manville, Sir Alexander Roger, Mr. B. O. Anson, Mr. Ll. B. Atkinson (*Past-President*), Major B. Binyon, O.B.E., Mr. A. C. Brown, Col. C. B. Clay, Mr. W. W. Cook, Mr. H. Cooper, Mr. W. J. Crampton, Col. R. E. B. Crompton, C.B. (*Hon. Member and Past-President*), Mr. W. M. Crowe, Mr. W. Cruickshank, Mr. R. A. Dalzell, C.B., C.B.E. (*Director of Telegraphs and Telephones, G.P.O.*), Dr. W. H. Eccles, F.R.S., Lieut.-Col. K. Edgcumbe (*Vice-President*), Mr. C. F. Elwell, Prof. J. A. Fleming, M.A., D.Sc., F.R.S. (*Hon. Member*), Prof. C. L. Fortescue, O.B.E., M.A. (*Member of Council*), Mr. R. Grierson (*Member of Council*), Mr. H. H. Harrison (*Past-Chairman, Mersey and North Wales Centre*), Major E. O. Henrici, R.E. (ret.) (*Member of Council*), Mr. J. S. Highfield (*Past-President*), Mr. J. H. Holmes, Mr. F. Hope-Jones, Mr. J. H. Jeans, M.A., D.Sc., F.R.S. (*Secretary, Royal Society*), Mr. W. Judd, Mr. J. E. Kingsbury, Mr. F. Laidlaw, Major A. G. Lee, M.C., Mr. T. D. Lockwood, Col. H. G. Lyons, D.Sc., F.R.S. (*Director, Science Museum*), Senatore G. Marconi, G.C.V.O., LL.D., D.Sc., Mr. W. M. Mordey (*Past-President*), Mr. S. R. Mullard, Lieut.-Col. W. A. J. O'Meara, C.M.G. (*Past Engineer-in-Chief, G.P.O.*), Mr. A. Page (*Vice-President*), Mr. W. H. Patchell (*Past-President, Institution of Mechanical Engineers*), Mr. R. W. Paul (*Member of Council*), Mr. G. F. L. Preston, C.B.E. (*Past-Controller, London Telephone Service*), Mr. J. C. W. Reith, Mr. G. Mure Ritchie, Mr. E. S. Ritter, Dr. Alex. Russell, M.A., LL.D., F.R.S. (*Past-President*), Mr. E. H. Shaughnessy, O.B.E. (*Member of Council*), Mr. Dane Sinclair, Mr. Roger T. Smith (*Past-President*), Mr. C. P. Sparks, C.B.E. (*Past-President*), Mr. F. Tandy, Mr. W. J. Thorrowgood, Mr. J. M. G. Trezise, Mr. W. A. Valentine (*Controller, London Telephone Service*), Mr. H. Laws Webb, Mr. W. B. Woodhouse (*Past-President*), and Mr. P. F. Rowell (*Secretary*).

After the Loyal Toasts had been duly honoured,

The President (Mr. R. A. Chattock) said :—" As members of the Institution, we celebrate to-day the Jubilee of that remarkable invention the telephone, which was born 50 years ago and, in the intervening period, has transformed the daily life of all civilized peoples. Alexander Graham Bell, a native of Edinburgh, but at the time of his invention a citizen of the United States, succeeded in devising instruments for the electrical transmission of speech, and in March, 1876, was granted a patent which was judicially pronounced as introducing a new art to the world. Bell's success, where so many others had failed, must be largely attributed to his environment. His interest in speech and the analysis of speech sounds arose from his association in the work of his father, who was a teacher of elocution. His electrical studies were undertaken primarily as a means of solving some of his acoustic problems. Together they resulted in designs for multiple telegraphy and eventually the telephone itself. The telephone, as a development of telegraphy, naturally aroused the greatest interest in our Institution, which was then the Society of Telegraph Engineers, and amongst our most valued records we count the paper read by Bell himself before the Institution on the 31st October, 1877. From this paper can be seen how Bell realized that before transmission and reproduction of speech could be achieved it was necessary to produce electrically the equivalent of aerial sound waves. This was Bell's primary discovery, and it was its application into instrumental form which constituted the invention. Once the transmission of speech was proved to be possible, subsequent developments were in the nature of improvements and of secondary value. There have been many developments, and the names of Edison and Elisha Gray at once suggest themselves in this connection. I propose, however, to refer to only one development, namely, that due to one of our members, Prof. Hughes, whose discovery of the microphonic effect was immediately applied to telephonic purposes and, as the microphone transmitter, has played so great a part in telephonic development. Hughes's work in this and many other lines is recorded in our *Journal*, as are many of the subsequent developments in the telephone itself and its allied appliances. To-day we pay homage to Bell's memory as one who was not only an inventor but also a discoverer, and whose application of his discovery to the useful arts has made the world so greatly his debtor. We could not have our celebration of this Jubilee either on the anniversary of the first telephonic conversation or on that of the acceptance of the patent, but to-day is as near as we have been able to arrange to a day fraught with great importance to the new instrument and not without its interest to ourselves, for it was on the 25th June, 1876, that Lord Kelvin, then Sir William Thomson, in his capacity as a juror at the Philadelphia Exhibition, had this new invention submitted to his notice. He realized at once its remarkable

nature and its possible utility. Undeveloped as the instrument then was, he appreciated its essentials, and there and then declared that, before long, friends would whisper their secrets over the electric wire. The enthusiasm which the telephone aroused in Sir William Thomson found immediate expression, and was continued throughout his life. His encouragement was of great value to Bell and did much, I think, to promote the development of telephony, for until that day very few, if any, other than Bell himself recognized the potentialities of the new instrument. That day the telephone was introduced to a larger world. It was only an instrument, but an instrument hitherto believed impossible of attainment—an instrument that talked. That instrument remains to-day almost identical in form with the original invention. Bell also conceived that interchange of talks which has since been realized as a telephone exchange. I have no toast to propose, and therefore there will be no responder to my remarks, but I am going to ask the Postmaster-General, as the head of the Post Office which is responsible for our telephone service and our telephonic development, to address us. No one realizes more clearly than Sir William Mitchell-Thomson the value of the telephone service to the community, or its great importance as an aid to industrial efficiency. I have alluded to the extreme simplicity of the telephone as an instrument. On the other hand, it is impossible to exaggerate the complexity of that which forms a telephone system as a whole, and the skill which is called for in its personnel and management, and we welcome the Postmaster-General amongst us, not only for himself, but also as the head of a highly-trained organization undertaking national work of vast importance."

Sir William Mitchell-Thomson, Bart., K.B.E., M.P. (*Postmaster-General*) said: "I have to thank you and the President for the honour which you have done me in inviting me to be here to-day to take part in this auspicious celebration. I have no intention of anticipating an address which Sir Oliver Lodge is to deliver later in the day, but at the same time I could not help reflecting, while the President was speaking, that it is perhaps a coincidence that it should fall to another native of Edinburgh to be present in an official capacity along with his officers to celebrate the Jubilee of the Telephone. I am glad to be here as an outward and visible sign of the interest which the Post Office takes in these celebrations. We have been glad to do what we could by lending apparatus for exhibition purposes. In the Science Museum will be seen the model of the first Bell telephone and also an illustrative practical working model of the very latest type of automatic exchange. When we look from one to the other I confess that although, as the President said, the instrument remains in essentials the same, there is an amazing technical growth. I sometimes think, in looking back over the last half century, that the telephone deserves to be ranked among the greatest contributions, if not the greatest, of science to industry. It is hardly too much to say that the telephone has now become a practical necessity of civilized life. In this country, perhaps, we have not got quite as much of that practical necessity as I should like to see and hope to see, but we are getting on. Last year we installed as many telephones as were installed during the first 20 years of development. At the present moment there are about 1 430 000 telephones in the country, and the number of effective calls for last year was over 1 000 million. We are pushing on with the development of the underground trunk system and also with the development of rural telephones generally. In the last three years we have had something like 800 rural telephone exchanges. This Jubilee year of the telephone coincides with a number of interesting events in connection with telephone development. In the first place it will, I hope, coincide with the installation and completion of the first large automatic exchanges. It will, in the second place, coincide with a deliberate and co-ordinated effort to improve international European telephone facilities generally. At this moment—and that is the reason why the Chief Engineer of the Post Office cannot be here to-day—a conference is being held in Paris for that purpose.* There has just been completed a new submarine cable to Holland with 12 speech channels, which will bring the cities of Germany into complete telephonic touch with this country. Later in the year a new cable is being laid to France with 21 speech channels, and a similar one later to Belgium. The third event—and it is a great event—in this Jubilee year is that, for the first time, our experiments have reached such a stage that ordinary two-way transatlantic telephony has come well within sight. For the moment our experimental work, owing to the coal shortage, has had to be suspended, but we are taking part now in the birth of a great new branch of the science of telephony and I hope that, when our present difficulties in the coal industry are at an end, we shall be able to resume those experiments and bring them to a successful conclusion. I said a moment ago that we were more backward in this country in telephone development than I liked to see. It is not altogether our fault. The telephone in this country had a somewhat chequered career at the start. Then, just in the most critical stage of its development when the nation had taken it over, there came the great war which put an end to the reconstruction that was about to take place and left us with a vast legacy of arrears which we are only just overtaking. I think the efforts which the Post Office is making to improve and develop the telephone system are being appreciated by the community. I am perfectly certain that before long the growth of telephone development in this country will show that the public realize and appreciate the value of improved service. At all events, in that very lively hope I, and all my officers, work, and it is because we believe in the telephone and its advantages and in the possibility of its development, and because we want to see this country taking a place amongst the great telephone-using nations in the world—a place that she

* I learn since that I ought to have given credit for this effort to the Institution of Electrical Engineers, for it was in the Presidential Address to the Institution delivered on the 2nd November, 1923, that attention was called to the urgent necessity of treating international telephony on a unified basis, and of three definite proposals then made, one was that the operating telephone authorities should form an association for this and other matters, and that an early International Conference should be held to initiate the matter.

In March, 1923, an international meeting took place in Paris, at the invitation of the French Government, expressly to consider these proposals, and the existing Comité Consultatif International is the direct and immediate descendant of that meeting. W. M.-T.

ought to take—that I am particularly glad to be here to-day."

Presentation of Faraday Medal.

At 2.45 p.m. in the Lecture Theatre of the Institution, the Faraday Medal was presented to Col. R. E. Crompton, C.B.

The President: On behalf of the Institution I am going to ask Colonel Crompton to accept the Faraday Medal as a mark of our appreciation of his life-long work in the interest of electrical engineering. It is the particular wish of the Council that there should be no suggestion of any intrinsic value in the Medal itself; it is made of bronze and not of gold; it owes its value first of all to the fact that it was instituted to commemorate the foundation of the Institution, and secondly that it is offered for world-wide services to electrical science and engineering. The Council hope that, as time proceeds, the importance of the Medal will be enhanced by the names of its illustrious holders. I will ask Mr. Woodhouse to say a few words.

Mr. W. B. Woodhouse: Every now and then in the field of human endeavour we find a new worker, a man of genius who not only throws a light on the dark places in which he works himself to help progress but who, by his example and by his great and striking personality, encourages all other workers in the field. When the spark of genius which illuminates new problems is accompanied by the persistent and continuous energy necessary to bring the results into the field of practical use, then we have indeed an exceptional type of man. We are here to-day to pay honour to Col. Crompton, a man of that very striking type. The country to which such a man belongs must be proud of him. The age in which such a man appears is blessed in having his energies turned to works for the improvement of methods and for the help of mankind, and those who work in the same field are greatly privileged to know him. Col. Crompton combines many great qualities—the spirit of invention which begins a thing, the diligence and energy and the capacity for taking pains by which the work can be brought into the practical field, and, perhaps the rarest of all in a man with scientific attainments, the common sense and the judgment by which he can make these things commercial and available in the everyday affairs of life. I do not propose to review the work that Col. Crompton has done, because it is well known and is recorded in our *Journal* and in the proceedings of other learned societies. I think, however, that we must not forget, as electrical engineers, that Col. Crompton is distinguished not only in our own particular field but in many other fields as well. He became a Member of this Institution in 1877, was President first in 1895 and again in 1908, and in 1923 was made an Honorary Member. We have heard to-day something of the wonderful progress of the telephone, but I think the progress of the electricity supply industry has been in its way just as wonderful, and we must remember that a very large part of that progress has been due to the work of Col. Crompton. In the very earliest days he devoted his attention to the use and development of electricity for lighting and, later, for other purposes. He invented one of the most successful arc lamps, and subsequently modified entirely the design of the dynamo of that day. I think we may say that he improved everything which he touched. He invented the term "load factor" and immediately proceeded to improve it. He invented the potentiometer, which enabled us accurately to measure things that were formerly guessed at. Throughout he has combined highly technical, constructional and commercial abilities. He was the first, I think, to teach us how to keep our costs in the electricity supply industry. In every way, therefore, we are very greatly indebted to Col. Crompton. Apart from this special work, we must recognize the great work which he has done in standardization and in bringing the nations together in this matter. He has not only been a loyal son of his own country, but has taken a wide international view of the possibilities of electricity, a view from which I am sure we have all benefited. I have spoken of his attainments; I cannot conclude without some reference to the man himself. His amazing energy, his hatred of humbug, his complete forthrightness in all the matters with which he deals, one must admire very greatly. Behind that we have the most delightful and kindly personality, and I feel, as I am sure everyone does who has come in contact with him, how greatly honoured we are to have Col. Crompton as a member of our profession and a Member of our Institution.

Mr. Roger T. Smith: I met Col. Crompton at the first Electrical Exhibition in Paris in 1881, when he was an exhibitor and I a schoolboy. To me, 45 years ago, Col. Crompton seemed very grown up, but ever since that time he has become younger and younger. Perhaps Faraday would be content to know that his Institution Medal should go to a man like Col. Crompton. Of all his multitudinous activities in the electrical industry, probably the one Col. Crompton would like most to connect with this Medal is his interest in the International Electrotechnical Commission. That body was formed in order that electrical machinery and plant made in different countries should be bought and sold on a fair basis, manufacturers and users in five continents agreeing through a method of standardization that things which were called by the same name should really be the same things. Col. Crompton has been recognized throughout these five continents as the father of this Commission. Considering what happens in diplomacy and politics, it is no small achievement that so much agreement in standardization should have resulted from the efforts of the Commission. This agreement is bound by no law and can impose no penalties, but succeeds by the exercise of good will. Col. Crompton has worked, first to create that good will, and secondly to foster it, and I feel sure that the whole of this audience is delighted to offer their hearty congratulations to him on this token of the regard and esteem in which he is held by his brother electrical engineers.

The President then presented, in the name of the Institution, the Faraday Medal to Col. Crompton.

Col. R. E. B. Crompton: It is very difficult for me to reply in any suitable terms to what has been said about me. It is, as applied to me personally, wholly or, at any rate, partially untrue. I have only been one of a band of workers, and, if I have any merit at all,

it has been that I have been like the captain of the cricket eleven—I have chosen good men, and always praised the good men when they did a good thing. The result was progress of a kind which has been useful. In speaking of good men I must speak of one of the best of all—a good woman—that was my wife. When, in those days which Ferranti and I so well remember, we were pushing the idea of electricity supply, we were looked upon as amiable lunatics, or described by the word "cranks," a crank being always a term of opprobrium, and it was very difficult to get the right people to listen to us. My wife, with the splendid instinct of women, had found out who were the people likely to be interested and who were the people likely to help, and she brought them together and succeeded in bringing other people to meet them, so that we had a party of friends who supported us with money and sympathy and, what is more, with a belief in our future, and it was to that band of friends, largely engineered by my wife, that the advance of the electrical supply industry, at all events in London, was chiefly due. So many of them are dead; Spottiswoode, Moulton, Willans, Macfarlane Gray, Lord Kelvin, Rankine, James Thomson—all gone. When I think how much I owe to those great men, and how much I owe to my wife's advice not to proceed solely on my own ideas, but to talk over with others the knotty problems which presented themselves, I feel I have been a very lucky man in taking that advice by which the world has benefited. Something has been said about our international work, and I agree that the last 20 years of this work has been a great pleasure to me. It must be the right thing to get at the best thoughts of other countries as well as of our own, and not be so conceited as to think that we in England are the only people in the world; we have had to find out who were the best people in each country, to bring them together, and get their thoughts. Even so, those who have worked with us will say that we have triumphed, for England is still looked upon as the clear-thinking country where ideas are worked out logically, practically, and usefully, and I think I may correctly say that we are still preserving the position of being the centre of the world of electrical thought. It is very difficult, after the eloquent things that have been said by others, to thank you sufficiently, but I am so deeply touched that I cannot say more.

Lecture on the Telephone.

After the presentation of the Faraday Medal, Sir Oliver Lodge gave a lecture on "The History and Development of the Telephone." (See page 1098).

Mr. J. E. Kingsbury, in proposing a vote of thanks to the lecturer, said :—"In this audience there are those who have followed the development of the telephone over the period referred to by Sir Oliver Lodge, and there are those to whom the subject is in the nature of a novelty, but whether they be experts or whether they take a simple interest in the subject, one and all have found inspiration and instruction from the lecture. It is 50 years since the telephone was invented, and this is its Jubilee, and yet even during this year I have seen many references to other inventors of the telephone, the assumption being that Bell had introduced or improved upon something which had previously existed. Sir Oliver Lodge has made it clear, and I think it is desirable that it should be more widely known, that the telephone was invented by Alexander Graham Bell and that he owed nothing to those who had preceded him or to his contemporaries. He had, of course, the benefit of those researches and investigations in pure science which inevitably lead sooner or later to some practical application for the benefit of mankind. Such information he had in common with his contemporaries, together with some knowledge of the principles of telegraphic transmission. But no contemporary was so equipped as Bell was to comprehend the importance of physical discoveries in acoustics, to realize the methods by which they could be applied for speech transmission, and to apply them. The Institution, and the Council, are to be congratulated on organizing this celebration. Bell's memory ought to be kept green by such commemorations as this. The President, earlier in the day, called attention to Lord Kelvin's appreciation of the telephone. I think Lord Kelvin's prompt and enthusiastic appreciation of the telephone did a great deal to promote its practical development—and however great an invention may be, if it be not practically developed and widely used, it is but a talent buried. The telephone received a stimulus from Lord Kelvin, and I believe that the development and applications of the telephone and its wider use for the benefit of mankind will receive a further stimulus from the lecture of Sir Oliver Lodge. Fifty years hence when in this, or perhaps some other even more imposing building, the Institution celebrates the Centenary of the Telephone, it would not be at all surprising if the lecturer of the period harked back to this day and pointed out how the application of the telephone to the uses of mankind was stimulated by the address of Sir Oliver Lodge."

Prof. J. A. Fleming, in seconding the vote of thanks, said :—"It is perhaps not altogether inappropriate that I should be asked to thank Sir Oliver Lodge for his lecture, because our scientific acquaintance with one another goes back more than 50 years, to a time when we were fellow-students together in the laboratory of Sir Edward Frankland. I was also a fellow-student of Alexander Graham Bell at University College. It is not generally known that the father of the inventor, Mr. Melville Bell, was a lecturer on elocution at University College, London, between 1866 and 1870, and it was there that he developed some of his remarkable work on lip-reading for the deaf. His brilliant son was thus early introduced to the study of phonetics and acoustics. In 1870 Mr. Bell, senior, left England for Canada, taking Alexander with him, and there the beginnings of his great invention were laid. In 1878 Bell came back to London to assist in the establishment of the first telephone company in London and the first early rudimentary exchange. By that time Edison had come into the field with his carbon transmitter and his curious chalk-cylinder receiver, which required to be turned by a handle like a grindstone. The Edison Company was established at 11 Queen Victoria Street, and the Bell Company in Coleman Street. The Bell Company had acquired the rights of the Blake carbon transmitter, and litigation was pending between the

two companies on the subject of the carbon transmitter. The strife was interrupted by the Post Office threatening to attack them both, under the Telegraph Acts of 1868 and 1869, and they had to turn their attention from one another to the Post Office. That celebrated case came on in 1880 and was tried before Mr. Justice Stephen and Baron Pollock—"The Attorney-General *v.* The Edison Telephone Company of London." An army of experts were engaged on both sides, many of whom were Past-Presidents of this Institution, and I think I am the only survivor of that group of experts. That case was settled in favour of the Government, and after that the telephone companies agreed to join together and form the United Telephone Co. It is remarkable how closely the development of the telephone is connected with this Institution. The modern transmitter is more a development of the Hughes microphone than Edison's transmitter, and the Bell receiver remains to-day almost what it was when he conceived it. Therefore the modern telephone system is closely associated with the names of Bell and Hughes. Many present will remember the charming personality of Prof. Hughes, at one time President of this Institution, a great genius and a great inventor. He was born in Great Britain and educated at Edinburgh and received his college education in London, retaining his interest in England to the end of his life. I have much pleasure in seconding the vote of thanks to Sir Oliver Lodge."

The vote of thanks was then carried with acclamation and Sir Oliver Lodge briefly replied.

Annual Conversazione.

At the Annual Conversazione of the Institution held in the evening of the same day at the Science Museum, South Kensington, which was attended by over 1 800 persons, there was shown a very complete exhibit of telephonic apparatus, including specimens of the instrument in all its stages. The exhibit was arranged by engineers of the General Post Office by kind permission of the Engineer-in-Chief, Colonel T. F. Purves, O.B.E.

THE HISTORY AND DEVELOPMENT OF THE TELEPHONE.

By SIR OLIVER LODGE, D.Sc., F.R.S., Honorary Member.

(Lecture delivered before THE INSTITUTION, *24th June,* 1926, *on the occasion of the Jubilee of the Telephone.)*

The majority of mankind deal with material objects, and seldom are concerned with electricity and magnetism, except in the form of completed apparatus designed and constructed for practical use. Their only touch with the ether is through the eye, and that again only tells us about the material objects which have either emitted or scattered the light. Light primarily tells us nothing about itself, nothing about its electromagnetic constitution, and still less about the ether which conveys it.

With matter we are at home, for our bodies are composed of it, while everything about electricity and magnetism has to be inferred from their effects on matter. An electric current can be appreciated as heat, or as the deflection of a galvanometer needle, or as an unpleasant shock. Mankind's first acquaintance with electricity was in the thunderstorm. We only learnt about magnetism because the earth happened to be a magnet. For generations even civilized man knew nothing about these etherial manifestations, and only began to make serious metrical experiments on them in the 19th century. Those phenomena still feel rather aloof from practical life, though it is true that in the 20th century their applications have become numerous. Consequently, when the serious study of electrical phenomena was begun, discoveries were made in a fast and furious manner, and anyone who worked with even simple apparatus of that novel kind might hit upon something new to science.

The articulating telephone is an instrument of absurd simplicity. It was invented by one who was no professed electrician, who was not really learned in physical science, but was interested mainly in introducing precision and clear intelligibility into human speech. Most of us, in talking, slur over words in a careless and incomplete and barely intelligible manner. Clear utterance was never the strong point of the pulpit, though it used to be prevalent on the stage. Even that can hardly be said now: actors are liable to say their parts in a manner which cannot be followed by a foreigner or by the partially deaf: they talk in what is considered a natural way, the way that people talk in ordinary life, a way which is not really admirable.

Graham Bell's own articulation was of the most precise character: his manner of speech was a specially noticeable feature of his lectures, when he came over to England in the year 1877, and excited the admiration of us early members of the Physical Society by his clear enunciation. He had been concerned with the training of the deaf and dumb; he had married, so I understood, a deaf and dumb wife; and had devoted himself to the accurate production of human speech, whether by his own lips and larynx or through its reproduction by instrumental means. He once said, so I am told, that it was fortunate that he was not a scientifically trained physicist; for if he had been he would probably have known (or thought he knew) that an articulating machine of a simple character was an impossibility.

The instruments he had primarily and essentially to deal with, were the human voice at one end and the human ear at the other; and he realized that if one of these was defective the other must be made still more precise and accurate. Thus the telephone arose from a study of articulation. This study he must have inherited from his father, Alexander Melville Bell, the author of a book called "Visible Speech," and other works relating to pronunciation, whose whole life had been employed in teaching people to speak. Clerk Maxwell amusingly said:—

> "He brought the art to such perfection that, though a Scotchman, he taught himself in six months to speak English, and I regret extremely that when I had the opportunity in Edinburgh I did not take lessons from him."

Mr. Melville Bell had made a complete analysis and classification of all the sounds capable of being uttered by the human voice, from the Zulu "clicks" to coughing and sneezing, and had embodied his results in a system of symbols, not alphabetical symbols, but founded on the different configurations of the organs of speech: and a test made by Mr. Alexander J. Ellis, author of "The Essentials of Phonetics," demonstrated the value of Melville Bell's system. His son, inventor of the telephone, was thus prepared by early training in the practical analysis of the elements of speech, and applied his father's system in the Boston School for the Deaf and Dumb; where the results were so successful that, as Clerk Maxwell says, they were not only the most valuable testimonial to his father's system, but an honour which the inventor of the telephone may well consider as the highest he has attained.

Talking machines had been invented before, but they were fearfully complicated—special arrangements for producing vowel sounds (which in our own day have been developed so successfully by Sir Richard Paget); other devices for the explosive noises of consonants; escape of air for sibilants; a toothed wheel for the rolling r's; and so on. By skilled manipulation of a keyboard it was thus possible to make a rough imitation of speech and to utter a few sentences.

Graham Bell's instrument did not aim at thus producing speech *de novo*. It took the sounds emanating from the human voice, and sought to reproduce them at a distance by electrical means; so that at any,

even great, distances, aerial vibrations could be reproduced and interpreted by the human ear, after the same fashion as the original aerial vibrations could be interpreted by an ear close to. The way in which he ultimately found that this could be accomplished was of surpassing and surprising simplicity; and if asked suddenly what was the simplest and greatest invention of the 19th century I should be disposed to say the telephone, for it has not only had its wide effect on extending human intercourse, it has put into the hands of experimenters an instrument of great value. It has revolutionized the detection of minute currents in all manner of sciences; it has made measurements easy which without it would be difficult; in many cases it has superseded the eye as an observing instrument; and now in the present century, supplemented by further discoveries, it bids fair to make wireless telephony possible all over the earth, with international results which can only dimly be foreseen.

It must never be forgotten that the real wonder of this mode of communication between mind and mind lies in the larynx and its associated cavities at the sending end, and in the ear and brain at the receiving end. The thought of an agent A is understood by a percipient P, through a mechanical system of vibration to which we have grown so accustomed that we are liable to forget its marvellous character. By delicate muscular adjustments the air is thrown into vibrations corresponding to the thought in the mind. Those vibrations are received and analysed by the complicated mechanism of the ear; their effects are somewhat mysteriously conveyed by the auditory nerve to the brain, and there are still more mysteriously interpreted by the mind of the percipient; so that if he knows the code called language (and unfortunately mankind has invented far too many of such codes) he can become aware of the thought originally in the mind of the agent or communicator.

Transmission is thus under ordinary circumstances a purely mechanical operation, involving brain-cell, nerve, muscle, vibrating tissue, condensations and rarefactions of the air; then again a vibrating membrane, bones, liquid, nerve endings, with discriminating arrangements for analysing a great range of frequency for notes of different pitch; then nerve again, brain-cell, and so to the perceiving mind, where all this mechanical and physiological disturbance is reinterpreted as thought. The only difference between this ordinary case of conversation, and the modern method of communication across great tracts of space, is that intervening electrical or etherial machinery is employed to effect the transmission over a hundred or a thousand miles of distance in a rapid and almost instantaneous manner. This is done by making the air vibrations either generate or modify an electric current, that is to throw docile and responsive electrons into a corresponding state of motion; the electric impulses being then either broadcast into space, or else guided by a wire to their destination; where, by aid of the magnetic effect of the moving electrons, which again take up the vibrations, an iron plate, itself full of magnetic whirls, is acted on and made to vibrate in a corresponding manner; thus once more producing condensations and rarefactions in the air in contact with that plate; and so ultimately reach the diaphragm of the receiving ear. No sound is transmitted between the two stations, only electric impulses, which travel through the ether with the speed of light, no matter whether they are guided by a wire or not.*

The remarkable novelty in this long-distance transmission method is not so much that the ether is able to pick up and transmit the pulses, by aid of the ingenious mechanism provided: the ether is so docile that it will nearly always do all that is wanted of it, except display and enforce its own existence. The wonder is that a simple iron plate is able thus magnetically to be so affected that it can reproduce and follow accurately, not only the intonations of the human voice, but the sound from every instrument in an orchestra, in a perfect and detailed manner, so that the ideas of Bach and Beethoven in their fulness and entirety can be taken up, at least on the mechanical side, by such a plate, and given to any hearer whose mind is attuned to the reception of the delights of refined musical composition.

This was essentially the surprising discovery of Graham Bell. Crude sounds had been transmitted electrically, before, by Philipp Reis and others. Wheatstone had transmitted the sounds of a musical instrument through a wooden rod to a distant soundboard—an easy and interesting thing to do. But Bell found how to make the vibrations of an iron plate at one end generate fluctuating electric currents which should cause an iron plate at the far end to vibrate in a precisely similar manner, and thus invented the articulating telephone.

Those, now comparatively few, who have lived through the 70's of last century, vividly remember the surprise which the simplicity of the apparatus capable of achieving so far reaching a result aroused when it was first announced. I remember, for instance, the enthusiasm with which Lord Kelvin, after a visit to America, came back to the British Association Meeting in Glasgow, bringing with him a couple of Bell's early instruments, which the inventor had given him, and which he enthusiastically showed to Section A, then meeting in his own lecture theatre, and described his astonishment when he heard a clock-spring actually talk. He had heard it say—a misquotation—" To be or not to be, there's the rub." This early demonstration by Lord Kelvin in this country, under our system of Patent Laws, threatened at one time to have a serious and quite undesired effect in preventing the completion of Bell's patent; a strange anomaly, as I think. But fortunately Lord Kelvin was able to exert his influence; and sensible judicial people found themselves able to evade the technical point and grant the inventor his just right.

The instruments shown by Lord Kelvin were of the simplest character; the sending end and the receiving end were much the same. At one end mechanical

* The speed of light is the ideal speed aimed at but not actually attained on a real line. Even an aerial land line has some troublesome properties, the same as are accentuated in any cable, and greatly accentuated in a submarine cable. Applying Heaviside's complete theory to a well-loaded line, we find that we ought to be able to attain a speed of from 10 000 to 20 000 miles a second; and this speed, Mr. Appleyard assures me, corresponds to what in practice a Pupinised telephone cable actually gives.

vibration generated a current; at the other end that current magnetically reproduced mechanical vibration: that was the whole thing. No energy was put into the circuit, except what the voice put into it, in those early days. Very soon afterwards an Edison carbon transmitter and a Hughes microphone, consisting of granulated carbon in the circuit of a battery, were introduced, so that the voice merely altered the resistance of the carbon granules; the energy came from the battery, and by that means it was possible to magnify the voice, and transmit to a distance any reasonable amount of fluctuating energy. But this microphonic transmitter, still in use at the present day, though it slightly differentiated the apparatus at the sending and receiving ends, did not really complicate matters much: the essential apparatus remained quite simple. There are plenty of complications now; but those complications have to do with the distribution of the messages and the selection of the person talked to. It is obviously no easy matter to enable any one person in the British Isles to communicate with any other by a system of wires; of which each subscriber to the telephone exchange need only have a single pair. A further complication arises when the calling-up is attempted to be done mechanically or automatically, without human intervention, at the central station.

These complications have called for the utmost ingenuity and skill on the part of those engineers who have been engaged in carrying it out. Whenever an invention or a discovery gets into extensive practical use, on the large scale, innumerable difficulties are always encountered, and are nearly always successfully overcome by those who devote their life to the work. To understand these things involves a long apprenticeship, a long period of study with the actual apparatus. For in practical use a device has to be made foolproof, able to be worked by operators with no special skill, and by subscribers who doubtless manage to pick out every weak point and make the thing go wrong if any loophole for misuse is left them. Furthermore, any wide scale application of engineering invention and discovery is open to perturbations of a quite different kind from any which are studied in physics. Operators may strike, peaceful progress may be interrupted by wars of one kind or another; all which complications, if they belong to science at all, belong not to physics or engineering, but, I suppose, to the science of sociology. Human free will is a great asset, but, like everything else of value, it is capable of abuse—sometimes, strangely enough, even when actuated by class-loyalty and other excellent motives.

To return to the early history of the telephone. It was received in this country by some men of science with a certain amount of scepticism, which is only instructive now as showing its novelty. That great chemist, Prof. A. W. Williamson, for instance, was very doubtful whether the messages were really transmitted by electrical means at all; he thought it more probable that the sound actually travelled between the two places by the wire; and he urged me as a young man to look into it and see whether there was not some hocus-pocus in it.

Lord Kelvin, however, as we have seen, received it with enthusiasm, and was able as a mathematical physicist to realize and state the theory of the means by which electrical transmission was really accomplished; though naturally in his lifetime he was not acquainted with the wireless or radio methods now in vogue, made possible by Fleming's introduction of the valve detector, based on a stray observation of Edison's of the unilateral conductivity of electrodes in a vacuum, akin to the unilateral conductivity of a modified coherer or crystal detector.

In 1878 one of the greatest mathematical physicists of the 19th century—possibly one whom posterity will consider, by reason of his far-reaching influence, the greatest of all—viz. James Clerk Maxwell, gave what is called the Rede Lecture before the University of Cambridge, taking "The Telephone" as his subject. And the reasonable attitude of enlightened scientific men in this country to the subject is well illustrated by his opening paragraph, which I will here quote:—

> "When, about two years ago, news came from the other side of the Atlantic that a method had been invented of transmitting, by means of electricity, the articulate sounds of the human voice, so as to be heard hundreds of miles away from the speaker, those of us who had reason to believe that the report had some foundation in fact, began to exercise our imaginations in picturing some triumph of constructive skill—something as far surpassing Sir William Thomson's Siphon Recorder in delicacy and intricacy as that is beyond a common bell-pull. When at last this little instrument arrived, consisting, as it does, of parts, every one of which is familiar to us, and capable of being put together by an amateur, the disappointment arising from its humble appearance was only partially relieved on finding that it was really able to talk." *

Sir Richard Paget tells me that when a talking machine, sent by Graham Bell, arrived for Lord Kelvin in this country he happened to be staying with Lord Winchelsea, who sent a farm wagon to the station to collect it.

I suppose it may be said that the articulating telephone was born on the 10th March, 1876. Up to that time Bell had been working at telegraphic communication, using tuning forks and Morse signals. He was Professor of Vocal Physiology at Boston University. We are told that during his experiments one of the transmitter springs got out of order and made a faint sound in the receiver. He had hoped till then to get the deaf to interpret musical sounds transmitted by what he called "the harmonic telegraph," making a kind of modified and rapid Morse-code system. He thought that if they could not hear, they could see, the signals which were being transmitted, and gradually become able to interpret them; just as they were able to interpret his father's system of visible speech or lip-reading. The accidental observation, however, gave him another clue; and though at first he only got his receiver to make strange and discordant noises, on the 10th March, 1876, his efforts were crowned with success.

* *Nature*, 1878, vol. 18, p. 159.

On this memorable day Bell spoke into an instrument fixed in an attic, to his assistant in the basement, at the other end of 100 feet of wire. All he said was, "Mr. Watson, come here. I want you!" The assistant rushed upstairs into the attic, shouting excitedly, "I heard you; I could hear what you said!" This is the story of the birth of the telephone, as told by Bell himself.

A writer in the *Wireless World* of the 26th May this year goes on to say that, at an Exhibition held in Philadelphia later in 1876, the Emperor of Brazil placed the receiver to his ear and was astonished to hear it speak. Lord Kelvin was there too, and declared, as he listened to the steel spring or diaphragm, which at that time he was told to press against his ear, so as to get the necessary damping—"It does speak! It is the most wonderful thing I have seen in America!"

Now that a telephone is to be found in most households (though not indeed so many in this country as in others, for in America there seems to be a telephone in nearly every room), and now that the younger generation is so accustomed to it that they can hardly imagine a time when it was not in existence, it is well to remember the surprise and delight with which the invention was received. In these days, indeed, it is occasionally customary to regard the telephone as rather a nuisance. I found it so when I was in America in 1920: at any time, day or night, I might be called up by reporters and others. It was very little use to tell the hotel clerk not to switch people on, they got through any ordinary barriers; and, when too much bored, my plan was to turn the receiver on to the transmitter and let the communicator talk back to himself, instead of to me! This usually had the desired effect, and was better than Herbert Spencer's device of stuffing his ears with cotton wool when he was bored by a conversation! The writer in the *Wireless World* says that it is amusing to find that towards the close of his life Graham Bell himself sometimes found the telephone such a source of annoyance that he had it removed from his room. I do not vouch for that; but it seems quite possible, at any rate in certain moods.

Complications.

When we come to consider the developments of the telephone and the complications which naturally inevitably arose during its widespread application, we must go beyond the complications of the telephone exchange, whether automatic or otherwise, and the devices whereby any one subscriber was able to speak to any other; for a more interesting series of difficulties arose in connection with long-distance transmission, especially with international transmission between different countries. So far as England is concerned, that can only be done by submarine cables; and cable signalling is never so easy as free space signals or signalling along land lines. Capacity, in combination with resistance, comes in as a serious consideration, producing distortion and rendering speech through an ordinary cable more than 40 or 50 miles long practically impossible. A cable from Dover to Calais is short enough to be manageable; so that speech from London to Paris is quite good. From Holyhead to Dublin the cable is longer, and speech from London to Dublin must be more difficult. To speak from England to America by an Atlantic cable is impossible, though through the free ether there is no particular difficulty if the power used is sufficient and the receiving instrument sufficiently delicate.

The theory of line or cable transmission, and the mode in which good long-distance telephony has become possible, say over the Continent of America, where long distances really exist, is of high scientific interest, and in any lecture on the telephone must be referred to; but as some of this inevitably involves mathematical treatment, I propose to put in an Appendix a summary or concise exposition of the chief features concerning transmission, whether through land lines, or cables, or through the free ether of space; for the subject naturally divides itself into three portions—the apparatus at the sending end, the apparatus at the receiving end, and the facts and peculiarities about transmission.

But as to the other complications, such as those connected with telephone exchanges, with automatic calling-up, and the elaborate methods necessitated by large-scale telephony and prompt and efficient service, I see here present many who possess real knowledge in these subjects, and who indeed have already communicated information about them. For instance, only last July Colonel Purves gave a valuable paper * on "The Post Office and Automatic Telephones." And I see that in April this year Messrs. Cohen, Aldridge and West read a paper entitled "The Frequency Characteristics of Telephone Systems and Audio-frequency Apparatus." † Mr. Kingsbury's standard treatise on "The Telephone and Telephone Exchanges" is known to all interested in the subject.

I have had offers of help both from Mr. Kingsbury and from your Ex-President, that great telephone authority, Mr. Gill, who is now at Madrid teaching the Spaniards how to develop their system properly. My friend, Mr. Rollo Appleyard, representing him, has put at my disposal any amount of information; but it is impossible to deal with it in one lecture; and, moreover, all this mass of knowledge is best treated by experts with first-hand information. I wish to express gratitude to all those who have so freely offered help, and I regret that I have been unable to make more use of it. I have thought it best to confine myself to the fundamental principles with which my own knowledge is more directly concerned.

I shall not deal with controversial points, nor with the history of previous attempts at electrical conveyance of sound, but shall limit myself strictly to the articulating telephone and its concomitant devices.

By the use of accurate tuning and syntonized circuits it is possible, as everyone knows, to select from a multitude of disturbances in the ether and attend only to the waves of a desired frequency, all others being excluded or tuned out. This process is now worked by a system of carrier waves, where each sending station operates on one definite wave-length, and where the voice at each station merely modifies the amplitude of this wave, with very slight changes of frequency on either side, so as to give the proper fluctuations. This

* *Journal I.E.E.*, 1925, vol. 63, p. 617. † *Ibid.* 1926, vol. 64, p. 1023.

principle, so extensively applied in radio telegraphy, where a number of signals are transmitted through the same ether, can also be applied in line telephony when a number of messages are being sent along the same wire; each speaking only to a suitably tuned receiver. It is also found practicable to use the same wire for telegraphic purposes as well, thus making a composite system. The development of all this elaborate selective method, in practice, involves many technicalities; and I propose to ask Mr. Appleyard to give in an Appendix some indication of the modern practice in that respect. Meanwhile it is interesting to note that this method of composite signalling may be regarded as to some extent a development of the old harmonic telegraph system with tuned reeds, attempted in the early days by Graham Bell before he discovered that it could give voice production. He used tuned reeds where we use high-frequency tuned circuits; but on his plan a number of different tones could be sent by the same wire, and picked out each by its corresponding receiver, the other otherwise-tuned reeds only responding to their own frequencies.

Thus wired and wireless telephony have constantly tended to approximate to one another. Morse signals, as we know well, are transmitted through the ether as well as speech; and though if they are strong they do to some extent interfere, the disturbances are not very prominent and can for the most part be ignored.

Line telephony is, as we know, now much used as a supplement to broadcasting, the transmission from (say) 2LO to a big broadcast station like Daventry being accomplished by line methods, in order there to be imparted freely to the ether. And the sending and receiving devices are not dissimilar in the two cases. Indeed, through a land wire with very little capacity the law of transmission is much the same as in free space. The two are represented by the same equations, as was incidentally pointed out by myself in my paper in the *Philosophical Magazine* of August 1888.* And on the

* *Philosophical Magazine*, 1888, vol. 26, p. 227. A further demonstration of electric waves is reported in the *Philosophical Magazine* for July 1889, pp. 48–65. Heaviside's remarks on the subject will be found in "Communications" to the *Electrician* for 17th August, 1888, p. 479, and 19th October, p. 772; reprinted in vol. ii of "Electrical Papers," p. 486 onwards. And from this volume, p. 489, I make the following extract. He is there upholding the importance of self-induction against the attacks of Sir William Preece. He points out that it is self-induction, or rather electric inertia, which really keeps the waves going; and then he says:—

> "On this question of waves I take the opportunity of referring to a point mentioned at the Bath meeting [of the British Association in 1888] by Prof. FitzGerald [then President of Section A]. That physicist, in directing attention to Hertz's recent experiments, considered that they demonstrated the truth of the propagation of waves in time through the ether; but that, on the other hand, the waves sent along a circuit did not do so, because they might be explained by action at a distance.
>
> "It seems to me, however, that the more closely we look at the matter the less distinction there is between the two cases, and that to an unbiassed mind the experiments of Prof. Lodge, sending waves of short length into a miniature telegraph circuit, with consequent 'resonance' effects, are equally conclusive to those of Hertz on the point named; in one respect, perhaps, more so, because their theory is simpler, and can be more closely followed."

In Heaviside's article on the "Theory of Electric Telegraphy," written for the 10th Edition of the "Encyclopædia Britannica" in 1902, he emphasizes similarity between free and wired transmission, especially if inductance is emphasized and capacity kept small; and gives the whole theory in comparatively simple form. This article is reproduced near the end of vol. ii of his "Electromagnetic Theory," pages 331 *et seq.* He gives in fact "the radiational theory of telegraphy," whether wired or wireless, saying that "it is founded upon Maxwell's theory of light, and had been proved in all essential points and in various details by important experiments of Hughes, Lodge, Hertz, and others." His reference to loaded lines will be found on pp. 344 and 345 of vol. iii of his "Electromagnetic Theory."

In other places he deals with the reflection of waves in wires and cables, the so-called "echo" effects which are often troublesome, and shows how they can be avoided by proper absorbing arrangements at the receiving end.

strength of that fact Mr. Heaviside was accustomed to emphasize the similarity between my observations on wires and Hertz's discovery in free space. We both discovered at about the same time how to generate the waves and detect them. We both measured the wavelength by reflecting the waves and converting them into stationary waves; employing at first sparks or scintillæ, or brush discharge, as the imperfect and inconvenient form of detector; but afterwards using the coherer principle described by me to this Institution in 1890,* and independently rediscovered and improved by Prof. Branly with his smeared metallic powders and assemblage of iron filings. Branly's method of detection enabled the beginning of wireless telegraphy; but the rectifying power of crystals, and especially of the Fleming valve, so greatly improved the power of detection that the transmission of speech and music began to be possible in the first decade of the present century, and has gone on improving ever since.

Advantage of Permanent Magnetism in the Telephone.

In saying that the telephone is simple, it must not be supposed that that simplicity was arrived at straight away, or that the theory of it is unworthy of attention. The instrument consists essentially of a magnet, a coil, and an iron plate. The coil naturally has an iron core, so as to be an electromagnet; but in combining these three things, an electromagnet, a permanent magnet, and an iron plate, many varieties of arrangement are possible; only one of which is really efficient. The inventor's problem was therefore rather like those bridge or chess problems where a certain key move, or a certain discard, is necessary to the solution, and where all others fail.

Even about the iron plate there were many things to ascertain, especially its best thickness or flexibility, and especially the right amount of damping. But the most interesting part of the problem was the need for a permanent magnet. It seemed at first as if an electromagnet ought to do all that was wanted in the receiver, and probably the permanent magnet was introduced in order to enable it to act as a transmitter; for the three things, electricity, magnetism, and motion, are vitally connected. Where two coexist the third follows.

In the transmitter we make use of Faraday's discovery, now nearly a century old—on which manifestly there will have to be a Centenary some time in the coming thirties; for that discovery was nothing less than the birth or rather the conception of the dynamo, the birth, we may say, of electrical engineering, and therefore of this Institution. The discovery, regarded theoretically, was the essential connection between the three things:—in the transmitter magnetism and motion are combined, and the result is an electric current; whereas in the receiver the magnetism of that electric current produces motion. One is a kind of dynamo; the other is a kind of motor.

The transmitter produces alternating currents which synchronize in every detail with the mechanical vibrations of sound, the sound being caused by a regulated blast of air from the lungs through the larynx. In the

* *Journal I.E.E.*, 1890, vol. 19, pp. 352 and 354.

receiver those currents produce corresponding infinitesimal vibrations in an iron plate in front of an electromagnet. The vibrations are of nearly infinitesimal or rather molecular magnitude: they may be quite below the visibility of the eye, but their detection is within the capacity of the ear. Not that the ear is more sensitive than the eye; both instruments are about equally sensitive. The amount of energy which can affect them has been measured by the late Lord Rayleigh and others: he found that the amount of energy is about the same in the two cases. But it must be of the right kind. The ear is sensitive to the motions of matter of a suitable frequency or pitch; and of that kind of disturbance it can detect an amount almost infinitesimally and incredibly small. The eye is sensitive to etherial vibrations, and of those it can detect an amount almost infinitesimally and incredibly small. The one detects infinitesimal motions in the air; the other motions (if they are motions) in the ether. The eye cannot see the vibrations of the iron plate; it is not sensitive to the motions of matter; it can see them only when they are large. The ear does not respond to ether vibrations at all; the eye does. Each instrument has its own field of usefulness, its own function; and in its own field each is supreme.

The telephone makes use of the sensitiveness of the ear, and gives it that with which it is competent to deal. An electromagnet close to a suitably clamped iron plate would seem to be the right detector. An electromagnet is a coil wound on a soft iron core. Why use a permanent magnet at all? Yet it was found essential to employ a permanent magnet to back up the electromagnet. The soft iron core close to the iron plate at one end had to have a permanent magnet at its other end; so that the iron plate should be in a permanent magnetic field. The soft iron core transmitted the lines of force of the permanent magnet, and thus constantly attracted the iron plate. All that the received currents had to do was not to cause that attraction, but to modify it, that is to strengthen or weaken the force of attraction according as the currents were positive or negative.

The theory of that is simple enough but was not at first obvious, and there was some amount of discussion as to why a permanent magnet was necessary. The reason may be put in various ways; it may be expressed geometrically in terms of a curve. Imagine a curve like a hanging chain, and then consider a point oscillating horizontally near the bottom of that curve. The changes in elevation are very slow: an inch of horizontal motion along such a curve corresponds to very little elevation. But if instead of working at the bottom of the curve we work where the curve is steep, then even 1/100th of an inch of horizontal motion would send the point up and down the curve quite a considerable amount. If the slope were 45° the vertical and horizontal motion would be the same; but if the gradient or steepness of the curve were 80° or 89° the vertical motion would be far in excess of the horizontal. Applying that geometrical fact to the special case, we realize that if we were using an electromagnet with soft iron only we should be working at the bottom of the curve; but that if we reinforced it by permanent magnetism we should be working on the steep part of the curve.

But perhaps it is clearer to put the thing algebraically as Heaviside did. The force of attraction depends on the square of the magnetic field. If that field varies between plus and minus h, and if we have to depend on the square of that small quantity, we shall get hardly any result. If, however, we reinforce it by a fixed quantity H, so that we now oscillate between $(H + h)$ and $(H - h)$, and take the difference of those squares, we shall have a very different result. The difference between $(a + b)^2$ and $(a - b)^2$ is $4ab$; and although b may be very small, $4ab$ may be got as big as we please by making a big. Thus the permanent field H comes in as a factor; and what the telephone observes is not the fluctuation in h, but the fluctuation in $4Hh$, which may be of a totally different order of magnitude, depending on the size of H—which is the permanent field supplied in the instrument by the permanent magnet.

In the first instruments the coil was wound over a considerable length of iron core; but it was soon found that the right plan was to use a very short length, to concentrate the coil at the top of the permanent magnet, and to utilize only the fluctuations in a strong permanent field; thus working on the steep part of the curve, and making the permanent magnet contribute to the sensitiveness by supplying a constant factor to the periodic or fluctuating disturbances which had to be observed.

Whether a double-pole or horseshoe magnet was used, or whether a steel bar magnet was employed, is a mere detail of construction and convenience. The essential thing was the need for permanent magnetism in the receiver.

This mode of regarding the influence of a permanent magnet in the receiving telephone is, however, incomplete; for it would suggest that the stronger the magnet the better, and that if greater sensitiveness were required it could be obtained by the use of a strong electromagnet instead of a steel one. But if that were tried it would be found to defeat its own end. The soft iron inside the coil must not be saturated with magnetism; for then its magnetism would not fluctuate: the currents in the coil would have no effect upon it. The permeability of iron is rather a delicate matter—for reasons which Sir Alfred Ewing was able to demonstrate by his flock of compass needles. It is known that the act of magnetization is the turning round and facing in one direction of a large number of pre-existing magnets or magnetized molecules, and that there are three stages in this operation in most kinds of iron:—

> First, when the applied force is too small to disturb them in any large number;
>
> Second, when they begin to topple over, or turn round, in an almost unstable condition under their mutual forces; and
>
> Third, when the majority of them have already faced round; so that a further force has little or no effect.

That third stage is saturation, and in the telephone must be avoided. The application of a permanent

magnet of moderate strength brings the iron into the intermediate or sensitive stage, when its permeability is very high. If the applied magnet is too weak the iron remains in the first stage, with low permeability. If the applied magnet is too strong it gets into the final stage, which is also of low permeability. The intermediate stage is the one to aim at when sensitiveness is required.

Hence there is a best strength of permanent magnet, which presumably is hit upon by the experience of instrument makers. The magnet may be too weak, but it may also be too strong. In other words, though it is true to say that the result depends on the product of H and h, we must also remember that h is not independent of H. Its value depends not only on the received currents, but on the condition of the iron core, and if H is too strong, variations in h will be zero.

So much for the receiving instrument. As for the transmitter, similar considerations will apply to that if Bell's original magnetic transmitter were used; but as it has been entirely superseded by the microphone, which depends on the fluctuations of resistance in the contacts of carbon granules in circuit with the battery, there is nothing much to be said about that, except that it is undesirable to send the battery current itself into the line and through the receiving instrument. It is better to employ a transformer, for that transmits no steady current at all, but only the currents induced by the variation in the primary current. The line thus receives nothing but alternating currents, which are able to do all that is wanted without exerting any polarizing or steady perturbing effect on the receiver; the strength of the induced currents being proportional, not to the strength of the primary current, but to its rate of variation.

Transmission.

We have now to consider the transmission of these alternating currents along the wire or cable or whatever is used to connect the sending and receiving stations. Any perfectly insulated transmitting line possesses three definite characteristics, which are independent of each other, none of which can be entirely obliterated, but any one of which might be reduced to a comparatively small amount. These three are resistance, inductance, and capacity.

A land line has small capacity; whereas in a submarine or buried cable capacity is emphasized. Every line unfortunately has resistance; and resistance is wholly obstructive to transmission: it does not help it in the least; it dissipates energy and converts it into heat. Resistance is therefore a necessary evil. The only way to reduce the resistance of a metallic conductor to zero is to cool it within a few degrees of the absolute zero of temperature. This can be done in the laboratory by means of liquid helium—as was done with astonishing results by Kammerlingh Onnes. But in practice no such device is ever likely to be feasible: if it were, signalling by such wire to any distance would be very easy.

The effect of resistance alone is attenuation of the signals, their energy being gradually absorbed and consumed in warming the wire. There is another cause of attenuation, viz. leakage. If the wire is not perfectly insulated, part of the current does not reach its destination; it leaks out through the imperfect insulation, and returns to its source without having gone the whole way. Leakage, therefore, would cause attenuation even if there were no resistance; but, by the use of good insulation, leakage can be diminished to such an extent that its effect may be almost negligible, and hence the leakance characteristic of a wire is not usually mentioned along with the other three.

Capacity differs from leak, though it too is a lateral effect, inasmuch as it wastes no energy; it stores the energy in an elastic manner, and therefore by itself does not cause attenuation. It does not stop transmission; it only retards it, making the process slower than it otherwise would be—somewhat as if we rang an ordinary bell by an elastic cord instead of by a rigid bell wire. The pulse would reach the distant end in time, though it would arrive smoothed out and slowly, instead of as a definite jerk—just as elastic springs are used in a road vehicle to smooth out the shocks of the road, and deliver them in a gentle and indefinite and inoffensive manner.

The deleterious effect of resistance and capacity in combination is "distortion," which means the obliteration of features and the transmission of pulses of different frequency at different rates: so that if a note and its harmonics were being transmitted as a complicated curve, that curve would not arrive in the same shape as it was sent. The different harmonics would travel at different rates, and accordingly the features of the curve would be unrecognizable; the shape of the curve would be altered or distorted, and the definiteness required for clear signalling would be unattainable.

This was the main difficulty which the early telegraphists were up against, when they began to construct and utilize long cables; and Lord Kelvin gave the theory of cable signalling, taking into full account the combined effect of resistance and capacity, devising what was called the "*KR*" law, familiar to all the older telegraphists, especially to the Society of Telegraph Engineers, which preceded the establishment of this Institution. Probably it is now often called "*CR*." Kelvin, then Professor William Thomson of Glasgow, worked out this diffusion theory of cable signalling in the later fifties of last century, and showed that the law of transmission was exactly analogous to the transmission of heat. He showed that it was a process of diffusion, analogous to the diffusion of salt or sugar or any other substance in water, or the diffusion of smells through air. No definite velocity could be assigned; the rate of transmission depended only on the sensitiveness of the receiving instrument. If a bottle of ammonia were opened on this platform a dog at the back of the hall might smell it at once; but the people would not smell it for some time, though after a time everybody in the hall would smell it, though a person with a cold might be a long time before he perceived it.

Another analogy is furnished by an imaginary attempt to signal by means of fluctuations of temperature at the far end of a long rod swathed in cotton wool, to the near end of which alternate flame and ice

are discriminatively applied. The quickness of response by a thermometer at the far end of the rod would depend entirely upon how sensitive that thermometer was. If it could only feel, say, the tenth of a degree rise or fall, signalling would be very slow; but if it could feel a millionth of a degree, or less, there need be but little delay in receiving the signals. For the heat pulses have no definite velocity, they begin to diffuse at once, and by a sufficient (perhaps impossibly) sensitive instrument could be detected almost immediately.

It was on this theory that Lord Kelvin knew that the solution of cable signalling was to be found in receiving instruments of surpassing delicacy: that is how he came to invent first his mirror galvanometer, and next his siphon recorder—instruments which were able to detect, like the dog's nose or the hyper-sensitive thermometer, the very first beginnings of the transmission. Each pulse sent was therefore to be extremely feeble and to be curbed by an opposite pulse as soon as possible, so as to be ready for the next pulse, without allowing time for any accumulation, such as would be needed to affect a coarser instrument.

But although this served well enough, and is still in use for telegraphy, distortion is only thereby minimized; it is not avoided; and even a small amount of distortion is destructive as regards telephonic transmission. Speech through a long submarine cable is impossible. The combination of resistance and capacity might allow it through a cable 50 miles long, but not more. For the distance to which an alternating current of frequency n can be received without too much attenuation is inversely proportional to $\sqrt{(nCR)}$. The higher frequencies, on which the characteristics of speech depend, are therefore rapidly blotted out. The fundamental note might be received, but the harmonics would be wiped out; and nothing would be got but a featureless and unintelligible drone.

The amplitude is reduced to $1/e$th of its value, or the energy to $1/7$th, in a length

$$\sqrt{\left(\frac{1}{\pi n C_1 R_1}\right)}$$

which may be called the damping distance.

It will be observed that this distortion is due to the inclusion of n, the frequency, along with the CR. If any one of the three factors could be kept small then the transmission might be clear and definite. We cannot keep n small in telephony; for the high harmonics are necessary. We cannot make R small, except by the use of an unwieldy amount of copper or by the impracticable device of excessive cooling; but we have some control over C. Instead of surrounding the copper wire with gutta-percha and a metallic sheath, such as is needed in submarine cables, we may surround the wire by air, supporting the wire by paper; and these air-spaced cables are in actual use for telephonic purposes. Even if we support the wires on poles a good distance above the ground, capacity effects are only minimized; they cannot be wholly avoided. Is there any way of avoiding distortion altogether?

This problem was attacked by that remarkable mathematician Oliver Heaviside, who took into consideration a factor neglected by Lord Kelvin, viz. inductance; or rather inductance and leakance in combination; and showed for the first time how to produce a distortionless cable. Heaviside's theory was not well received by practical electricians. It seemed to them quite natural that the two factors which he introduced must be harmful, not helpful. Leakage (which, when measured in mhos, like conductance, he called "leakance") seemed clearly a thing to avoid; for it could only result in attenuation; while inductance seemed merely to add to impedance; it seemed likely only to obstruct the signals, not in any way to help them. Consequently it was some time before his theory received practical application.

It was taken up to some extent or advocated in this country by Silvanus Thompson; and somehow the genius of Pupin in America enabled him to perceive that inductance would be a help. The addition of inductance is equivalent to an increase of inertia; and Pupin was able to persuade American financiers to risk the construction of loaded cables. It was true that inductance increased impedance; but that by itself turned out not to be deleterious. What was wanted in order to avoid distortion was to get all frequencies to travel at the same rate, so as to preserve the features. A massive disturbance with plenty of inertia behind it could overcome the elastic effect of capacity, and enable the signals to arrive in much the same condition as they started.

Heaviside had shown that when the factor of inductance was introduced, the law of transmission was entirely modified, that there was some approach to a true wave propagation with a definite velocity, and that the head or front of the signal would reach its destination with some approach to the velocity of light. There might then be more attenuation; but attenuation alone was not the evil. It was the discriminative attenuation that was bad. Mere attenuation would not prevent telephony, if only distortion could be avoided. If all frequencies could travel at the same rate, it did not so much matter what that rate was. The addition of inductance makes some approach to this condition; and accordingly many loaded cables are now in use: some of them with extra inductance coils arranged at regular intervals; but some with the copper conductor surrounded by iron tape or wire whipping, thus adding to the inertia of the current, and enabling it to reach its destination sufficiently unimpaired even for telephonic purposes.

Outline of Transmission Theory.

Denoting the resistance per unit length by R
the capacity or permittance by C
the inductance by L
and the leakance by G

the distortionless condition is that

$$CR = GL$$

The velocity of waves through the cable is then

$$\frac{1}{\sqrt{(CL)}}$$

which is independent of the frequency n.

In the general case the cable theory equations are two:—First, the Ohm-law or current equation,

$$RI = -\frac{dV}{dx} - L\frac{dI}{dt}$$

Second, the capacity or potential equation:—

$$C\frac{dV}{dt} = -\frac{dI}{dx} - GV$$

(See Appendix II.)

The first two terms in each of these equations constituted Lord Kelvin's theory, which ignored L and G, and they are analogous to those for diffusion of heat through a slab. Heaviside's completion of the theory consisted in adding the third term to each equation, and thereby laying down a law which, being much more complete and satisfactory, has proved intensely useful in practice.

The leakance or G term can occur in heat also, when the flow of heat is along a rod instead of a slab, but there is nothing in heat to correspond with the inductance L. That is a sort of inertia term characteristic of matter, and likewise of electricity. It is that term which gives to electrical waves their definite velocity, and it is practical emphasis on and exaggeration of that term which has so greatly improved telephonic transmission. We now know that this factor L confers a definite velocity upon electric waves, even in a cable—at least upon the initial pulse or head of a series. The rest of the series cannot live up to it, they draggle along in a diffusive manner in an ordinary cable; but the first pulse or head travels clearly and definitely; it does not reach the distant end instantaneously, it gets there, in the ideal case, with the velocity of light. The subsequent series of waves shuffle along as best they can, unless the cable is distortionless. In that special case they manage to shed their troublesome portions, with inevitable attenuation, leaving a fine naked residue to travel as a free unhampered true wave, feeble but effective up to the limit of its strength.

I am not aware that a really and fully distortionless cable, constructed in accordance with Heaviside's theory, has ever been made, nor do I know if it is practicable; but every approximation to it helps. He showed that the right condition was to apportion the four characteristics, resistance, inductance, capacity and leakance, in such a way that the ratio $R:L$ was equal to the ratio $C:G$, G being the leakance. In that case the velocity of transmission would be quite independent of the frequency; so that all the harmonics would arrive together and every feature would be preserved. The attenuation would undoubtedly be great; but as there was no distortion, considerable power might be applied; or on the other hand, since the signals would be received in unimpaired condition, however weak, they could be magnified up to any desired extent.

Whether such a cable will ever be constructed I do not know; it seems probable that modern discoveries have rendered it unnecessary. Fleming's invention of the valve detector has put into our hands an automatic relay of surpassing docility; further improved by Lee de Forest; and long-line transmission can now be attained by a succession of short lengths of cable or land line, connected together by valve relays; so that the currents from the sending station are not sent very far before they are relayed on, with fresh energy, by a valve transmitter, and started afresh on their new journey. The American Telephone and Telegraph Co. have in this way, so I understand, effected admirable speech transmission across that Continent.

Is there any other way of avoiding distortion? There certainly is if we are content to eliminate the transmitting line altogether, and instead of directing the signal to a desired destination, to broadcast it through the free ether of space; for the ether has properties far more perfect than any form of matter. None of the difficulties of metallic conduction apply to that. It is entirely devoid of resistance—by which I by no means mean that it is a perfect conductor; it is not a conductor at all. It has no resistance because its resistance is infinite. It does not act by conduction. Neither has it any leakage. It acts simply and solely by inductance and capacity. It transmits true waves, all at the same definite speed, no matter what the wave-length or frequency may be. Accordingly it transmits without a trace of distortion. Whatever disturbances are imparted to the ether travel unchanged and arrive unchanged. There is not even any real attenuation. Of course the waves spread out by reason of distance; but the same amount of energy passes through any spherical envelope, however large. The ether is absolutely transparent.

Whether the interstellar spaces contain particles of matter, stray electrons, and other particles of dust, may be argued. But that for all practical purposes the interstellar spaces are absolutely transparent, is certain; else we should not see the distant stars, some of which are 30 thousand light-years away. Indeed it has been estimated that there are some spiral nebulæ as much as a million light-years away; and yet they can be photographed in a large telescope! And the message they convey as to their atomic composition can be accurately deciphered!

Thus in free space there is no attenuation and no distortion. Signals transmitted by free ether, whether they be those of light, or of longer ether waves carrying with them the peculiarities of speech or music, can be detected at any distance—weakened by the spreading out, but otherwise unimpaired. And by suitable magnifying devices the conserved peculiarities can be magnified up and can reproduce the speech and music in any part of the earth. This shows how little mere attenuation matters, so long as distortion is avoided. If the features are there, even though they are infinitesimal, they can be magnified, if necessary a millionfold, till they become perceptible. The theory of wave transmission in the ether is the simplest possible: there are no complications, such as the presence of matter necessarily introduces.

All the complications introduced into wireless or radio telephony belong to the atmosphere. Some of them are hurtful, but some are strangely helpful. The Heaviside layer of free ions and electrons has been shown both by Dr. Eccles and by Sir Joseph Larmor

to have the effect of curving the waves round the earth in a surprising and unexpected manner; thus tending to preserve them in the earth's neighbourhood, where they are useful, and prevent their spreading out too lavishly into the depths of space. Nevertheless, into the depths of space some of them must go; and though they would be violently attenuated by the time they reach the planet Mars, I see no reason why one of our skilled amateur observers, if he could take his instruments with him to that planet, should not be able to detect them and interpret them. Whether the inhabitants of Mars (if there are any) have the skill to detect them I do not know; and whether they could interpret them if they did is more than doubtful. The ether conveys to us a large amount of information about the other worlds in space; but it conveys it not by human artifice or code, but by means of the waves of light which humanity has somehow learnt not only to receive but also to interpret. The interpretive powers of the mind seem nearly unlimited. We are a part of the universe, and the universe seems gradually apprehensible by us. Many things are still mysterious, but nothing seems likely to be ultimately and deeply unintelligible. The progress of science is based upon faith in the ultimate intelligibility of everything; and so far wisdom has been justified of her children.

APPENDIX I.

The Tones of an Iron Plate.

A telephone plate is a flexible disc of iron clamped at the edges. The modes of natural vibration possible to such a plate were calculated by the late Lord Rayleigh,* with his usual comprehensive power, and shown to require for their solution certain Bessel functions whose values have been calculated by my brother, Alfred Lodge.

A simplified expression for the natural frequency of a plate of radius a and thickness z is :—

$$n = \frac{2 \cdot 5\, z}{\pi a^2}\sqrt{\left(\frac{Y}{3\rho(1-\mu^2)}\right)}$$

where Y is the Young's modulus of elasticity, ρ the density, and μ the Poisson ratio, of the material of which the plate is made.

It appears from this that an iron plate of, say, 4·4 cm diameter, and thickness 0·2 mm, has a fundamental frequency of vibration about 990 per second. The first harmonic comes out about two octaves higher. But a telephone plate is well known to respond to all manner of frequencies, much lower as well as far higher than these natural tones, consequently resonance must play but a small part in the reception of vibrations by such a plate; it must be damped so as to be actuated only by forced vibrations, and must respond to almost any frequency whatever. The astonishing thing is the perfection with which it does so respond. That fact alone may be regarded as a practical discovery of Graham Bell's. Precision of utterance by a damped plate was not expected, and the fact took the scientific world by surprise.

Such a plate is also very effective as an auxiliary to the ear. The amplitude of vibration needed for audibility when a plate is held close to the ear is exceedingly minute, comparable indeed with 1 ångström, or the atomic dimension of 10^{-8} cm. The minimum amplitude necessary for audition was measured by Lord Rayleigh as less than 8×10^{-8},* and was estimated as perhaps as low as 10^{-8}. The current needed to produce such amplitudes was also measured, and found to be of the order 10^{-8} ampere, at least for the pitch to which the ear was most sensitive, i.e. for a rate of vibration between 500 and 1 000 per second. Much lower figures for minimum currents have been obtained by Prof. Tait and others.

The telephone used by Lord Rayleigh for this determination was a unipolar Bell telephone of 70 ohms resistance; but he points out that—

> "the effect of a given current depends, of course, upon the manner in which the telephone is wound. If the same space be occupied by copper [of given quality] in the various cases, the current capable of producing a particular effect is inversely as the square root of the resistance."

Hence with a high-resistance telephone it is not surprising that currents as low as 10^{-12} ampere, or the millionth of a microampere, have been found to yield a faintly audible result, especially if the note happened, or was arranged, to correspond to one of the natural harmonics of the plate, so as to be reinforced to some extent by resonance.

APPENDIX II.

Transmission Theory.

The theory of the cable is to determine, on fundamental principles, what sort of current is produced at one end, when either a sudden or an alternating E.M.F. is applied at the other. For that purpose we write down the relation between current I and potential V at every point; and if we take nothing but resistance R and capacity C into account, we have first to express Ohm's law, namely that the current in any element is the difference of potential between its ends divided by its resistance: in other words that RI equals the gradient of potential, if R is the resistance of the wire per unit length. So our first equation is :—

$$RI = -\frac{dV}{dx}$$

Next we have to say that the accumulation of charge at any point per second dQ/dt or $Cdx \,.\, dV/dt$ (C being the capacity per unit length) must correspond to the defect of current that flows away from that element compared with that which arrives; that is to say $-dI$; or in other words that C times the rate of

* See Rayleigh's "Sound," vol. 1, § 221*a*.

* *Proceedings of the Royal Society*, 1877, vol. 26, p. 248.

change of potential must equal what may be called the gradient of current.

$$C\frac{dV}{dt} = -\frac{dI}{dx}$$

Those two equations contain the essentials of the theory, and only need solving by the devices of pure mathematics. The simplest solution is when the applied disturbance is sinuous, with a frequency $p/(2\pi)$; and Fourier taught us that any disturbance may be analysed into a selected series of such harmonic or sinuous components, with their frequencies proceeding in regular order, 1, 2, 3, etc. But first the two equations —the one which expresses what happens longitudinally along the core of the cable, where resistance is dominant, and the one which expresses what happens laterally, or in the insulator surrounding the cable, where capacity is dominant—can be combined into one, so as to eliminate either I or V and to retain the other. This simple process gives us the equation for either I or V in the form :—

$$\frac{d^2I}{dx^2} = CR\frac{dI}{dt}$$

which is the recognized diffusion equation, or equation for the conduction of heat; the solution of which for the case of an applied sinuous variation of frequency $p/(2\pi)$ is :—

$$I = I_0e^{-kx}\cos(pt - kx)$$

where k is an abbreviation for the controlling constant

$$\sqrt{(\tfrac{1}{2}pCR)}$$

This equation represents waves of diminishing amplitude, and shows that the amplitude of these waves will be reduced to $1/e$th of its value in a length $1/k$ or $\sqrt{(2/pCR)}$. Hence the energy, which depends on the square of the amplitude, will be reduced to 1/50th of its value in the length $2/k$; and to the 1/2 500th part in double that length. The high frequencies are therefore wiped out very rapidly, even though CR is kept as small as possible, and the features of a complicated disturbance—which depend on high harmonics—are lost.

The bracketed or cosine part of the equation represents waves of a kind, advancing with the velocity p/k or $\sqrt{(2p/CR)}$, and therefore with a velocity which differs for every frequency; as if the treble notes of a distant band were heard first and then the bass notes—rendering music from it impossible.

Heaviside's Generalized Theory.

Such was the theory on which Atlantic cables were constructed and laid in 1865 and 1866. It ignores both leakage and inductance, since these are supposed to be, and in ordinary cases are, small. But Heaviside's complete theory took them into account. Call the leakance per unit length G, and the inductance L; then the two equations with which we started become :—

First, $$RI = -\frac{dV}{dx} - L\frac{dI}{dt}$$

for the gradient of potential is supplemented or interfered with by a self-induced opposition E.M.F. proportional to the rate of increase of current strength;

and second, $$C\frac{dV}{dt} = -\frac{dI}{dx} - GV$$

for the accumulation of charge at each point is diminished by the leakage, which will be proportional to the potential there.

Combining these two equations into one, so as to retain one of the variables V or I and eliminate the other, is in the general case rather complicated; but the sinuous case is easily represented by the dodge of expressing a sinuous disturbance as e^{ipt}. For e^x is well known to be its own differential; and so

$$\frac{d}{dt}e^{ipt} = ipe^{ipt}$$

Moreover, as Euler showed long ago,

$$e^{ix} = \cos x + i\sin x$$

so that both its real and imaginary parts, which are easily kept separate, are of sinuous character.

The single equation, in the simply harmonic or sinuous case, can therefore be written (whether for I or V) thus :—

$$\frac{d^2V}{dx^2} = (R + ipL)(G + ipC)V$$

There is one very simple and definite relation which might hold among the constants of such a cable, namely when $CR = GL$; and then the old bugbear CR can be neutralized by a combination of the previously neglected quantities G and L. There will now be inevitable and even great attenuation, but there will be but little distortion; none at all if the specified condition is exactly fulfilled. Only we observe that the two things which had hitherto been neglected—because in practice they could be kept small—namely leakance and inductance, have now to be increased artificially, so that their product shall equal the product of the inevitable and deleterious quantities C and R.

If that is so adjusted, the attenuation constant or logarithmic decrement of amplitude will be :—

$$q = \frac{R}{L} = \frac{G}{C}$$

so if we allow for this, and take U instead of V, such that $V = e^{-qt}U$, the above equation can be got into the form :—

$$\frac{d^2U}{dx^2} = LC\frac{d^2U}{dt^2}$$

which shows an undamped quantity U, travelling along x, as a true wave, with a velocity independent of frequency, and equal to $1/\sqrt{(LC)}$.

The actual wave is the same, only damped or violently attenuated in accordance with e^{-qt} or $e^{-Rx\sqrt{(C/L)}}$. We might therefore write the current or the potential in such a distortionless cable at any point x and at any time t as proportional to :—

$$V = e^{-(R/L)t}f\left(x - \frac{t}{\sqrt{(LC)}}\right)$$

if $f(x)$ represents the initial value of V. While the current is :—

$$I = V\sqrt{\frac{C}{L}}$$

This equation represents true damped waves, all travelling at the same speed. But for this to hold it is essential that R/L shall equal G/C, which is not a condition easy to fulfil. It is usually only approached: and, in considering the approach, we note that leakage contributes greatly to attenuation, while inductance does not. In fact, inductance usually diminishes the attenuation constant; hence of the two factors G and L, whose product aims at being equal to the product CR, L is the factor to encourage. Loaded cables therefore aim at some not very close approximation to the distortionless case; and they do this by increasing L to every practicable extent, and by allowing such amount of G as shall not attenuate the signals too much. The signals are clarified, though weakened, by an increase of G.

Wireless operators are familiar with the extra clarity of weakened signals when distortion is avoided. Their kind of distortion is not produced by the complication of cable theory, for they are transmitting through free ether; their kind of distortion is caused by the extra complication of mutual induction between coils, i.e. by the reactions between different parts of their receiving circuit, or by overpressing of valves, so as to get more out of their set than it is entitled to give.

Transmission through Space.

As soon as we abandon guiding lines or wires, and trust to transmission broadcast across space, i.e. as soon as we abandon matter, and entrust our messages to free ether, we get rid at a stroke of a multitude of transmission difficulties—caused some of them by selective dissipation of energy, and some by different waves going at different speeds. The only distortion we now experience is instrumental distortion. In radio transmission there is no other kind; the ether dissipates no energy and generates no heat, except in regions where traces of matter are present. The waves spread out with distance, and therefore we get dilution, but no proper attenuation; all the energy is transmitted without loss, though over a gradually increasing area. And so, even at a distant place some energy is there, unimpaired in quality, ready to be picked up by a collector, and able to be magnified to any desired extent.

The damping constant, which in cables and land lines is $\sqrt{(\frac{1}{2}pCR)}$, is zero in free space, because the factor R is zero. Nor is there any leakage; the term ceases to have meaning. The only controlling constants are C and L, the elastic term and the inertia term, and they are reduced to their essentials. The capacity per unit length of wire is dependent on its diameter and surrounding material and on its distance from earthed surfaces. The inductance depends also on the wire's dimensions and on the medium surrounding it; in each case these quantities have a geometrical factor dependent on the shape and arrangement of matter, and also an essential factor dependent on the unknown but utilized properties of the ether. A capacity is usually an area divided by a thickness (or what is essentially a length, expressible in centimetres) multiplied by the specific inductive capacity of the surrounding medium, commonly called k. An inductance depends on the dimensions of wire, sometimes multiplied by the square of a number of turns, and also multiplied by the magnetic permeability of the surrounding medium, commonly denoted by μ.

In free space none of the geometrical dimensions appear; they have no significance; nothing but the two constants k and μ remain; and the velocity of wave transmission is given no longer by the product CL, as in the distortionless cable case, but by their rudimentary essentials or residues $k\mu$. In fact the velocity of waves in space, instead of being $1/\sqrt{(CL)}$, is simply $1/\sqrt{(\mu k)}$. Such velocity is quite independent of frequency or wave-length; all waves travel at the same pace.

Moreover, instead of the attenuation factor $e^{-\sqrt{(\frac{1}{2}pcR)}}$, we have simply unity, for the index is zero.

The whole transmission is effected by the elasticity and inertia-like properties of the ether, and the two fundamental equations would become :—

$$\frac{dV}{dx} + \mu\frac{dI}{dt} = 0$$

$$\frac{dI}{dx} + k\frac{dV}{dt} = 0$$

if we were entitled to write them like the wire equations, and ignore, rather absurdly, the three dimensions of space.

The true equations must be expressed in terms of magnetic field H and electric field E, and may be briefly written :—*

$$\text{curl } H = k\dot{E}$$

and $$\text{curl } E = \mu\dot{H}$$

These equations represent the essential interaction of those two fields, and exhibit the production of waves when they coincide at right angles and agree in phase. For, using the imperfect one-dimensional equations above, and combining them into one as before so as to eliminate I, we get for the propagation of potential (or of displacement currents if we eliminate V) :—

$$\frac{d^2V}{dx^2} = \mu k\frac{d^2V}{dt^2}$$

an equation well-known to represent true waves advancing with a definite and uniform speed $1/\sqrt{(\mu k)}$. These are what wireless aerials pick up, and turn their elastic displacement currents into conduction currents; such currents of course dissipate energy, but, nevertheless, they operate on the valve or other detector, either through a transformer or by direct tapping, or else they start a syntonized circuit oscillating.

* See for further explanation, if necessary, my Address to the Physical Society on "Opacity," in February 1899, *Proceedings of the Physical Society of London*, 1899, vol. 16, p. 343; or *Philosophical Magazine*, 1899, ser. 5, vol. 47, p. 407.

APPENDIX III.

NOTES ON PRACTICAL DETAILS.

By ROLLO APPLEYARD, O.B.E., J.P., Member.

In response to the request of Sir Oliver Lodge, these few notes have been put together to indicate in broad outline some of the features of telephone development. The written history is contained in innumerable technical books and papers throughout the countries of the world. To those of us, however, who, like Sir Oliver Lodge, can recall the early and subsequent triumphs of telephone engineers as exemplified by results, there is an unwritten history, even more concise and impressive, in the universal telephone-network itself, with its associated apparatus that listens and speaks so faithfully to humanity that humanity forgets the mechanism and thinks the power its own. Twenty years ago Lord Kelvin invited those who desired to learn the story of telephony, to look around. To-day, his words may be repeated as an appropriate tribute to Graham Bell. *Si monumentum requiris, circumspice.*

EXCHANGE AND SUBSCRIBERS' EQUIPMENT.

The earliest form of equipment for interconnecting subscribers followed closely that used in telegraphy, i.e. either a dial type or a peg type of switch. The calling was effected by a separate electric-bell circuit. As the number of subscribers increased, this system became too slow and too cumbersome. The standard switchboard, with spring jack and cords, was next evolved; it was more compact and more easily operated than the preceding arrangement. A battery for the calling and the speaking circuits was at first retained. With increase of distance, however, magneto calling and clearing, with drop-indicators, was introduced; but as the number of telephone users increased, the interconnections between the various standard switchboards involved complicated methods of operation with consequent delay.

The next advance was the magneto multiple-board, in which each operator at an exchange, besides having a certain assigned group of subscribers to attend to, had within reach, for interconnecting purposes, a jack field enabling each operator to connect with any subscriber in the exchange.

As this jack field involved line contacts at each jack, i.e. as each line passed through the contacts of its corresponding jack in series in each multiple field, there was trouble from dust and other causes. To overcome this, the jack connections were branched from the lines, i.e. they were put in parallel. At the same time, was also introduced the self-restoring indicator. At this stage each subscriber's apparatus comprised a receiver, a microphone, an induction coil, primary cells for speech current, a magneto-generator for the calling and clearing currents, and a switch-hook for making circuit changes.

It was realized that great saving could be brought about by transferring as much equipment as possible from the subscribers' stations to a central point, i.e. to the exchange. In accordance with this principle, the common-battery system was developed. The common-battery subscribers' set consisted only of a receiver, a microphone, an induction coil, and a switch-hook. This system had the additional merits of: (1) Centralized maintenance, because the whole battery-supply for calling, talking, and clearing is centralized at the exchange, where it is under constant care and supervision. (2) Lamp-signalling, which is more positive and effective than the drop-indicator. Moreover, with the common-battery system, transmission over the connecting cords, i.e. over the cord circuits, is much more efficient than with the preceding systems. The common-battery system is still in use throughout the world; but in districts where labour-charges and space-costs are high it is being superseded by automatics or machine-switching.

The machine-switching system, though it embodies the transmission features of the common-battery system, eliminates the human element for operation purposes, except for special services. Automatic systems employ either step-by-step or machine-driven switches. In automatic systems the subscriber's apparatus is similar to that of the common-battery system, with the addition of an impulse sender, i.e. a dial-switch. In the step-by-step system the various automatic switches that enter into a connection are actuated directly by the impulses sent from the subscriber's dial. In a power-driven system the switches are actuated by gears or clutches worked from a continuously rotated shaft; the switches are controlled, however, by a group of apparatus known as a register, which receives the current impulses from a subscriber's dial, stores them, and at the appropriate moment controls the switch movement in conformity with the setting of the register. The step-by-step system has been further developed by the introduction of the director which acts in a similar way to the register of a power-driven system, i.e. it receives the impulses from a subscriber's dial and later sends out the impulses necessary to operate the step-by-step switches.

GROWTH AND DISTANCE.

As soon as the principles and methods of transmission began to be understood, they were applied with the object of ensuring a service specified to be not inferior to a prescribed standard of "commercial speech" between any two users. For accomplishing this, several alternatives present themselves, and in any particular case it is necessary to take economic factors into account. The forecast of telephonic growth over a given period, and similar calculations, are usually comprised in a development study. Under present circumstances, preparation has to be made for future increase in the number of channels of telephonic communication, and for differences in the number and character of demands upon lines and equipment. These particulars govern such requirements as the number of operators, the number of switchboard positions, the scope of switchboards, operators' loads, and the design of line plant.

The relationship between traffic and conditions of operation depends upon certain numerical factors such as the average duration of a call, the number of subscribers allocated to each answering operator, the number

of calling switchboard positions, and the number of junctions and groups of junctions between exchanges. From this and similar data can be settled the best route for telephone traffic throughout the system.

At the time of the introduction of telephony on a commercial scale, it was the practice to erect single wires having an earth return, and to use the cheapest material, i.e. galvanized iron. With the demand for more efficient service, however, transmission requirements generally necessitated the adoption of bronze or copper wires, and the provision, for each subscriber, of a metallic circuit. Stated broadly, with growth came congestion of telephone conductors, especially towards switching centres. Moreover, with growth, the carrying limits of the poles were quickly reached, and open-wire lines became so congested that further expansions could scarcely be contemplated.

It was soon realized that in order to surmount difficulties from congestion, to reduce trouble from storms, and to secure other advantages, it would be necessary ultimately to put the telephone conductors into cable. Early telephone cables were insulated with gutta-percha or india-rubber, but the high electrostatic capacity of those materials severely limited the number of conductors that could be laid up into a cable. Cotton yarn impregnated with an insulating wax or oil and protected by a metallic envelope was tried; so also was paper. Then followed paper lead-sheathed and not impregnated, i.e. air-spaced cable. This development reduced the electrostatic capacity, it diminished the thickness necessary for the dielectric, and in consequence it enabled many more conductors to be carried in a cable of given diameter.

For use within towns for connecting subscribers to exchanges, the weight of a single conductor per statute mile may be 6½ lb., 10 lb., 20 lb., or more, according to the distance to be traversed. In the case of the 6½ lb. type, these conductors are made into cable containing up to about 1 200 pairs. The 10 lb. type may be made into cable of about 900 pairs, and the 20 lb. type into cable of about 400 pairs.

The great bulk of the world's telephone cables consists of comparatively short lengths of the types just described. These short cables, being in towns, are generally laid in ducts.

Simultaneously, with the development of local service between subscribers, just described, the growth of long-distance traffic brought about a state of congestion on pole routes between towns. The first development to relieve congestion was the phantom circuit which made possible an increase of line facilities up to 50 per cent. This was only a partial solution. The introduction of the paper-insulated, air-spaced, lead-covered cable, however, provided means to advance.

Notwithstanding all the advantages of paper as a dielectric, the length of cable through which speech could be commercially transmitted was at first limited to comparatively short distances. It was not until the suggestion by Oliver Heaviside of loading had materialized, that this difficulty was surmounted sufficiently to enable cables to be used for long-distance circuits. Loading consists in the insertion of inductance in series with the line, either "continuously," as a whipping, or "lumped" in the form of coils inserted at definite intervals. Loading of the "continuous" type is restricted chiefly to submarine cables. For long-distance land circuits, loading coils are now almost universal.

With a non-loaded cable, the attenuation rises rapidly with frequency. An important and valuable feature of the improvement due to loading is that, over a wide range of frequency, the attenuation of the loaded circuit is nearly constant.

For a given size of conductor, however, there is in practice a limit to the improvement that can be effected in this manner. This limit is reached when the cable leakance losses and the losses in the loading-coils themselves begin to predominate over the losses in the cable conductors. Further reduction of attenuation in a loaded non-repeatered circuit can only be obtained by providing heavier cable conductors, and loading coils of greater efficiency, which would involve prohibitive cost.

The next step in the development of the long cable circuit was the introduction of a device to replenish the energy in the circuit from an external source at certain space intervals—this device is the telephone repeater.

At first this was an electro-mechanical device, but it soon gave place to the more efficient thermionic-valve type, to which Sir Oliver Lodge has referred.

It might be thought that, with the installation of repeaters, loading would be rendered unnecessary. In practice it is found that the most economical solution of the problem of long-distance transmission is in the combination of the two expedients.

The distance over which a repeatered loaded circuit can be employed is limited by (1) echo currents and (2) transient phenomena. The first limitation, which was encountered on circuits extending beyond 1 000 miles, has been removed by the recently developed echo suppressor. The second limitation has not been encountered up to any length yet contemplated in practice. Phase-compensating devices have, however, been developed with a view to meeting this contingency.

To summarize the present position in regard to the interconnection between long-distance stations, the cases that arise are as follows:

(1) Where open-wire lines are sufficiently free from congestion, both inside and outside towns, to be taken direct to the exchanges.
(2) Where, by means of cables, congestion has to be avoided inside towns, but where open-wire lines are free from congestion outside towns.
(3) Where there are underground cables inside towns, and aerial cables outside.
(4) Where there are underground cables throughout the whole distance between exchanges.

In cases (2), (3) and (4) a quadded type of cable is usual, and the weight of a single conductor per statute mile is either 20 lb. or 40 lb.

In England, long-distance cables are always laid in ducts; in America such cables are more often erected aerially, and on the Continent of Europe they are as a rule armoured and laid direct in the ground. Long-

distance cables are usually made to the required size up to about 150 quads. Such cables when loaded and repeatered have been made to traverse a length of 1 000 miles and there is every reason to believe that this distance could be considerably extended.

Carrier Systems.

Although the idea of increasing the traffic capacity of telegraph lines by applying the principle of frequency discrimination was conceived long ago, it was not until the development of the three-electrode vacuum tube that multiplex systems depending upon frequency discrimination began to assume practical importance. Continuous-wave wireless telephony and wireless telegraphy, which followed the introduction of the three-electrode vacuum tube, found a counterpart in carrier telegraphy and carrier telephony applied to wire lines. A *carrier* is now recognized as being generally an alternating current which may have impressed upon it telegraph or telephone currents. To impress the carrier with the signal characteristics in this manner is to *modulate* it. The reverse process is called *demodulation*.

In telegraphy, modulation may be simply done by interrupting the carrier in accordance with the telegraph signals. In telephony, owing to the complex nature of the voice, no such simple method of modulation is possible.

When operated under suitable conditions, the three-electrode tube has a characteristic such that the output current has one component in linear relation to the input voltage, and others that are not in that relation. Of these others, the most important is proportional to the square of the input voltage, and if the input is sinusoidal it gives rise to a current of frequency double that of the input. Carrier practice is so intimately concerned with frequencies, that for brevity the language relating to this part of the subject during the last decade has extended the meaning of the word "frequency" so that, if required, it shall include the current or voltage to which it appertains.

If the input, instead of consisting of a single frequency, consists of a signal frequency and a carrier frequency, the "square" term in the equation for the output current of the three-electrode tube gives rise not only to currents of double the respective input frequencies, but also to currents of frequencies equal to both the sum and the difference, respectively, of the input frequencies. The chief result of modulation therefore is the production of frequencies corresponding respectively to carrier plus signal, and carrier minus signal.

Again, if the signal itself consists of a band of frequencies, as is the case with speech, there is produced by modulation a band of frequencies on either side of the carrier, each band being of the same width as the originating signal band. These are known as side bands, and they are sometimes considered to be the signal band itself translated in the frequency spectrum.

By employing suitably-selected carrier frequencies, a number of independent signal bands may be translated to different parts of the frequency spectrum and may thereafter be impressed upon a common transmission line, at the receiving end of which they may be separated by means of circuits depending for their operation on frequency discrimination. By a process similar to that employed at the transmitting end, the selected side-band currents may be reconverted into the original signal band.

While in the case of radio receiving circuits it has been usual to employ simple tuned circuits for frequency discrimination, for line carrier systems this is not very satisfactory; for since only relatively low frequencies are suitable for transmission over lines, the various bands must be closely spaced in order to make the best use of the frequency range available. On account of the relatively low carrier frequencies used, the ratio of band width to carrier frequency is large. Consequently, as with tuned circuits all frequencies in the band will not be equally affected, distortion would result. It is therefore the practice to employ electric wave filters which can be designed to select a wide band of frequencies without distortion and to discriminate effectively between closely adjacent frequencies. The development of these wave filters has been one of the principal factors in the success of the present carrier systems.

The following different types of carrier systems are now in use:—

(1) Voice-frequency cable carrier telegraph.
(2) High-frequency open-wire carrier telegraph.
(3) High-frequency open-wire carrier telephone.
(4) High-frequency power-line carrier telephone.

Systems (2) and (3) are suitable for use on open-wire lines to provide traffic channels in addition to those provided by the normal telephone and telegraph circuits. On account of the characteristics of modern loaded cables neither of these systems is suitable for use on underground circuits. For this reason, system (1) has been developed to provide a number of telegraph channels in place of one telephone channel.

The extent to which carrier systems may be employed for increasing the traffic capacity of existing lines depends on the relative cost of providing equivalent facilities by new line construction. This normally limits these systems to distances not less than one or two hundred miles, but cases may arise where they will enable the construction of a new pole route or cable to be deferred for a number of years, in which case they may be justified for considerably smaller distances.

That these systems play an important part in the provision of the world's telephone facilities may be seen from the following table, which gives approximate information concerning high-frequency open-wire carrier systems in service at the end of 1925.

Total number of systems in service	100
Total system mileage	45 000
Total number of telephone channels provided	170
Total number of telegraph channels provided	400
Telephone channel miles	60 000
Telegraph channel miles (duplex)	210 000

The Composite System.

An important step in the direction of economy of line plant has been the development of the so-called

"composite system" in which combined telephone and telegraph operation is secured over the same conductors. The principle involved is frequency discrimination, the composite set being merely a network of inductances and condensers which divides the line into two branches, one for the telephone and another for the telegraph. The two line conductors are connected to two filters, one of which permits only current within the speech range of frequency to pass, and the other permits only frequencies between zero and about 80 cycles per second to pass. Fast hand-speed telegraph working is only about 16 cycles per second. Speech, as usually transmitted by telephone, covers a range of the order 200 cycles to 2 500 cycles per second, and it is because of this distinction that the separation of the telephone and the telegraph currents is practicable.

The composite system is in daily use over the longest circuits in the United States, and more than 600 000 miles of telegraph circuits in accordance with this system are in operation. The average length of the circuits is about 700 miles, and one circuit is over 4 000 miles with 17 repeater stations intervening.

The composite system differs from the high-frequency carrier telegraph or telephone system in that the superposed communication in the composite system occupies a range of frequencies *below* that occupied by speech, instead of *above* as in the case of carrier systems. It is possible in practice to operate the composite system and the carrier system simultaneously on the same conductors.

The Transmission of Pictures over Telephone Lines.

Ever since the introduction of the electric telegraph many investigators have endeavoured to develop a system whereby facsimiles of documents or of photographs might be obtained at a distant station by electrical transmission. The simpler of the systems arrived at usually involve an application of the principle of the electric telegraph in which the received record is a series of dots and dashes, constituting a two-tone record of black and white, where the dark and light greys are effectively obtained by the spacing of the dots as in newspaper photographic reproductions. In many cases these processes give good results, but they fail to provide the fine detail and resolution of a good photograph.

Good resolution entails the transmission of rapid changes of illumination, i.e. of relatively high frequencies. For this fundamental reason, telephone circuits have been found to be suitable as transmission media.

Telephoto systems consist essentially of a light-sensitive cell upon which are incident light rays that vary in intensity with the density of a slowly moving photographic transparency of the subject-matter to be transmitted. In some cases the light-sensitive cell and the photographic transparency have been replaced by a moving coil with an attached stylus that traverses a chemical depth-record of the subject-matter. After amplification, the minute voltage variations set up in the photo-electric cell, or similar apparatus, are transmitted to the receiving end, where they are caused to control the light emitted from some fixed source. This control arrangement may be regarded as a light valve. Light thus controlled, in accordance with the density of the original, is caused to act upon a photographic blank which moves in synchronism with the sending-end record. The result is a photographic reproduction of the original.

The light valve may take the form of a string galvanometer—a moving-coil oscillograph—or it may be an electro-optical device, utilizing the phenomenon of electrical double refraction in a manner similar to the decomposition of polarized light into two components of different velocity of propagation. Difficulties at first presented themselves with reference to the construction and adjustment of the apparatus, and the maintenance of synchronism. Persistent efforts, however, have so successfully solved the problems, that to-day there are in Europe and America several systems in commercial operation. Pictures have in this manner been transmitted satisfactorily over telephone lines for more than 3 000 miles. With radio-transmission, chiefly on account of the properties of the transmitting medium, the results have been less perfect.

Wireless Telephony.

At the meeting of the British Association in 1882, attention was directed to a telephone receiver which had then recently been devised by Prof. A. E. Dolbear. The instrument depended entirely upon electrostatic forces, and it consisted simply of two metal diaphragms rigidly fixed parallel to one another, close together, but not touching, in an insulated case of ebonite. When telephonic voltages were applied to the diaphragms, sonorous vibrations were obtained, with consequent reproduction of speech. The fact that the empty space between the diaphragms was traversed by telephonic impulses, may have suggested the extension of this distance.* Twenty years later R. A. Fessenden obtained a patent for voice modulation of nearly continuous waves, and he led the way to the present wireless carrier system. Throughout the world, investigators then attacked the problem in various ways. Success of a decisive character was achieved in 1912 by Prof. Giuseppe Vanni, of Rome, who transmitted speech sounds by wireless telephony between Rome and Treviso (420 km), and between Rome and Tripolo (1 000 km). In the following year it was announced that German experimenters had established wireless telephony between Berlin and Nauen. These and many other endeavours culminated on the 30th September, 1915, in the transmission of speech and music from the United States naval establishment at Arlington (Washington) to Honolulu. On the 23rd October, 1915, a successful demonstration was given of radio-telephone transmission from Arlington to Paris.

In principle, wireless telephony differs from carrier transmission over wires in little else than in the fact that it employs a different medium and higher carrier frequencies. It consists first in the production of a carrier wave of limits in practice usually of the order of between 50 and 15 000 kilocycles a second. The power delivered to the antenna varies from a few watts to several hundred kilowatts. The modulation of this carrier wave in accordance with speech waves is effected

* See *Journal of the Society of Telegraph Engineers and of Electricians*, 1882, vol. 11 p. 130.

by means of a microphone which, in powerful transmitters, is associated with vacuum tube amplifiers by means of which the voice currents are built up in successive stages until they become sufficiently powerful to control the radio carrier wave. Modulation of the carrier in wireless telephony produces two bands of waves, one of lower and the other of higher frequency than the carrier. In the ordinary method of transmission, as used for example when broadcasting, all these three components, i.e. the carrier and the two side-bands, are impressed upon the antenna and are radiated. It is generally considered that the carrier component itself contains two-thirds of the total energy transmitted. The two side-bands together occupy twice the frequency range needed for the transmission of all audible sounds.

In the high-power transatlantic radio-telephone station, at present under test, a new system of transmission is adopted in which only one side-band is radiated. The carrier and the undesired side-band are suppressed at the transmitting station and the amount of carrier necessary to render the signal audible is re-introduced by a local oscillator at the receiving station. Besides the high efficiency obtained in consequence of this suppression, the system has other advantages. The effects of fading are reduced, and the problem of designing a satisfactory antenna is made less difficult. The vacuum tubes at the Rugby station, in the last stage of the radio transmitter, are of the 10 kW water-cooled type. The final stage of amplification is effected by two groups each containing 15 of these high-power tubes. This station made possible the provision of two-way telephonic conversation—trustworthy and continuous—across the Atlantic: a task successfully accomplished for the first time on Sunday, 7th February, 1926, and publicly demonstrated a month later, just 50 years after the establishment of Graham Bell's invention on a practical basis—a fitting tribute to his imperishable memory.

Bibliography to Appendix III.

The following list of books relating to telephony includes some standard treatises. Most of them contain references to papers relating to the various branches of the subject in technical and scientific journals.

THE MAGNETIC FIELD OF THE DYNAMO-ELECTRIC MACHINE.*

By F. W. CARTER, M.A., Sc.D., Member.

(*Paper first received* 16*th January, and in final form* 25*th February,* 1926.)

SUMMARY.

The first portion of the paper is for the most part written around the subject of the reluctance of the magnetic circuit, particularly of the air-gap and teeth. Other matters are, however, referred to, such as that of the shape of the curve of flux traversed by the armature conductors, and that of the flux variation along the pole-face. Much of the analysis was indeed originally developed with other ends in view, such as the determination of harmonics in the e.m.f. wave, of losses in the pole-face and elsewhere, or the investigation of the cause of noises and like incidental effects of the magnetic changes. These are for the most part particular applications of the analysis.

The determination of the reluctance of the gap is made to depend on two factors; one, an equivalent length, which has, in the normal portion of the gap, the same reluctance per unit area as the actual gap; the other, an equivalent area, made up of the area of the radial projection of the normal gap on the cylindrical surface midway between armature and field, with additions for the fringe effects at the boundaries, and, where necessary, reductions to take account of ducts and band recesses. The magnetization of teeth is also discussed.

The second part of the paper deals particularly with slots in which conductors carrying currents are located. The subjects of distributed excitation and of the reaction of the load on the exciting field are here discussed. Finally the reactance of the imbedded conductors is investigated.

A number of Appendices deal with details of the calculations.

(1) INTRODUCTION.

The designer of electrical machinery usually endeavours, in his primary calculations, to follow a rational scheme, based on sound physical assumptions; but in many secondary matters he is compelled to resort to methods of an empirical or imperfectly reasoned nature, which in some instances have little relation to facts. In reality he relies on his experience to bring the performance of the machine sufficiently near to his purpose to be within the limits of toleration permitted to him. It is the object of the present paper to examine some of the secondary problems of design, and to establish the calculations as far as possible on a rational basis, with the double purpose of assisting the designer and of elucidating some of the more recondite actions of the machinery. The problems which form the subject of the paper are concerned with the magnetic field, which it is proposed to discuss with greater particularity than has hitherto been attempted.

A large part of the paper is based on the use of conjugate functions in the solution of two-dimensional problems involving equipotential and flux-line boundaries.* Such use has long been current among physicists, but it seems to have been reserved for the author to initiate their application to practical problems of machine design,† and some of his results are now in general use among designers. Other results have been established at various times but not hitherto published, while others have been developed to give completeness to the present paper. Certain problems germane to the subject but using other methods are also discussed.

It need hardly be pointed out that a solution of so complicated a magnetic problem as is presented by an

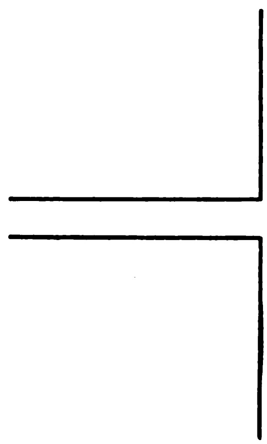

FIG. 1.

electric machine is not attainable. The most that can be expected is that the problem may be divisible, and a number of solutions obtainable, each substantially correct in a limited region. Here, however, an obvious precaution may be mentioned; it is not possible to combine such partial solutions unless, in the neighbourhood of the common boundary of any two of the limited regions considered, the lines of force and equipotential lines may, without sensible error, be considered as belonging indifferently to either of the regions. Neglect of this has led to the publication of some very misleading results.

Another matter to which attention may be directed arises from the fact that, in most practical problems, some of the boundaries have to be assumed to extend to infinity in certain directions; and, in most cases, the total flux dealt with is infinite. Unless, therefore,

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

* See MAXWELL: "Electricity and Magnetism," ch. 12; and JEANS: "Electricity and Magnetism," ch. 8, par. 306 *et seq.*; see also Appendix I.

† F. W. CARTER: "Note on Air-Gap and Interpolar Induction," *Journal I.E.E.*, 1900, vol. 29, p. 925; also "Air-Gap Induction," *Electrical World and Engineer*, 1901, vol. 38, p. 884.

the boundaries can be so arranged that the portion of the flux with which the problem is concerned is localized and suitably delimited, the solution is a matter of judgment rather than of calculation. Consider, for instance, the case of an iron-core reactance having an air-gap. The edge of the gap may be represented by a pair of opposing faces, with flanks extending to infinity (Fig. 1), and the field near the gap may be computed from this representation. The flux in the gap becomes uniform at a short distance from the edge, and this portion of the field presents no difficulty. But the fringe flux is infinite in amount, and has no natural limit short of infinity. A general solution is therefore impossible in this case; the whole magnetic circuit is involved in the problem, which is thus of a particular nature and outside the purpose of the present paper (see Appendix 2).

(2) Curvature of Surfaces.

The problems to be considered are concerned with regions bounded by planes; whereas the actual regions are in most cases bounded, in part, by cylindrical surfaces. In some of the problems the region under consideration occupies so small a fraction of the circumference that the curvature is negligible. In others, as in the interpolar fringe, the divergence is only sensible where the field is weak, so that its effect is small. The determination of the reluctance of the air-gap, however, presupposes a radius on which its area is measured, and the chief effect of curvature is provided for in the proper choice of this radius.

Consider the case of a smooth armature of radius a and at potential zero, surrounded concentrically by a smooth field of radius $a + g$, at unity potential. The potential function is

$$\phi = \frac{\log \dfrac{r}{a}}{\log \left(\dfrac{a+g}{a}\right)} \quad . \quad . \quad . \quad . \quad (1)$$

The total flux is $2\pi/\log [(a + g)/a]$, and, if this be written $2\pi R/g$,

$$R = \frac{g}{\log\left(1 + \dfrac{g}{a}\right)}$$
$$= a + \tfrac{1}{2}g \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

when g/a is small. Thus the area should be reckoned at the middle of the air-gap. This, however, does not settle the question when one or both of the opposing surfaces are slotted, for the gap has then to be defined. The following may serve to throw light on the matter.

Assume, as potential function :—

$$\phi = \frac{c \log \dfrac{r}{c-\frac{1}{2}g} + \frac{1}{2}\lambda g\left[\left(\dfrac{r}{c-\frac{1}{2}g}\right)^{n} - \left(\dfrac{r}{c-\frac{1}{2}g}\right)^{-n}\right]\cos n\theta}{c \log \dfrac{c+\frac{1}{2}g}{c-\frac{1}{2}g} + \frac{1}{2}\lambda g\left[\left(\dfrac{c+\frac{1}{2}g}{c-\frac{1}{2}g}\right)^{n} - \left(\dfrac{c+\frac{1}{2}g}{c-\frac{1}{2}g}\right)^{-n}\right]} \quad (3)$$

This, with a certain limitation in the size of the constant λ, and with n a whole number, gives the distribution between a pair of concentric boundaries, the inner one smooth, of radius $c - \frac{1}{2}g$, and at zero potential; the outer one corrugated, of minimum radius $c + \frac{1}{2}g$, and at unity potential. The denominator of ϕ in (3) is, to the second order in g/c—which may be assumed small—

$$g\left[1 + \lambda \sinh \frac{ng}{c}\right] \quad . \quad . \quad . \quad . \quad (4)$$

The mean value of the radial force at radius c is accordingly, to the second order in g/c

$$\frac{1}{g\left[1 + \lambda \sinh \dfrac{ng}{c}\right]} \quad . \quad . \quad . \quad . \quad (5)$$

The quantity designated the equivalent gap in this paper, is the reciprocal of the mean value of radial force per unit difference of potential between the sides of the gap, when the radius is made infinite. Calling this quantity G, in the present instance

$$G = g\left[1 + \lambda \sinh \frac{ng}{c}\right] \quad . \quad . \quad . \quad (6)$$

If R is the radius sought, the total flux is

$$\frac{2\pi R}{G} = \int_0^{2\pi} \frac{d\phi}{dr} r\, d\theta = \frac{2\pi c}{g\left[1 + \lambda \sinh \dfrac{ng}{c}\right]} \quad . \quad . \quad (7)$$

Accordingly $R = c$, or the area of the field should be reckoned at the middle of the minimum gap. The problem is, of course, a particular one, furnishing evidence rather than proof of the conclusion as applied to machine design.

(3) Equivalent Gap with One Surface Slotted.

In the *Electrical World* article cited on page 1115, the equivalent gap, or the uniform gap having the same mean reluctance per unit area as the slotted gap, was deduced from the consideration of a single slot, of width s and of infinite depth, in one of the opposing equipotential surfaces (see Fig. 2). The effect of the slot was shown to be equivalent to annulling a certain fraction, σ, of its width given by

$$\sigma s = \frac{2}{\pi}\left\{s \arc\tan\left(\frac{s}{2g}\right) - g \log\left[1 + \left(\frac{s}{2g}\right)^2\right]\right\} \quad (8)$$

Accordingly, if t is the width of the tooth (at the crown), and G the equivalent gap

$$\frac{t+s}{G} = \frac{t+s-\sigma s}{g} \quad . \quad . \quad . \quad . \quad (9)$$

or

$$G = \frac{t+s}{t+s-\sigma s} g \quad . \quad . \quad . \quad . \quad (10)$$

The curve connecting σ and s/g is reproduced in Fig. 3.

The transformation between the plane of z and the plane of ζ may be written:

$$z = \frac{g}{\pi}\int\frac{\sqrt{[(\zeta+\lambda)(\zeta+\lambda^{-1})]}}{\zeta(\zeta+1)}d\zeta$$
$$= \frac{1}{\pi}\left\{g\left[\operatorname{arc\,cosh}\frac{2\zeta+\lambda+\lambda^{-1}}{\lambda-\lambda^{-1}} - \operatorname{arc\,cosh}\frac{2\zeta^{-1}+\lambda+\lambda^{-1}}{\lambda-\lambda^{-1}}\right] + s\operatorname{arc\,cos}\left(\frac{1-\zeta}{1+\zeta}\cdot\frac{\lambda-1}{\lambda+1}\right)\right\} \quad . \quad (11)$$

in which
$$\frac{s}{g} = \lambda^{\frac{1}{2}} - \lambda^{-\frac{1}{2}} \quad . \quad . \quad . \quad . \quad . \quad (12)$$

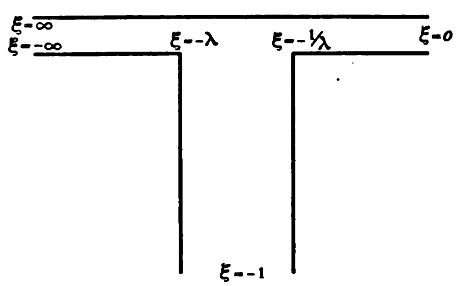

FIG. 2.

The force at the pole-face is given by

$$F = \frac{1+\zeta}{g[(\zeta+\lambda)(\zeta+\lambda^{-1})]^{\frac{1}{2}}} \quad . \quad . \quad . \quad (13)$$

the location being given in terms of the same parameter ζ by equation (11). The variation of this force is accordingly from a maximum of $1/g$ to a minimum of $1/g[1+(s/2g)^2]^{\frac{1}{2}}$. This has an important application in the computation of the pole-face losses.*

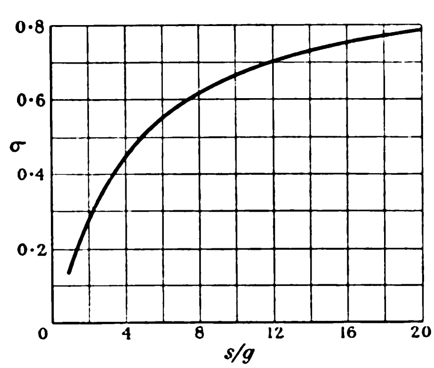

FIG. 3.

The solution thus obtained, although based on an unattainable ideal, satisfies fully the needs of the designer. It is true that the slot is assumed of infinite depth; but, inasmuch as the field hardly penetrates beyond the mouth, this is of no consequence. In the case of partially closed slots, indeed, s should be taken as the width at the mouth. The region considered has been cut off on each side at the position of the centre of the tooth, and other regions of half tooth and slot applied, thus introducing some discontinuity in the field. It is possible, however, to give a solution which avoids the discontinuity, and thereby to show that it is of little consequence.

The problem now proposed is that of determining the field between the plane and slotted equipotential surfaces shown in Fig. 4. A feature of the problem is that the median lines of tooth and slot, where they cross the gap, are flux lines; and the area bounded by these lines, by the half tooth and the plane equipotential, can be segregated without altering the problem.

Consider the range of points C′, B′, A′, O, A, B, C on the real axis, shown in Fig. 5, these being disposed symmetrically about O. Write k for OA/OB, and sn α for OB/OC. The transformation

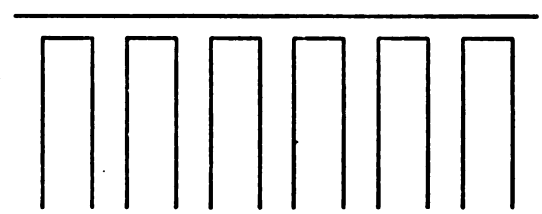

FIG. 4

$$z = M\int\left(\frac{1-k^2\zeta^2}{1-\zeta^2}\right)^{\frac{1}{2}}\frac{d\zeta}{1-k^2\operatorname{sn}^2\alpha\zeta^2} \quad . \quad . \quad (14)$$

converts the half-plane of ζ into the plane of z bounded as shown in Fig. 6.

The field determined by

$$\chi = \phi + j\psi = \frac{1}{F}\int\frac{d\zeta}{[(1-\zeta^2)(1-k^2\operatorname{sn}^2\alpha\zeta^2)]^{\frac{1}{2}}} \quad . \quad (15)$$

in which ϕ is the potential function and ψ the flux function, represents a system in the plane of ζ (Fig. 5) in which AC and A′C′ are at equal and opposite unity potentials, in which AA′ is a flux line and C ∞ C′ also a flux line.* In the plane of z accordingly (Fig. 6) AA′ and CC′ are flux lines, and ABC, A′B′C′, equi-

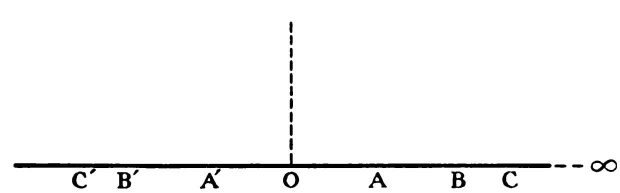

FIG. 5.—Plane of ζ.

* F. W. CARTER: "Pole-Face Losses" *Journal I.E.E.* 1916, vol. 54, p. 168.

* This, as a problem in electrostatics, is discussed in J. J. Thomson's "Recent Researches in Electricity and Magnetism," ch. 3, par. 245. The field in the plane of z is plotted in a paper entitled "The Calculation of Air-space Flux," by Prof. W. Cramp and Miss N. I. Calderwood, *Journal I.E.E.*, 1923, vol. 61 p. 1063.

potentials at equal and opposite unity potentials. The total flux between ABC and A′B′C′ is:

$$\psi_0 = \frac{1}{F}\int_1^{1/k\,\mathrm{sn}\,\alpha} \frac{d\zeta}{[(\zeta^2-1)(1-k^2\,\mathrm{sn}^2\,\alpha\,\zeta^2)]^{\frac{1}{2}}}$$

$$= \frac{F'}{F} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (16)$$

The change in z as ζ passes through C is [see equation (14)]:—

$$\tfrac{1}{2}js = M\frac{\pi}{2}\cdot\frac{\mathrm{cn}\,\alpha}{\mathrm{sn}\,\alpha\,\mathrm{dn}\,\alpha}j \quad . \quad . \quad . \quad (17)$$

The change in z between O and B is, writing $\zeta = \mathrm{sn}\,u$ in equation (14),

$$g+\tfrac{1}{2}jt$$

$$= M\int_0^{K+jK'} \frac{1-k^2\,\mathrm{sn}^2\,u}{1-k^2\,\mathrm{sn}^2\,\alpha\,\mathrm{sn}^2\,u}du$$

$$= M\left\{K+jK' - \int_0^{K+jK'} \frac{k^2\,\mathrm{cn}^2\,\alpha\,\mathrm{sn}^2\,u}{1-k^2\,\mathrm{sn}^2\,\alpha\,\mathrm{sn}^2\,u}du\right\}$$

$$= M\left\{K+jK' - \frac{\mathrm{cn}\,\alpha}{\mathrm{sn}\,\alpha\,\mathrm{dn}\,\alpha}\Pi(K+jK',\alpha)\right\}$$

$$= M\left\{K+jK' - \frac{\mathrm{cn}\,\alpha}{\mathrm{sn}\,\alpha\,\mathrm{dn}\,\alpha}\left[(K+jK')Z(\alpha)+j\frac{\pi}{2}\cdot\frac{\alpha}{K}\right]\right\} \quad (18)$$

From equation (15) we have

$$\frac{d\chi}{d\zeta} = \frac{1}{F}\cdot\frac{1}{[(1-\zeta^2)(1-k^2\,\mathrm{sn}^2\,\alpha\,\zeta^2)]^{\frac{1}{2}}}$$

From equation (14)

$$\frac{dz}{d\zeta} = M\left(\frac{1-k^2\zeta^2}{1-\zeta^2}\right)^{\frac{1}{2}}\frac{1}{1-k^2\,\mathrm{sn}^2\alpha\zeta^2}$$

Whence
$$\frac{d\chi}{dz} = \frac{1}{MF}\left(\frac{1-k^2\,\mathrm{sn}^2\,\alpha\,\zeta^2}{1-k^2\zeta^2}\right)^{\frac{1}{2}} \quad . \quad . \quad . \quad (23)$$

in which, if absolute values are required, the value of M may be written [equation (18)]

$$M = \frac{g}{K\left[1-\frac{\mathrm{cn}\,\alpha}{\mathrm{sn}\,\alpha\,\mathrm{dn}\,\alpha}Z(\alpha)\right]} \quad . \quad . \quad (24)$$

The imaginary axis in Fig. 5, which is the equipotential line at zero potential, becomes the unslotted pole-face in Figs. 4 and 6. Equation (23), in which $\zeta = j\eta$, gives the density of the field at this face, the position being given by equation (14). Opposite the centre of the tooth ($\eta = 0$) the field is at its maximum, and opposite the centre of the slot ($\eta = \infty$) at its minimum. The ratio of the minimum to maximum field is therefore as $\mathrm{sn}\,\alpha : 1$.

The chief difficulty in applying the results of this investigation lies in the determination of k and α to give specified proportions to the parts, through equations (19) and (20). Fortunately, the previous investigation differs so little in its results from the present that, in any ordinary case, a close approximation to k and α is immediately deducible from it. Thus, comparing equations (9) and (21):

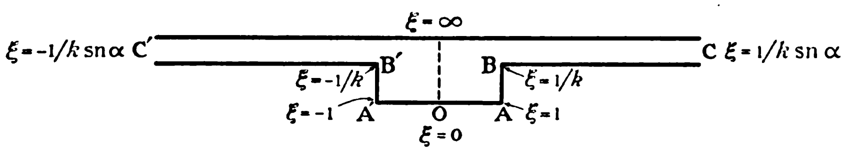

FIG. 6.—Plane of z.

whence
$$\frac{2g}{s} = \frac{2}{\pi}K\left[\frac{\mathrm{sn}\,\alpha\,\mathrm{dn}\,\alpha}{\mathrm{cn}\,\alpha} - Z(\alpha)\right] \quad . \quad . \quad (19)$$

$$\frac{t}{s} = \frac{2}{\pi}K'\left[\frac{\mathrm{sn}\,\alpha\,\mathrm{dn}\,\alpha}{\mathrm{cn}\,\alpha} - Z(\alpha)\right] - \frac{\alpha}{K} \quad . \quad . \quad (20)$$

If G is the equivalent gap [equation (16)]

$$\psi_0 = \frac{F'}{F} = \frac{t+s}{2G} \quad . \quad . \quad . \quad . \quad (21)$$

and the slot factor, or gap coefficient, is

$$\frac{G}{g} = \frac{F}{F'}\cdot\frac{t+s}{2g}$$

$$= \frac{F}{F'}\left\{\frac{K'}{K}+\frac{\pi}{2}\cdot\frac{1-\frac{\alpha}{K}}{\frac{\mathrm{sn}\,\alpha\,\mathrm{dn}\,\alpha}{\mathrm{cn}\,\alpha}-Z(\alpha)}\right\} \quad . \quad . \quad (22)$$

It should be noted that the modulus of the complete elliptic integrals F and F' is $k\,\mathrm{sn}\,\alpha$, all other elliptic functions having modulus k.

$$\frac{t+s}{2G} = \frac{F'}{F} = \frac{t+s-\sigma s}{2g} \quad . \quad . \quad . \quad (25)$$

and from a table of complete elliptic functions the modulus, $k\,\mathrm{sn}\,\alpha$, can be found. Again, from equations (13) and (23) we find, by considering the ratio of the minimum to maximum field,

$$\mathrm{sn}\,\alpha = \left[1+\left(\frac{s}{2g}\right)^2\right]^{-\frac{1}{2}} \text{ approx.} \quad . \quad . \quad (26)$$

A specimen calculation is given in Appendix 3.

(4) EQUIVALENT GAP WITH BOTH SURFACES SLOTTED.

When both of the opposing equipotential surfaces are slotted, the problem is complicated, and an exact solution hardly to be expected. This case was discussed

in a short article contributed to the *Electrician* some years ago,* but the reasoning is here presented more fully. It assumes the disturbance produced by a slot to be strictly local, a condition sensibly fulfilled, for the purpose in view, in most cases, and notably in the large class in which the air-gap is small and the slot in one of the members semi-closed.

If s_1 and s_2 are the widths of the opposing slots, the

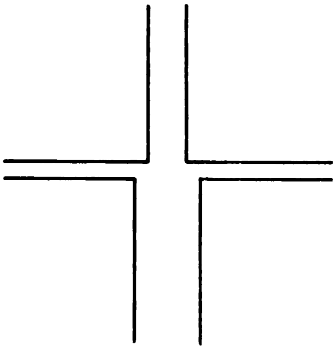

FIG. 7.

amount of periphery that must be annulled to allow for the slots when exactly opposing, as in Fig. 7,† is

$$w=\frac{2}{\pi}\left\{\frac{s_1+s_2}{2}\arctan\frac{s_1+s_2}{2g}+\frac{s_1-s_2}{2}\arctan\frac{s_1-s_2}{2g}\right.$$
$$\left.-\frac{g}{2}\log\left[1+\left(\frac{s_1+s_2}{2g}\right)^2\right]\left[1+\left(\frac{s_1-s_2}{2}\right)^2\right]\right\} \quad (27)$$

If w_1 and w_2 are given by the same equation with s_2 and s_1 put zero in turn,‡ $w_1 + w_2$ is the amount that must be annulled when the slots are remote from one

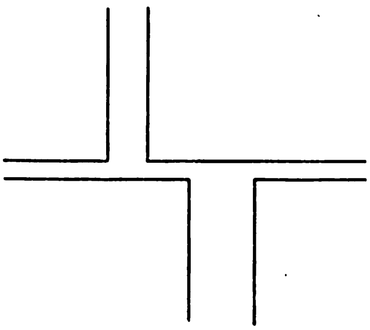

FIG. 8.

another (Fig. 8). The total decrease in the permeance of the gap as the slots are displaced from opposite to remote relation is accordingly $(w_1 + w_2 - w)/g$; and the curve of variation plotted against displacement takes the general form of Fig. 9. If the area of this curve be divided by the total variation of the ordinate, a linear magnitude c is determined which is such that, for the purpose in view, the slots may be considered opposite as long as their centres are not more than $\frac{1}{2}c$ apart, and remote for the remainder of the pitch. If a_1, a_2 are the slot-pitches in the two members respectively, c/a_1 is the proportion of slots of the second member that are opposite those of the first; and $c/(a_1a_2)$ the number of opposite slots per unit length of periphery, the remainder, or $(1/a_2) - [c/(a_1a_2)]$, being remote.

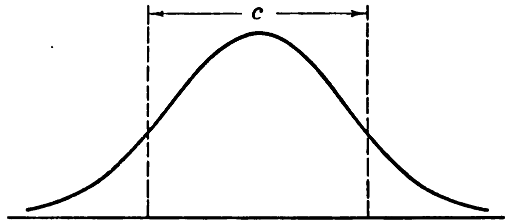

FIG. 9.

The unit length is therefore diminished in effect to the value—the reciprocal of the air-gap coefficient—

$$\begin{aligned}\frac{1}{k} &= 1-\left(\frac{1}{a_1}-\frac{c}{a_1a_2}\right)w_1-\left(\frac{1}{a_2}-\frac{c}{a_1a_2}\right)w_2-\frac{c}{a_1a_2}w\\ &=\left(1-\frac{w_1}{a_1}\right)\left(1-\frac{w_2}{a_2}\right)+\frac{c(w_1+w_2-w)-w_1w_2}{a_1a_2}\\ &=\frac{1}{k_1k_2}+\frac{c(w_1+w_2-w)-w_1w_2}{a_1a_2} \quad . \quad . \quad . \quad . \quad (28)\end{aligned}$$

where k_1, k_2 are the respective gap coefficients of the members when the other is assumed unslotted.

FIG. 10.—Plane of ζ.

The calculation of c in the general case of rectangular slots in the members is hardly practicable; but an analogous problem of gaps in opposing planes probably meets all requirements.

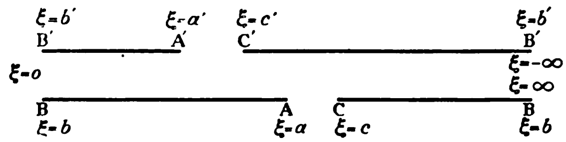

FIG. 11.—Plane of z.

The transformation

$$z=\int\frac{(\zeta-a)\,(\zeta-c)\,(\zeta-a')\,(\zeta-c')}{\zeta(\zeta-b)^2\,(\zeta-b')^2}d\zeta \quad . \quad (29)$$

with the relations *

$$\left.\begin{aligned}\frac{1}{b-a}+\frac{1}{b-c}+\frac{1}{b-a'}+\frac{1}{b-c'}-\frac{1}{b}-\frac{2}{b-b'}=0\\ \frac{1}{b'-a}+\frac{1}{b'-c}+\frac{1}{b'-a'}+\frac{1}{b'-c'}-\frac{1}{b'}-\frac{2}{b'-b}=0\end{aligned}\right\}(30)$$

convert the positive half-plane of ζ (Fig. 10) into the plane of z (Fig. 11); and, together with the field functions,

$$\phi + j\psi = \frac{j}{\pi}\log\zeta \quad . \quad . \quad . \quad . \quad (31)$$

* *Electrician*, 1918, vol. 81, p. 400.

‡ See equation (8).

* These are the conditions that the pairs of lines AB, BC, and A′B′, B′C′ are respectively collinear.

gives the required solution; viz. a pair of equipotential planes, differing in potential by unity, in which are gaps of dimensions and location depending on the values of the constants. For the designer's purpose, however, the result is of small value, as the connection between his data and the constants is too involved.

The problem is simplified when the gaps in the opposing planes are equal. In this case

$$ac' = a'c = bb'$$

and the two relations of equations (30) become identical. The data are now expressible in terms of two quantities, and by a process of cross-plotting the curve of variation of flux can be obtained. The calculation is somewhat tedious and need not be reproduced here. A few cases have been worked out and the results are given in Table 1, together with the numerator of the last term in equation (28).

TABLE 1.

$\frac{s}{g}$	$\frac{c}{s}$	$\frac{c(w_1+w_2-w)-w_1w_2}{s^2}$
2	1·25	0·061
3	1·13	0·088
4	1·07	0·099

As a typical case, assume $a_1/s = 2$, $a_2/s = 2·5$; Table 2 gives the gap coefficients, k_1 and k_2 from equation (10) and k from equation (28): k_1k_2 and $k_1 + k_2 - 1$, which may be regarded as approximations to k, are also given. It would seem that the approximation $k = k_1 + k_2 - 1$, is the better, although tending a little towards the low side. Designers generally appear to favour the approximation $k = k_1k_2$.

(5) RELUCTANCE OF TEETH.

The present paper deals for the most part with the field in air-spaces; but the subject of the reluctance of the teeth is a cognate one, and moreover necessary to the discussion on account of its reaction on the field in the gap. Where the flux density in the tooth is low, the magnetizing force required is insignificant compared with that needed for the air-gap; and the usual designers' rule of treating the density as uniform at its value one-third of the distance from the root of the tooth allows approximately for the varying saturation. But where, as in the class of machinery with the design of which the author has been most closely associated,* the density at the root of the tooth may amount to 27 000 lines per cm^2, the magnetizing force required for the teeth is comparable with that needed for the gap, and a more reasonable practice is desirable. The author has used the following method since 1912,* with results which agree very well with experience.

Before entering upon the discussion, however, it is expedient to dispose of a small matter of detail. This is the effective length of the teeth, particularly those on the outside of the cylindrical surface. It is usual to consider only the portion between crown and root of the tooth; thus, in the case of outside teeth, extending the problem to the point where the magnetic density is greatest, and no further. It is more reasonable, for the present purpose, to assume that the tooth extends to where the density is reduced to the value it has at the crown. In Fig. 12, if n is the number of teeth in the periphery, l the length from crown to root, l' the effective length, t and r the widths at crown and root

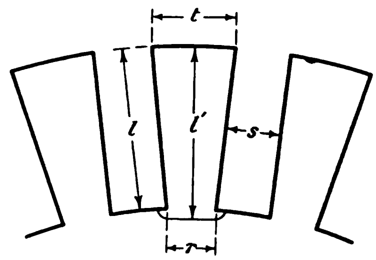

FIG. 12.

respectively, then, in accordance with the above assumption,

$$t = r + (l' - l)\left(\pi - \frac{2\pi}{n}\right) \quad . \quad . \quad . \quad (32)$$

but

$$\frac{(t-r)}{l} = \frac{2\pi}{n} \quad . \quad . \quad . \quad . \quad . \quad (33)$$

hence

$$l' = l + l\frac{2\pi}{n} \cdot \frac{n}{(n-2)\pi} = \frac{n}{n-2}l \quad . \quad (34)$$

When the flux density in the teeth is great, an appreciable flux is carried in the slots. It is usually assumed by designers that this can be computed by taking the difference in magnetic potential between the pole-face and bottom of slot, and dividing by the distance which separates these parts. This is far from being a reasonable assumption; the greater part of the difference of potential is used in the interval between the pole-face and level of the tooth crowns, in which the field follows closely that computed on the assumption of infinite permeability in the iron. The field in the slot consists chiefly of leakage lines from sides to bottom. The strength of the field at any level in the slot may be deduced approximately from the consideration that the tangential magnetic force is continuous through the side of the slot. Thus, in Fig. 12, if w is the width of the tooth at any level, s the (constant) width of the

* Railway motors. The figure given is computed in the conventional manner, i.e. on the assumption that the whole flux passes in the iron.

* The subject was recently discussed in a somewhat similar manner by J. ROCHE: "Détermination des Ampère-tours nécessaires à l'Alimentation des Dents et des Pertes dans les Dents," *Revue Générale de l'Électricité*, 1923, vol. 13, p. 563. See also W. B. HIRD: "The Reluctance of the Teeth in a Slotted Armature," *Journal I.E.E.*, 1900, vol. 29, p. 933

slot, B the density in the iron, H the corresponding magnetic force, and λ the ratio of iron volume to core volume (usually about 0·9 for 0·625 mm laminations), then

$$N = [\lambda B + (1 - \lambda)H]w + Hs \quad . \quad . \quad (35)$$

represents the flux carried by one tooth and slot, per unit length of core; and this, under the pole, is constant from top to bottom of the tooth. The quantity $\lambda B + (1 - \lambda)H$ is immediately deducible from the B, H curve of the iron (Fig. 13) and represents the average flux density in the laminated structure. It is here designated B', and equation (35) may be written

$$N = B'w + Hs \quad . \quad . \quad . \quad . \quad (36)$$

Using the same notation as before, viz. l for length of tooth, t and r for width of crown and root respectively, the distance x of the section w from the crown is given by

$$\frac{x}{l} = \frac{t - w}{t - r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (37)$$

Eliminating w from equation (36) we get

$$B'\left[t - \frac{x(t - r)}{l}\right] + Hs = N$$

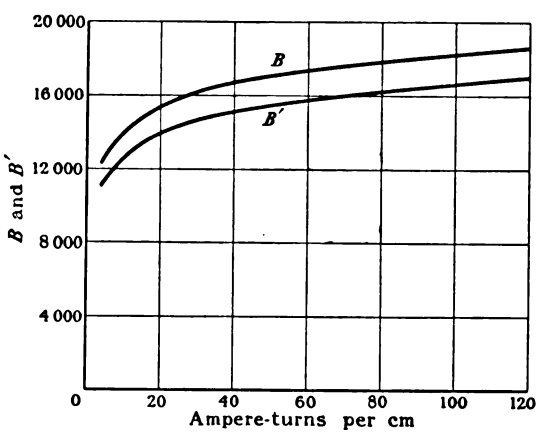

FIG. 13.

Whence

$$- B'\frac{t - r}{l}dx + (N - Hs)\frac{dB'}{B'} + s\,dH = 0$$

and

$$\int H\,dx = \frac{l}{t - r}\left\{\int \frac{NH - sH^2}{(B')^2}dB' + s\int \frac{H}{B'}dH\right\}$$

$$= \frac{l}{t - r}\left\{N\int \frac{H\,dB'}{(B')^2} + s\left[\frac{H^2}{B'} - \int \frac{H\,dH}{B'}\right]\right\} \quad (38)$$

This gives the magnetomotive force required for the teeth, the limits of the integrals corresponding to root and crown respectively. It has been shown [equation (33)] that $l/(t - r)$ is equal to $n/(2\pi)$, and the equation may be written, for inside teeth,

$$\int H\,dx = \frac{n}{2\pi}\left\{N\int \frac{H\,dB'}{(B')^2} + s\left[\frac{H^2}{B'} - \int \frac{H\,dH}{B'}\right]\right\} \quad (39)$$

For outside teeth, as already shown, there is a further small region of high density, in which the same conditions occur in inverse order, and l' should be written for l in equation (38). The appropriate equation for outside teeth is accordingly

$$\int H\,dx = \frac{n^2}{2\pi(n-2)}\left\{N\int \frac{H\,dB'}{(B')^2} + s\left[\frac{H^2}{B'} - \int \frac{H\,dH}{B'}\right]\right\} \quad (40)$$

The values of B' and H corresponding to any value of w are readily obtained as the intersection of the

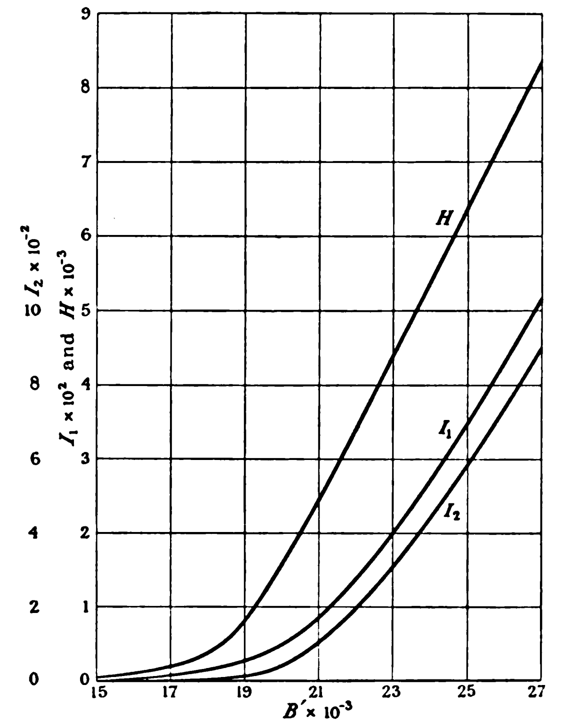

FIG. 14.

$$I_1 = \frac{10}{4\pi}\int \frac{H\,dB'}{(B')^2}$$

$$I_2 = \frac{10}{4\pi}\left\{\frac{H^2}{B'} - \int \frac{H\,dH}{B'}\right\}$$

straight line represented by equation (36) with the B', H curve of the laminated iron (see Fig. 13); and thus the limits of the integrals are obtained.

The coefficients of N and s within the brackets in equations (39) and (40) involve the laminated iron only, and can be computed once for all from the B', H curve. Fig. 14 gives the integrals in the form of curves, corresponding to the curve of Fig. 13. The upper part of the B, H curve on which the results are based is beyond the range of ordinary testing and is generally deduced from an extrapolation formula, making use of the established result * that the curve is asymptotic to the straight line

$$B = H + B_0 \quad . \quad . \quad . \quad . \quad . \quad . \quad (41)$$

in which B_0 is a constant of about 21 000 lines per cm².

* Sir ROBERT HADFIELD and Prof. B. HOPKINSON: "The Magnetic Properties of Iron and its Alloys in Intense Fields," *Journal I.E.E.*, 1911, vol. 46, p. 235.

Kennelly's extrapolation formula is of the form

$$B = H + B_0 \frac{H}{H + H'} \quad . \quad . \quad . \quad . \quad (42)$$

in which H' is a constant, so chosen as to make the experimental and extrapolated curves join. In the author's experience, however, the junction is not made without a distinct kink, and he prefers the form, involving two disposable constants,

$$B = H + B_0 \frac{H + H_0}{H + H'} \quad . \quad . \quad . \quad . \quad (43)$$

By means of this the curves can be made to join in the same direction. The curve of Fig. 13 is extrapolated above $H = 100$ by means of the formula *

$$B = H + 20\,730 \frac{H + 25}{H + 46} \quad . \quad . \quad . \quad (44)$$

and the integrals of Fig. 14 have, except at the lower end, been deduced from this formula.

The magnetomotive force required for the gap is proportional to N, being $GN/(s + t)$, so the whole magnetomotive force from pole-face to armature core is determinate. These are sensibly equipotential regions, and it is convenient to treat the intervening region as a unit. It may be noted that, in the interpolar space, the potential of the armature core is brought to the crowns of the teeth, and thus affects the interpolar fringe flux. The effect of the saturation of the teeth on armature reaction is discussed later (Section 11).

(6) Fringe Flux at Pole-Tips.

The interpolar field in the case of a pair of rectangular poles, opposite in polarity, and separated by a uniform gap from a plane armature surface, was discussed in the I.E.E. paper cited on page 1117. The actual salient pole is not usually rectangular at the tip, nor is the corner sharp; but its angle is generally less than a right angle, and the corner is rounded off to accord with limitations of manufacture. The following solution is proposed as being more in accordance with actual conditions.†

Consider the transformation

$$z = \frac{\gamma}{(1-\lambda)\pi} \int \frac{(\zeta - a)d\zeta}{a\zeta(\zeta + 1)^{\frac{1}{2}}}$$
$$= \frac{\gamma}{(1-\lambda)\pi} \left\{ 2\frac{(\zeta+1)^{\frac{1}{2}}}{a} + \log \frac{(\zeta+1)^{\frac{1}{2}} + 1}{(\zeta+1)^{\frac{1}{2}} - 1} + j\pi \right\} \quad (45)$$

This converts the positive half-plane of ζ into the quarter plane of z, bounded, as shown in Fig. 15, by the positive axes of x and y, and by the two sides of the line $A\infty$. With the latter line at potential $1/(1-\lambda)$ and the axes of x and y at zero potential, the field is determined by

$$\phi + j\psi = \frac{1}{1-\lambda}\left[1 + \frac{j}{\pi}\log \zeta\right] \quad . \quad . \quad (46)$$

* Leading (with $\lambda = 0{\cdot}91$) to $B' = H + 18\,860\,(H + 25)/(H + 46)$.

† The results of this calculation were given by the author in the course of a discussion on a paper entitled "The Reluctance of Some Irregular Magnetic Fields," by John F. H. Douglas. See *Transactions of the American I.E.E.*, 1915, vol. 34, p. 1130.

If λ is given some value about $0{\cdot}2$ or $0{\cdot}3$, the line of unit potential bears a close resemblance, in the neighbourhood of the point A, to the contour of a section of a pole-tip; and the flux which reaches the armature in the interpolar space issues from this neighbourhood. It remains, therefore, to determine an appropriate value for the constant a; and to select, from the system of equipotential lines, that which most nearly resembles the required contour.

The following appears to be a reasonable method of

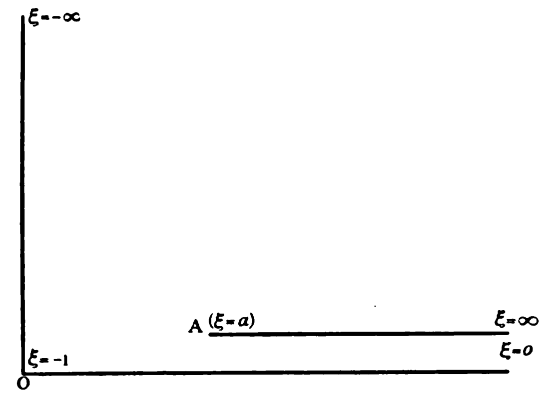

Fig. 15.—Plane of z.

making the selection. Let the origin in Fig. 15 be taken midway between the two poles when interpoles are absent, or at the nearer interpole tip when interpoles are present, since there is no appreciable drop of potential across the interpole face. Let the extreme limit of the equipotential surface selected to represent the pole, reckoned to the tangent normal to the armature face, be taken at the same distance from the origin as the extreme limit of the actual pole is from the interpole tip; and let the radius of curvature at the extreme limit be made the same as the radius of the actual pole-

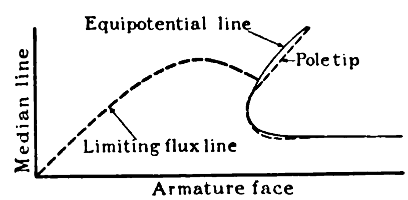

Fig. 16.

tip. The actual and assumed pole-tips in a typical case are shown in Fig. 16.

For the equipotential line at unit potential, equation (46) gives

$$\zeta = e^{(1-\lambda)\pi\psi + j\lambda\pi}$$
$$= qe^{j\lambda\pi} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (47)$$

and from equation (45)

$$\frac{dz}{dq} = \frac{\gamma}{(1-\lambda)\pi} \cdot \frac{qe^{j\lambda\pi} - a}{aq(qe^{j\lambda\pi} + 1)^{\frac{1}{2}}} \quad . \quad . \quad (48)$$

If ds is an element of the equipotential line and θ its slope,

$$dz = e^{j\theta} ds$$

Hence

$$\frac{ds}{dq} = \frac{\gamma}{(1-\lambda)\pi} \cdot \frac{[a^2 + q^2 - 2aq\cos\lambda\pi]^{\frac{1}{2}}}{q[1 + q^2 + 2q\cos\lambda\pi]^{\frac{1}{2}}} \quad . \quad (49)$$

$$\theta = \arc\tan\frac{q\sin\lambda\pi}{q\cos\lambda\pi - a} - \tfrac{1}{2}\arc\tan\frac{q\sin\lambda\pi}{q\cos\lambda\pi + 1} \quad (50)$$

$$\frac{d\theta}{dq} = -\sin\lambda\pi\left\{\frac{a}{a^2 + q^2 - 2aq\cos\lambda\pi} + \frac{1}{2(1 + q^2 + 2q\cos\lambda\pi)}\right\} \quad (51)$$

The radius of curvature $ds/d\theta$ is accordingly deducible from equations (49) and (51). At the extreme tip $\theta = \frac{1}{2}\pi$, and equation (50) gives

$$q^2 + 2q\cos\lambda\pi = a^2 + 2a$$

or $$q = (a^2 + 2a + \cos^2\lambda\pi)^{\frac{1}{2}} - \cos\lambda\pi \quad . \quad . \quad (52)$$

On the axis of x, representing the armature face, ϕ is zero, ζ lies between -1 and 0, and ψ lies between 0 and $-\infty$. Writing

$$\zeta = -e^{(1-\lambda)\pi\psi}$$

x is given by [see equation (45)]

$$x = \frac{\gamma}{(1-\lambda)\pi}\left\{\frac{2}{a}(1 - e^{(1-\lambda)\pi\psi})^{\frac{1}{2}} + 2\log\left[(1 - e^{(1-\lambda)\pi\psi})^{\frac{1}{2}} + 1\right] - (1-\lambda)\pi\psi\right\} \quad (53)$$

which, as ψ approaches $-\infty$, tends towards the value

$$x = \frac{\gamma}{(1-\lambda)\pi}\left\{\frac{2}{a} + \log 4\right\} - \gamma\psi \quad . \quad . \quad (54)$$

The total flux is accordingly the same as if the gap density extended over the whole armature face, with the exception of a distance, for each pole-tip, of

$$d = \frac{\gamma}{(1-\lambda)\pi}\left(\frac{2}{a} + \log 4\right) \quad . \quad . \quad . \quad (55)$$

For the purpose of determining the reluctance of the gap, the fringing is best expressed by the fraction of the length of the gap which must be added to the pole-face in a peripheral direction to give the same flux, if assumed at normal gap density throughout. It is accordingly the value of x/γ given by equations (45), (47) and (52), diminished by the value of d/γ given by equation (55). Values * of the fringing coefficient are given in Fig. 17.

It is, however, still necessary to determine an appropriate value for γ, the equivalent gap for the purpose, between pole-face and armature face, assumed plane. It has already been remarked that, in the interpolar space, the potential of the armature core appears at the tooth crowns, thus causing an increase in interpolar flux as the teeth under the pole become more saturated. It seems reasonable, accordingly, to assume as the value of γ the equivalent air-gap G as determined in Sections (3) and (4), plus the air equivalent of the teeth. This ensures continuity in the field between polar and interpolar spaces, and takes account of the ruling factors of the problem.

The strength of the field at the armature face is sometimes required and is readily found. Its value at the point determined, in terms of the parameter ψ, by equation (53) is

$$-\frac{d\psi}{dx} = \frac{a}{\gamma} \cdot \frac{(1 - e^{(1-\lambda)\pi\psi})^{\frac{1}{2}}}{a + e^{(1-\lambda)\pi\psi}} \quad . \quad . \quad . \quad (56)$$

Reviewing the problem in the light of the proposed solution, perhaps the most significant feature is that

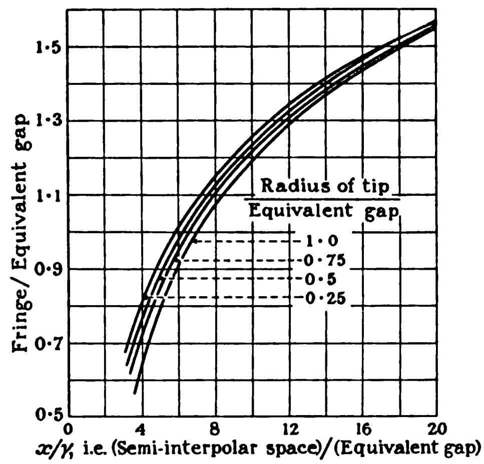

FIG. 17.

the precise form of the pole-tip, so that it be generally of the kind under consideration, has little effect on the total flux. This is clearly shown in Fig. 17. Even the differences indicated in this figure are probably exaggerated; for the assumed pole falls away sensibly from the actual pole before the tip radius is reached, as can be seen in Fig. 16, thus tending to reduce the

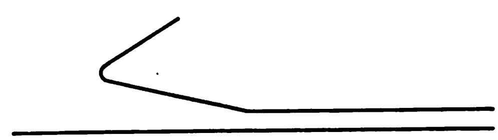

FIG. 18.

flux and to give too low a value for the coefficient. The reduction, moreover, is greater, the greater the value of λ, i.e. of the radius of the tip. Some such falling away of the pole-tip may, however, be taken as compensating for the falling away of the armature due to convexity. Accordingly, whilst the upper curves in Fig. 17 are probably in sensible agreement with the facts, the lower ones should be raised somewhat: and it is not unlikely that the highest curve of the figure fairly represents the facts, whatever the radius of the tip, within ordinary limits. The exact angle of the pole-tip is of small consequence, as very little of the flux issues from the flank beyond the radius. This is shown in Fig. 16, in which the limiting line of flux is indicated.

* The calculation involves a certain amount of cross-plotting; a note on the method used is given in Appendix 4.

In some machines the pole-tips are chamfered at a small angle, as in Fig. 18, in order to provide more gradual variation in the field. The determination of the fringe is thereby rendered more difficult. The field in the main gap rapidly approaches uniformity; and the field under the chamfer approaches a known limit, the lines of flux becoming ultimately arcs of circles. There are two regions, however, to which special consideration must be given, (1) the region of the beginning of the chamfer, and (2) the region of the pole-tip. Unless the chamfer is unduly short, these may be discussed separately.

The region of the beginning of the chamfer (Fig. 19) is not of very much consequence. At points remote from A the field in the main gap is uniform and equal to $1/\gamma$, that under the chamfer is sensibly equal to $1/(r\alpha + \gamma)$, where α is the angle of chamfer and r the distance from the point A. It will be convenient to treat these fields as extending to the point A, where they are continuous, and the disturbance as a correction to be applied to this assumed field.

If $n = \alpha/\pi$, the transformation

$$z = -\frac{\gamma}{\pi}\int\frac{(1-\zeta)^n}{\zeta}d\zeta \quad . \quad . \quad . \quad . \quad (57)$$

represents the gap of Fig. 19. With the pole at unity

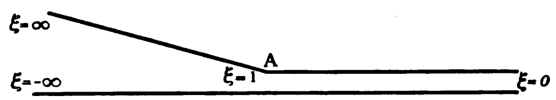

FIG. 19.

potential and the armature at zero potential, the field is determined in terms of ζ by

$$\chi = \phi + j\psi = 1 + \frac{j}{\pi}\log\zeta \quad . \quad . \quad . \quad (58)$$

and in terms of z by

$$z = j\gamma\int[1 - e^{-j\pi(\chi-1)}]^n d\chi \quad . \quad . \quad . \quad (59)$$

At the pole-face this reduces to

$$z = -\gamma\int(1 - e^{\pi\psi})^n d\psi \quad . \quad . \quad . \quad . \quad (60)$$

When $\psi < 0$ this may be written

$$z = -\gamma\int\Big[1 - ne^{\pi\psi} - \frac{n(1-n)}{2!}e^{2\pi\psi} - \frac{n(1-n)(2-n)}{3!}e^{3\pi\psi} + \ldots\Big]d\psi$$

$$= -\gamma\Big\{\psi - \frac{n}{\pi}\Big[e^{\pi\psi} + \frac{1-n}{2^2}e^{2\pi\psi} + \frac{(1-n)(1-\frac{1}{2}n)}{3^2}{}_{3\pi\psi} + \ldots\Big]\Big\} \quad (61)$$

This series is convergent as long as $\psi \ngtr 0$. Hence taking the origin at A ($\psi = 0$), when $e^{\pi\psi}/\psi$ has become small

$$x = -\gamma\Big[\psi_1 + \frac{n}{\pi}S_1\Big] \quad . \quad . \quad . \quad . \quad (62)$$

where

$$S_1 = 1 + \frac{1-n}{2^2} + \frac{(1-n)(1-\frac{1}{2}n)}{3^2} + \ldots \quad . \quad (63)$$

When $\psi > 0$, equation (60) may be written in the form

$$z = -\gamma e^{-j\alpha}\int e^{n\pi\psi}(1 - e^{-\pi\psi})^n d\psi$$

$$= -\gamma e^{-j\alpha}\int\Big[e^{n\pi\psi} - ne^{-(1-n)\pi\psi} - \frac{n(1-n)}{2!}e^{-(2-n)\pi\psi}\ldots\Big]d\psi$$

$$= -\gamma e^{-j\alpha}\Big\{\frac{e^{n\pi\psi}}{n\pi} + \frac{n}{\pi}\Big[\frac{e^{-(1-n)\pi\psi}}{1-n} + \frac{1-n}{2^2(1-\frac{1}{2}n)}e^{-(2-n)\pi\psi} + \ldots\Big]\Big\} \quad (64)$$

The series is convergent as long as $\psi \nless 0$; hence, when ψ is large

$$z = -\gamma e^{-j\alpha}\Big\{\frac{e^{n\pi\psi_2} - 1}{n\pi} - \frac{n}{\pi}S_2\Big\} \quad . \quad . \quad (65)$$

where

$$S_2 = \frac{1}{1-n} + \frac{1-n}{2^2(1-\frac{1}{2}n)} + \frac{(1-n)(1-\frac{1}{2}n)}{3^2(1-\frac{1}{3}n)} + \ldots \quad (66)$$

z may be written

$$z = re^{j(\pi-\alpha)} = -re^{-j\alpha} \quad . \quad . \quad . \quad (67)$$

and equation (65) gives

$$\psi_2 = \frac{1}{\alpha}\log\Big[\frac{r\alpha}{\gamma} + 1 + n^2S_2\Big] \quad . \quad . \quad (68)$$

The total flux from $z = -re^{-j\alpha}$ to $z = x$ is accordingly

$$\psi_2 - \psi_1 = \frac{1}{\alpha}\log\Big(\frac{r}{\gamma} + 1 + n^2S_2\Big) + \frac{x}{\gamma} + \frac{n}{\pi}S_1 \quad (69)$$

The distribution of flux assumed provisionally accounts for an amount $\frac{1}{\alpha}\log\Big(\frac{r\alpha}{\gamma} + 1\Big) + \frac{x}{\gamma}$, and the correction to be applied to this is therefore S_1n/π or $S_1\alpha/\pi^2$. S_1 is somewhat short of $\pi^2/6$ and the correction is nearly $\alpha/6$, this being an addition to the permeance of the gap per unit axial length.

The effect of this part of the chamfer on the distribution of flux at the armature face will now be given for what it is worth. The deviation from the assumed distribution is not very great, although much greater than might be surmised from the insignificance of its integral effect.

At the armature face, $\zeta = -e^{\pi\psi}$ and the point corresponding to $\psi = 0$ is to the left of the axis of y. Write accordingly

$$x = -c - \gamma\int^{\psi}(1 + e^{\pi\psi})^n d\psi \quad . \quad . \quad . \quad (70)$$

in which c has to be determined. When $\psi < 0$

$$x = -c - \gamma\Big\{\psi + \frac{n}{\pi}\Big[e^{\pi\psi} - \frac{1-ne_{2\pi\psi}}{2^2} + \frac{(1-n)(1-\frac{1}{2}n)}{3^2}e^{3\pi\psi}\ldots\Big] - \frac{n}{\pi}S_1'\Big\} \quad (71)$$

where $S_1' = 1 - \frac{1-n}{2^2} + \frac{(1-n)(1-\frac{1}{2}n)}{3^2}$. (72)

When $e^{\pi\psi}/\psi$ is small this reduces to

$$x = -c - \gamma\psi + \frac{n}{\pi}\gamma S_1' \quad . \quad . \quad . \quad (73)$$

Equating this to the value of x given in equation (62), since the lines of flux are here straight and normal to armature and pole-faces,

$$\begin{aligned} c &= \frac{n}{\pi}\gamma(S_1 + S_1') \\ &= 2\frac{a}{\pi^2}\gamma\left(1 + \frac{(1-n)(1-\frac{1}{2}n)}{3^2} + \ldots\right) \\ &= \tfrac{1}{4}a\gamma \text{ approximately} \quad . \quad . \quad . \quad . \quad . \quad . \quad (74) \end{aligned}$$

Equation (71) determines x when ψ lies between $-\infty$ and 0. When $\psi > 0$, x is given by

$$x = -c - \gamma e^{n\pi\psi}\left\{\frac{1}{n\pi} - \frac{n}{\pi}\left[\frac{e^{-\pi\psi}}{1-n} - \frac{1-n}{(1-\frac{1}{2}n)2^2}e^{-2\pi\psi} + \ldots\right]\right\} + \gamma\left\{\frac{1}{n\pi} - \frac{n}{\pi}S_2'\right\} \quad (75)$$

where

$$S_2' = \frac{1}{1-n} - \frac{1-n}{2^2(1-\frac{1}{2}n)} + \frac{(1-n)(1-\frac{1}{2}n)}{3^2(1-\frac{1}{3}n)} \quad (76)$$

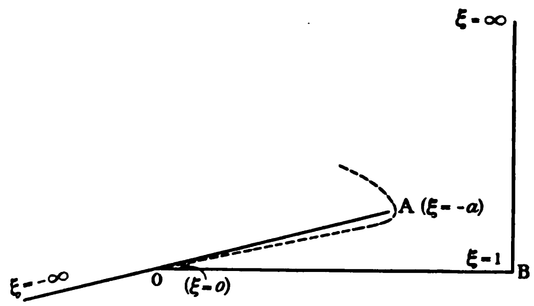

FIG. 20.

The flux density at the armature face is given in terms of the parameter ψ by

$$-\frac{d\psi}{dx} = \frac{1}{\gamma(1 + e^{\pi\psi})^n} \quad . \quad . \quad . \quad . \quad (77)$$

The field about the tip of the chamfered pole may be deduced by means of the transformation

$$z = Kb\int_0^{\zeta} \frac{(\zeta + a)\zeta^n}{\zeta(1-\zeta)^{\frac{1}{2}}}d\zeta \quad . \quad . \quad . \quad (78)$$

in which K is a constant to be determined, b represents the distance OB in Fig. 20, and n is now $a/(1-\lambda)\pi$, a being the angle of chamfer and λ having the same significance as in the fringing problem for uniform gap. This transformation converts the half-plane of ζ into the figure in the plane of z, bounded, as shown in Fig. 20, by the armature face OB, the median line at right angles thereto, the lower side of the line OA and its upper side throughout its length. If OA is at potential $1/(1-\lambda)$ and OB, with the median line, at zero potential, λ and a can be so chosen that the equipotential line of potential unity is similar in the neighbourhood of the tip, to the actual pole, as shown in broken lines.

It is not necessary for the present purpose to consider the case in which the modulus of ζ is greater than unity. The expression in equation (78) can accordingly be expanded and integrated term by term, giving

$$\begin{aligned} z &= Kb\left\{\frac{\zeta^{1+n}}{1+n} + \frac{1}{2}\frac{\zeta^{2+n}}{2+n} + \frac{\frac{1}{2}\cdot\frac{3}{2}}{2\,!}\frac{\zeta^{3+n}}{3+n} + \ldots + a\left[\frac{\zeta^n}{n} + \frac{1}{2}\frac{\zeta^{1+n}}{1+n} + \frac{\frac{1}{2}\cdot\frac{3}{2}}{2\,!}\frac{\zeta^{2+n}}{2+n} + \ldots\right]\right\} \\ &= Kb\zeta^n\left\{S_1(\zeta) - nS_2(\zeta) + n^2S_2(\zeta) \ldots + a\left[\frac{1}{n} + \tfrac{1}{2}(S_2'(\zeta) - nS_3'(\zeta) + \ldots)\right]\right\} \quad (79) \end{aligned}$$

in which $S_r(\zeta) = \zeta + \frac{1}{2}\cdot\frac{\zeta^2}{2^r} + \frac{\frac{1}{2}\cdot\frac{3}{2}}{2\,!}\cdot\frac{\zeta^3}{3^r} + \ldots \quad . \quad (80)$

$$S_r'(\zeta) = \zeta + \frac{3}{2}\cdot\frac{\zeta^2}{2^r} + \frac{\frac{3}{2}\cdot\frac{5}{2}}{2\,!}\cdot\frac{\zeta^3}{3^r} + \ldots * \quad (81)$$

The series $S_1S_2\ldots$ and $S_2'S_3'\ldots$ are convergent as long as mod. $\zeta \not> 1$. When $\zeta = 1$, $z = b$, and K is accordingly given by

$$1 = K\left\{S_1(1) - nS_2(1) + n^2S_3(1) \ldots + a\left[\frac{1}{n} + \tfrac{1}{2}(S_2'(1) - nS_3'(1) + n^2S_4'(1)\ldots)\right]\right\}\dagger \quad (82)$$

It may be noted that n is rarely as great as $0{\cdot}1$, and a few terms of the series give sufficient accuracy.

The field is determined by

$$\phi + j\psi = -\frac{j}{(1-\lambda)\pi}\log\zeta \quad . \quad . \quad . \quad (83)$$

and on the equipotential $\phi = 1$

$$\begin{aligned} \zeta &= e^{-(1-\lambda)\pi\psi + (1-\lambda)\pi j} \\ &= qe^{(1-\lambda)\pi j} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (84) \end{aligned}$$

Proceeding as before, on the equipotential $\phi = 1$

$$\frac{dz}{dq} = Kb\frac{(qe^{(1-\lambda)\pi j} + a)q^n e^{ja}}{q(1 - qe^{(1-\lambda)\pi j})} \quad . \quad . \quad . \quad (85)$$

whence $\quad \dfrac{ds}{dq} = Kb\dfrac{(q^2 + a^2 - 2qa\cos\lambda\pi)^{\frac{1}{2}}q^n}{q(q^2 + 1 + 2q\cos\lambda\pi)^{\frac{1}{4}}} \quad . \quad . \quad (86)$

$$\theta = \arc\tan\frac{q\sin\lambda\pi}{a - q\cos\lambda\pi} + \tfrac{1}{2}\arc\tan\frac{q\sin\lambda\pi}{1 + q\cos\lambda\pi} + a \, . \quad (87)$$

At the extreme tip, $\theta = \frac{1}{2}\pi + a$, and q is given by the equation [cf. equation (52)]

$$q = \sqrt{(a^2 + 2a + \cos^2\lambda\pi)} - \cos\lambda\pi \quad . \quad (88)$$

The radius of curvature at the extreme tip could be deduced exactly as in the problem of the uniform gap, and with little greater labour. It was shown, however,

* Note that

$S_1(\zeta) = 2[1 - (1-\zeta)^{\frac{1}{2}}]$; $S_2(\zeta) = 4[\log\frac{1}{2}[1 + (1-\zeta)^{\frac{1}{2}}] + 1 - (1-\zeta)^{\frac{1}{2}}]$;

$S_2'(\zeta) = -4\log\frac{1}{2}[1 + (1-\zeta)^{\frac{1}{2}}]$

† Note that: $S_1(1) = 2$; $S_2(1) = 1{\cdot}228$; $S_3(1) = 1{\cdot}087$; $S_4(1) = 1{\cdot}04$; $S_5(1) = 1{\cdot}02$; $S_6(1) = 1{\cdot}0$; $S_2'(1) = 2{\cdot}772$; $S_3'(1) = 1{\cdot}366$; $S_4'(1) = 1{\cdot}135$; ; $= 1{\cdot}04$; $S_6(1 = 1{\cdot}0$.

in discussing the results of this case, that they were not greatly affected by the radius of the tip, and for the purpose in view it is sufficient to work with a constant value of λ.

At the armature face [see equation (83)]

$$\zeta = e^{-(1-\lambda)\pi\psi} \quad . \quad . \quad . \quad . \quad (89)$$

If now x_1 is the value of z corresponding to a large value ψ_1,

$$x_1 = \frac{Kbae^{-n(1-\lambda)\pi\psi_1}}{n}$$

or

$$\psi_1 = \frac{1}{a}\left[\log\frac{Kba}{n} - \log x_1\right] \quad . \quad . \quad (90)$$

At the point B, $\psi = 0$, and thus ψ_1 is the total flux entering the armature between $x = x_1$ and $x = b$. If the normal field of the chamfer were extended indefinitely, the flux entering the armature between x_1 and x_2 would be

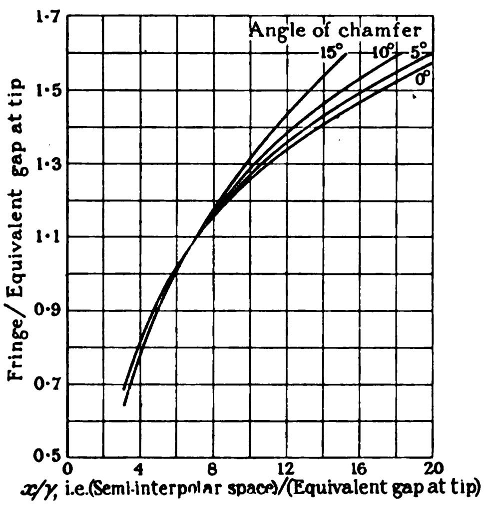

FIG. 21.

$$\psi_1 - \psi_2 = \frac{1}{a}[\log x_2 - \log x_1] \quad . \quad . \quad (91)$$

Accordingly the extent of normal chamfer field giving the same flux to the armature as the actual pole-tip is determined by

$$x_2 = \frac{Kba}{n} \quad . \quad . \quad . \quad . \quad . \quad . \quad (92)$$

Equations (79), (84) and (88) determine z at the extreme tip, and the modulus $\bar{z}$ of this is the distance of the tip from 0. The addition for the fringing is therefore

$$\frac{Kba}{n} - \bar{z} \quad . \quad . \quad . \quad . \quad . \quad . \quad (93)$$

The gap at the tip is $\bar{z}\sin\alpha$, and the distance of the tip from the median line, $b - \bar{z}\cos\alpha$. Fig. 21 gives values of $[Kban^{-1} - \bar{z}]/\bar{z}\sin\alpha$ plotted against $[b - \bar{z}\cos\alpha]/\bar{z}\sin\alpha$, for values of α, 0°, 5°, 10°, 15°. In computing these curves, λ was taken constant, at value $\frac{2}{3}$.* In using the curves, if g is the minimum, G the equivalent gap in the centre portion of the pole, ϵ the air equivalent of the teeth, the gap at the tip may be taken as the minimum gap at this place, plus $G - g + \epsilon$.

* It should be noted that the gap at the top of a chamfered pole is large, so that the fraction (radius of tip)/gap is correspondingly small.

The distribution of flux at the armature face can now be readily computed. The position of the point determined by ψ is given by equation (79), in which ζ is given by equation (89). The flux density at the point is

$$-\frac{d\psi}{dx} = \frac{e^{a\psi}[1 - e^{-(1-\lambda)\pi\psi}]^{\frac{1}{2}}}{(1-\lambda)\pi Kb[e^{-(1-\lambda)\pi\psi} + a]} \quad . \quad . \quad (94)$$

(7) FRINGE FLUX AT END OF CORE.

The fringes between the pole-ends and armature core are not susceptible to satisfactory determination by present methods, for two reasons; first, because the problem, if the armature teeth are taken into account, is three-dimensional; and secondly, because the flux is not entirely local or naturally delimited. With regard to the first, it is necessary to assume a uniform gap which, it is intended, shall have substantially the same effective fringe as the actual gap. For this purpose the gap used in the last Section is suggested, viz. the equivalent air-gap plus the air equivalent of the teeth, although for most purposes of design the last factor may be omitted. This assumption, if not correct, at least depends on the ruling factors and serves the purpose of a secondary calculation. With regard to the second difficulty, the problem on which the results are based involves an infinite fringe, although agreeing with actual conditions in the vicinity of the gap. It is accordingly a matter of judgment how much of the computed fringe should be taken as effective; but it is evidently something less in extent than the end connections of the armature winding.

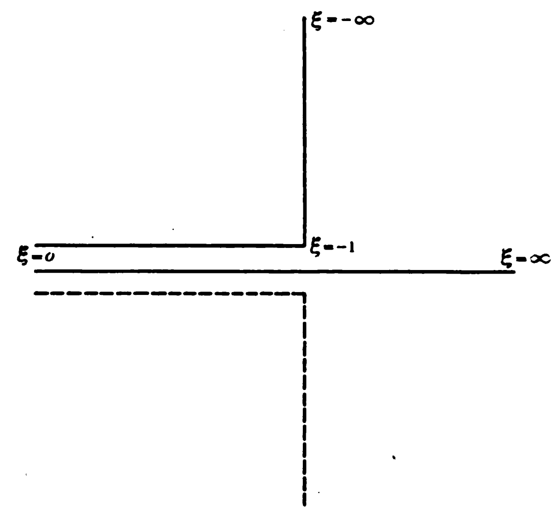

FIG. 22.

The transformation is

$$z = \frac{\gamma}{2\pi}\int\frac{(\zeta+1)^{\frac{1}{2}}}{\zeta}d\zeta$$
$$= \frac{\gamma}{2\pi}\left\{2(\zeta+1)^{\frac{1}{2}} - \log\frac{(\zeta+1)^{\frac{1}{2}}+1}{(\zeta+1)^{\frac{1}{2}}-1}\right\} \quad . \quad (95)$$

which converts the half-plane of ζ into a system in the plane of z bounded as shown in full lines in Fig. 22. The system is taken as being symmetrical about the middle line of the gap. The field is given by

$$\phi + j\psi = -\frac{j}{2\pi}\log\zeta \quad . \quad . \quad . \quad (96)$$

The relation between ψ and x is accordingly

$$x=\frac{\gamma}{2\pi}\{2(e^{-2\pi\psi}+1)^{\frac{1}{2}}-2\log[(e^{-2\pi\psi}+1)^{\frac{1}{2}}+1]-2\pi\psi\} \quad (97)$$

When ψ is large and positive this equation reduces to

$$\psi + \frac{x}{\gamma} = \frac{1}{\pi}(1 - \log 2) \quad . \quad . \quad . \quad (98)$$

If ψ' is the value given by equation (97) when x

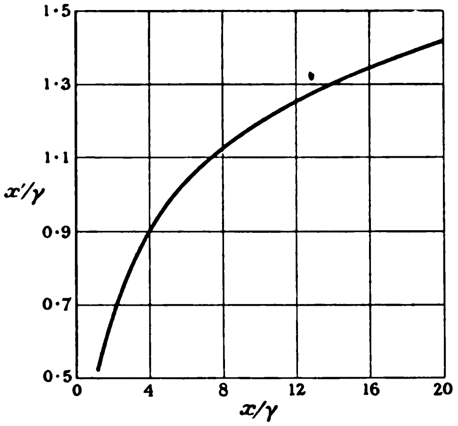

FIG. 23.

corresponds to the adjudged limit of the effective fringe, and if x' is defined by

$$\frac{x' - x}{\gamma} = \psi - \psi'$$

or

$$x' = \gamma\left\{\frac{1}{\pi}(1 - \log 2) - \psi'\right\} \quad . \quad . \quad (99)$$

then x' may be taken as representing the fringe, being the extension of the pole-face required to give the same total flux, normal density being assumed throughout. Fig. 23 gives this fringe as a function of the adjudged limit of effective fringe.

(8) Radial Ducts.

The effect of introducing a radial duct in armature core or pole-piece is to reduce the equivalent area of the pole-face, the reduction being found by annulling a certain fraction of the width of the duct, given by equation (8) or Fig. 3, in which, however, s is now the width of the duct, and g an equivalent gap. Where there are ducts in both members, opposite to one another, the appropriate reduction is given by equation (27). The solution is not perfect, since the problem is really a three-dimensional one when slots are present. The value of g is greater than the minimum gap, and may be taken as G, the equivalent gap of the slotted surface.

(9) Band Recesses.

Many armatures have their windings held in by means of binding bands, composed generally of steel

FIG. 24.

wire or strip, but sometimes of phosphor-bronze. The bands lie in recesses in the core surface (Fig. 24) and are separated from the laminations by an insulating layer, causing a local variation in the reluctance of the

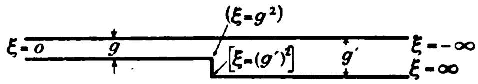

FIG. 25.

gap, which can be expressed as a variation in its equivalent area. The problem is again a three-dimensional one which has to be treated as two-dimensional, and two cases arise according as the band is magnetic or non-magnetic.

The case of a non-magnetic band may be deduced from consideration of a gap varying suddenly as shown

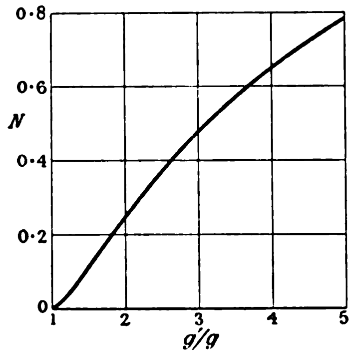

FIG. 26.

in Fig. 25. The appropriate transformation from the half-plane of ζ is

$$z = \frac{g'}{\pi}\int\left[\frac{\zeta - g^2}{\zeta - g'^2}\right]^{\frac{1}{2}}\frac{d\zeta}{\zeta}$$

$$= \frac{1}{\pi}\left\{g' \operatorname{arc\,cosh}\frac{2\zeta - (g'^2 + g^2)}{g'^2 - g^2}\right.$$

$$\left. - g \operatorname{arc\,cosh}\frac{(g'^2 + g^2)\zeta - 2g'^2g^2}{(g'^2 - g^2)\zeta}\right\} \quad (100)$$

The field is given by

$$\phi + j\psi = -\frac{j}{\pi}\log\zeta \quad . \quad . \quad . \quad (101)$$

When ζ is large, real and positive,

$$x_2 = \frac{1}{\pi}\left\{g'\left[-\pi\psi_2 - \log\frac{g'^2 - g^2}{4}\right] - g \operatorname{arc\,cosh}\frac{g'^2 + g^2}{g'^2 - g^2}\right\}$$

When ζ is small, real and positive,

$$x_1=\frac{1}{\pi}\left\{g' \operatorname{arc\,cosh} \frac{g'^2+g^2}{g'^2-g^2}-g\left[\pi\psi_1+\log \frac{4g^2g'^2}{g'^2-g^2}\right]\right\}$$

Whence

$$\psi_1-\psi_2=\frac{x_2}{g'}+\frac{-x_1}{g}+\frac{1}{\pi}\left\{\log \frac{(g'^2-g^2)^2}{16g^2g'^2}\right.$$
$$\left.+\left(\frac{g}{g'}+\frac{g'}{g}\right) \operatorname{arc\,cosh} \frac{g'^2+g^2}{g'^2-g^2}\right\} \quad (102)$$

Thus the flux, in excess of that required to fill both gaps, each at its appropriate density, is *

$$N=\frac{1}{\pi}\left\{2 \log\left[\tfrac{1}{4}\left(\frac{g'}{g}-\frac{g}{g'}\right)\right]+\left(\frac{g'}{g}+\frac{g}{g'}\right) \operatorname{arc\,cosh} \frac{g'^2+g^2}{g'^2-g^2}\right\}$$
$$=\frac{1}{\pi}\left\{2 \log\left[\tfrac{1}{4}\left(\frac{g'}{g}-\frac{g}{g'}\right)\right]+\left(\frac{g'}{g}+\frac{g}{g'}\right) \log \frac{g'+g}{g'-g}\right\} \quad (103)$$

Fig. 26 gives N as a function of g'/g (see also Fig. 42).

If b is the width of the band recess, and x the fraction of this which should be annulled to give an equivalent area of normal gap,

$$\frac{b}{g'}+2N=\frac{b}{g}(1-x)$$

or

$$x=1-\frac{g}{g'}-2N\frac{g}{b} \quad . \quad . \quad . \quad (104)$$

When steel bands are used the problem is different, for although iron is removed from the crowns of the

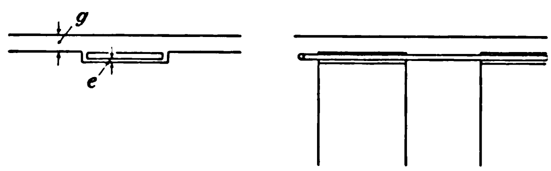

FIG. 27.

teeth, the magnetic band, carried over teeth and slots (see Fig. 27), tends to counteract the increase of reluctance caused by the removal. The band may be regarded as an equipotential region, at some potential (v) between that of the pole (unity) and that of the armature core (zero).

Let b be the breadth of the band space and $(1-x)b$ the equivalent breadth. Let g be the gap between pole-face and band, and e the gap between band and armature core (see Fig. 27), then †

$$\frac{s+t}{g}(1-v)=\frac{t}{e}v=\frac{(1-x)(s+t)}{G}=\frac{(s+t)t}{tg+(s+t)e}$$

or

$$x=\frac{(s+t)e-(G-g)t}{tg+(s+t)e} \quad . \quad . \quad . \quad (105)$$

This is the fraction of the breadth of the band recess to be subtracted from the core length, in order to allow for its presence, the remainder being treated as normal gap. The correction in this case is a small one, and, with certain dimensions, may conceivably be negative.

* The expression for N was originally deduced by the author in 1909 in connection with the problem of the reactance of a conductor imbedded in a semi-closed slot (see section 12). The same mathematical problem, however, is involved in determining the resistance of a strip of uniform material, shaped like Fig. 25, and the result (103) was given in this connection by Dr. C. H. Lees (*Philosophical Magazine*, 1908, ser. 6, vol. 16, p. 734). The problem of the stepped gap has been discussed by Prof. W. Cramp and Miss N. I. Calderwood (see *Journal I.E.E.*, 1923, vol. 61, p. 1068).

† Certain small fringes are here neglected.

(10) DISTRIBUTED EXCITATION.

Hitherto the discussion has been confined to problems of uniform magnetomotive force; but in certain classes of machine the exciting winding is distributed in slots in the pole-face, so that the magnetomotive force is graduated. The problem of a rectangular slot in which a conductor conveying a current is located, and which is opposed by a plane equipotential surface, is the same as that of a pair of rectangular poles of opposite polarity opposed by a plane armature surface. The latter problem was discussed in the I.E.E. paper cited on page 1117. The transformation used is essentially the same as that of a slot in one of a pair of opposing equipotential surfaces (see Section 3), but the source of the flux is differently located. The two solutions are in fact additive, and both sources may be present in any strengths. The field at any point due to a winding distributed in slots is therefore readily determined: in fact the total flux from the centre of one tooth to the centre of the next is the same as if no current were carried in the slot separating them.

If, in Fig. 2, u is the magnetomotive force due to the current in the slot, and v that due to the other agents creating a potential difference between the two sides of the gap, z being connected with ζ by equation (11), the flux function may be written

$$\psi=\frac{u}{\pi}\log(\zeta+1)+\frac{v}{\pi}\log\zeta \quad . \quad . \quad (106)$$

and the force at the unslotted face is

$$F=\frac{u\zeta+v(\zeta+1)}{g[(\zeta+\lambda)(\zeta+\lambda^{-1})]^{\frac{1}{2}}} \quad . \quad . \quad (107)$$

in which ζ is real and positive, and λ is given by equation (12). The variation in the field through which the armature conductors pass can accordingly be determined.

(11) LOADED MACHINES.

When a machine is under load, the field due to the load is added to the exciting field. Unless the machine is of the compensated type, the resultant excitation varies from tooth to tooth, presenting the same problem as was considered in the preceding Section. When the load is so disposed as to have a component in the direction of the axis of excitation, it reacts on this, in effect increasing or diminishing it. But even when the axis of the load is in quadrature with the axis of excitation, as in d.c. machines having brushes at the neutral point, there is an effect due to the saturation of the teeth which is usually, though with little reason, provided against by assuming a certain percentage of the armature ampere-turns to react on the field.

The excitation required for gap and teeth, for any specified mean flux density in the gap, can be readily determined by the methods already discussed; and it is of no consequence whether the excitation is due to outside agency or to the load itself. The form of the

curve of magnetization for gap and teeth is, for a particular machine, shown in Fig. 28; and from this the mean flux density at any point in the gap of the loaded machine can be found. In the important case of d.c. machines having no compensating or other windings in the pole-face, the excitation varies by equal steps from tooth to tooth; and the mean excitation accordingly varies uniformly with the tangential* distance. A section of the curve of Fig. 28, comprised between certain determinate points P and Q, therefore represents, to some scale of abscissa, the mean distribution of flux along the air-gap in a tangential direction. The mean abscissa ON of the section, or that corresponding to the middle of the pole-face, represents the imposed excitation, including the component, if any, of armature ampere-turns in the direction of the axis of excitation. The mean ordinate MR of the section is the effective mean flux density, and the defect MN of

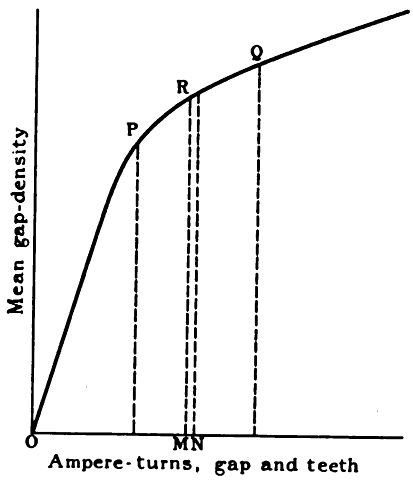

FIG. 28.

the corresponding abscissa from the mean abscissa represents the effect of saturation in causing a diminution of effective excitation. Expressed in the usual manner, as a percentage of the armature reaction, the effect is negligibly small at low saturation, rises to a maximum when the section includes the knee of the curve, and falls again to a low value when the teeth become saturated. The effects are noticeable in the speed curves of railway motors having a light exciting field.

The additional excitation due to the load has the effect of increasing the iron loss in the teeth, as compared with the light-load loss at the same speed and external excitation, the increase being of the nature of a load loss.

(12) Reactance of Conductors Embedded in Slots.

Hitherto the slot has been considered with regard to its effect on the field in the gap: the present Section deals with the flux-linkage of the current carried by the slot-embedded conductors, and is therefore concerned with the field in the slot itself, as well as that in the gap. In this discussion the form of the slot becomes a matter of importance.

When a current-carrying conductor is located in a rectangular slot, the field due to the current is small below the conductor, and becomes sensibly uniform at a short distance above the conductor. Fig. 29 shows a portion of the field due to an element of such a conductor. For the windings with which the engineer has

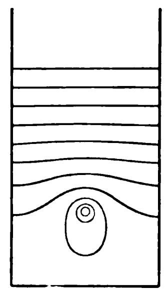

FIG. 29.

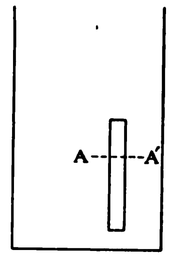

FIG. 30.

occasion to deal, it is generally sufficient to assume the field uniform above the conductors, until the neighbourhood of the mouth of the slot is reached; and further, when the current is distributed sensibly uniformly over a rectangular area as in Fig. 30, having two of its sides parallel to those of the slot, to assume that the flux-linkage is the same as if the current were

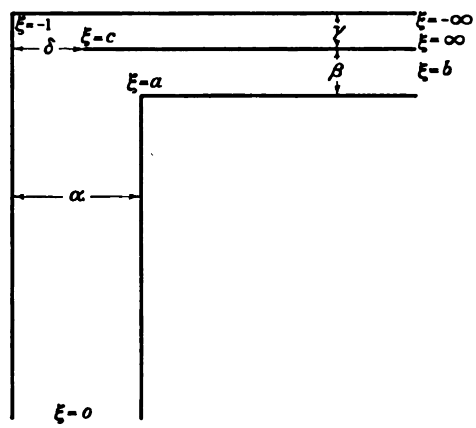

FIG. 31.

concentrated in a horizontal layer AA′ situated two-thirds of the height of the rectangle, measured from the bottom.* The present investigation is accordingly narrowed to that of the field about the mouth of the slot, with given difference of potential between the sides of the slot.

The case of a simple rectangular slot could readily be deduced from formulæ already given; but it is convenient here to treat this as a particular case of a more general problem.

* The principal directions in a dynamo may be referred to as: "radial," "axial," and "tangential."

* Where the rectangle is formed of a single conductor, the field itself tends to destroy the uniformity of the current, increasing its density towards the top. See A. B. Field: "Eddy Currents in Large Slot-wound Conductors," *Transactions of the American I.E.E.*, 1905, vol. 24, p. 761.

The transformation

$$z=\frac{\gamma}{\pi}\int\frac{(\zeta-c)\,(\zeta-a)^{\frac{1}{2}}}{\zeta(\zeta-b)\,(\zeta+1)^{\frac{1}{2}}}d\zeta$$
$$=\frac{1}{\pi}\left\{\gamma\operatorname{arc\,cosh}\frac{2\zeta+1-a}{1+a}+\alpha\operatorname{arc\,cos}\frac{(1-a)\zeta-2a}{(1+a)\zeta}\right.$$
$$\left.+\beta\operatorname{arc\,cosh}\frac{2(1+b)\,(b-a)+(1+2b-a)(\zeta-b)}{(1+a)\,(\zeta-b)}\right\}\quad(108)$$

in which a, b, c, are positive and in ascending order of magnitude, converts the half-plane of ζ into the plane of z bounded as shown in Fig. 31. In this equation

$$\frac{c}{b}a^{\frac{1}{2}}=\frac{\alpha}{\gamma}\quad.\;.\;.\;.\;.\;.\quad(109)$$

$$\frac{c-b}{b}\left(\frac{b-a}{1+b}\right)^{\frac{1}{2}}=\frac{\beta}{\gamma}\quad.\;.\;.\quad(110)$$

$$\delta=\frac{1}{\pi}\left\{\gamma\operatorname{arc\,cosh}\frac{2c+1-a}{1+a}+\alpha\operatorname{arc\,cos}\frac{(1-a)c-2a}{(1+a)c}\right.$$
$$\left.+\beta\operatorname{arc\,cosh}\frac{2(1+b)\,(b-a)+(1+2b-a)\,(c-b)}{(1+a)\,(c-b)}\right\}\quad(111)$$

For field write

$$\phi+j\psi=\tfrac{1}{2}\left(1+\frac{j}{\pi}\log\zeta\right)\quad.\;.\;.\quad(112)$$

which, when ζ is real and positive gives :—

$$\zeta=e^{2\pi\psi}\quad.\;.\;.\;.\;.\;.\quad(113)$$

When ζ is large, real and positive, equation (108) becomes

$$x=\frac{1}{\pi}\left\{\gamma\left[2\pi\psi_2-\log\frac{1+a}{4}\right]+\alpha\operatorname{arc\,cos}\frac{1-a}{1+a}\right.$$
$$\left.+\beta\operatorname{arc\,cosh}\frac{1+2b-a}{1+a}\right\}$$

When ζ is small, real and positive, equation (108) gives

$$y=-\frac{1}{\pi}\left\{-\gamma\operatorname{arc\,cos}\frac{1-a}{1+a}+\alpha\left[-2\pi\psi_1-\log\frac{1+a}{4a}\right]\right.$$
$$\left.+\beta\operatorname{arc\,cos}\frac{2a-b(1-a)}{b(1+a)}\right\}$$

whence

$$\psi_2-\psi_1=\tfrac{1}{2}\left\{\frac{x-\delta}{\gamma}+\frac{-y}{\alpha}+\frac{\delta}{\gamma}+\frac{1}{\pi}\log\frac{(1+a)^2}{16a}\right.$$
$$-\frac{1}{\pi}\left[\left(\frac{\alpha}{\gamma}-\frac{\gamma}{\alpha}\right)\operatorname{arc\,cos}\frac{1-a}{1+a}\right.$$
$$+\frac{\beta}{\gamma}\operatorname{arc\,cosh}\frac{1+2b-a}{1+a}$$
$$\left.\left.+\frac{\beta}{\alpha}\operatorname{arc\,cos}\frac{2a-b(1-a)}{b(1+a)}\right]\right\}\quad(114)$$

The flux may accordingly be computed by assuming that the gap is filled to the edge of the slot opening with a uniform field of appropriate density $1/(2\gamma)$ on one side and $-1/(2\gamma)$ on the other, that the slot is filled with appropriate uniform field $1/(2\alpha)$, and that there is, in addition, an amount of flux per unit length of core per unit difference of potential between the sides of the slot, given by

$$N=\frac{\delta}{2\gamma}+\frac{1}{\pi}\log\frac{1+a}{4\sqrt{a}}$$
$$-\frac{1}{2\pi}\left\{\left(\frac{\alpha}{\gamma}-\frac{\gamma}{\alpha}\right)\operatorname{arc\,cos}\frac{1-a}{1+a}\right.$$
$$+\frac{\beta}{\gamma}\operatorname{arc\,cosh}\frac{1+2b-a}{1+a}$$
$$\left.+\frac{\beta}{\alpha}\operatorname{arc\,cos}\frac{2a-b(1-a)}{b(1+a)}\right\}\quad(115)$$

In the more general case in which the slot is bounded by some equipotential of the field, the expression for

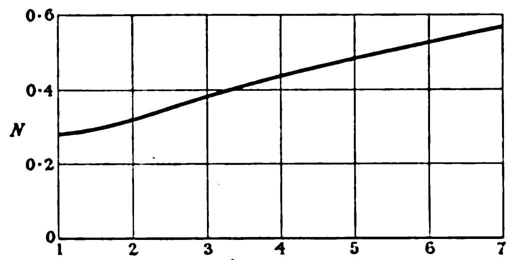

FIG. 32.

N is divided by $1-\lambda$ as in Section 6. If $p=a^{\frac{1}{2}}$ the general expression for N may be written [see equations (109) and (110)]

$$N=\frac{1}{1-\lambda}\left\{\frac{\delta}{2\gamma}+\frac{1}{\pi}\log\left[\tfrac{1}{4}(p+p^{-1})\right]\right.$$
$$-\frac{1}{\pi}\left[\left(\frac{\alpha}{\gamma}-\frac{\gamma}{\alpha}\right)\operatorname{arc\,tan}p+\frac{\beta}{\gamma}\operatorname{arc\,tanh}\frac{\beta p}{\alpha-\gamma p}\right.$$
$$\left.\left.+\frac{\beta}{\alpha}\operatorname{arc\,tan}\frac{\beta}{\alpha-\gamma p}\right]\right\}\quad.\;.\;.\;.\;.\;.\quad(116)$$

In the case of a simple rectangular slot (Fig. 2)

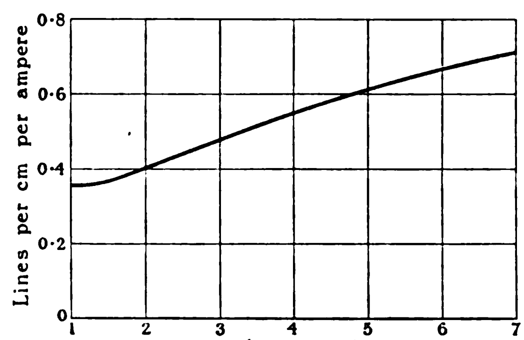

FIG. 33.

$a=b=c$, $\beta=0$, $\alpha=\delta=\frac{1}{2}s$, $\gamma=g$, $\lambda=0$, $p=\alpha/\gamma=s/(2g)$, and the expression for N becomes

$$N=\frac{1}{\pi}\left\{\log\left[\frac{1}{4}\left(\frac{s}{2g}+\frac{2g}{s}\right)\right]\right.$$
$$\left.+\frac{2g}{s}\operatorname{arc\,tan}\frac{2g}{s}+\frac{2g}{s}\operatorname{arc\,tan}\frac{s}{2g}\right\}\quad(117)$$

This is shown, plotted against $s/(2g)$ or $2g/s$, in Fig. 32. Multiplied by $4\pi/10$, the result is expressed in lines per ampere per cm length of core. This, which is in general the more convenient form, is given in Fig. 33.

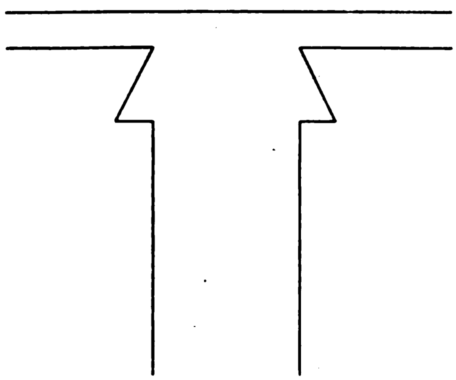

FIG. 34.

The simple rectangular slot is not generally used in machines of the class for which exact reactance calculations are important. Such machines, when designed to use formed coils, usually have open slots provided

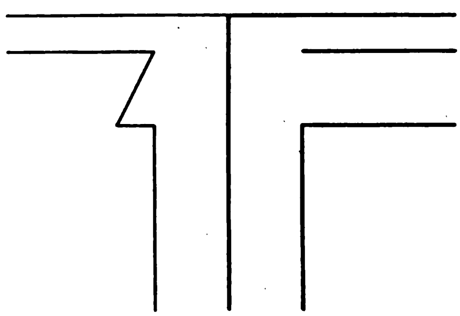

FIG. 35.

with recesses at their mouths in which are driven wooden retainers for holding the coils in place, as shown in Fig. 34. For these slots, the correction for mouth effect is somewhat smaller than is given by equation (117).

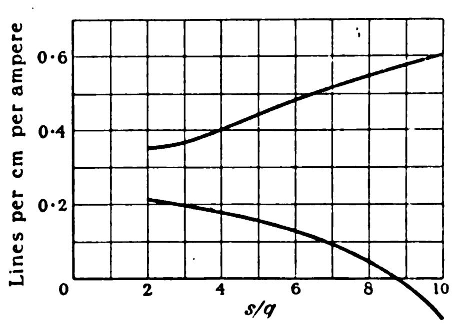

FIG. 36.

It is indeed possible to choose constants in equation (108) so that an equipotential of small inclination with the positive axis of ζ resembles more or less closely the boundary of such a slot as is depicted in Fig. 34, but the problem would be of difficulty out of proportion to the value of the result, since the solution has no absolute status but merely represents an individual judgment. The transformation, however, has its uses, for if the constants be chosen, in relation to the actual slot, to give the boundary shown in thick lines in Fig. 35, the flux determined therefrom may be regarded as an inferior limit, the simple rectangular slot furnishing the superior limit. The limits are shown in Fig. 36, for the case in which the recess extends to a distance equal to half the width of the slot.

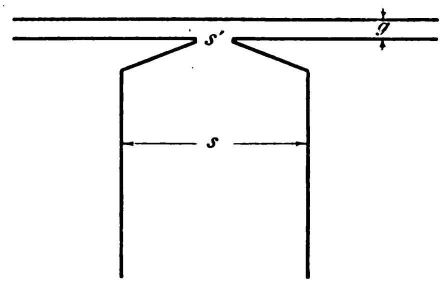

FIG. 37.

A common type of slot for which reactance calculations are of some importance is the partly closed slot, shaped generally as shown in Fig. 37. A reasonably close representation of this is obtained by making $a = b$ in the preceding formulæ and taking as boundary an equipotential line of small inclination with the real axis of ζ, resulting in a shape such as that shown in Fig. 38. It remains to choose constants to give a boundary approximating to that of the actual slot. The following course is suggested tentatively. Make $(1-\lambda)\gamma = g$, $2(1-\lambda)a = s$, $2\delta = s'$, and choose λ so

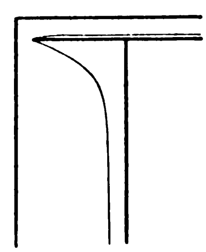

FIG. 38.

that the maximum slope of the boundary line agrees with that of the lip of the slot. The boundary thus determined is in most cases a little sharper at the tip of the lip than the actual slot, but, by way of compensation, it is caused to protrude a little further.

Consider the line of potential 1/2 in the field determined by

$$\phi + j\psi = \frac{1}{2(1-\lambda)}\left(1 + \frac{j}{\pi}\log\zeta\right) \quad . \quad (118)$$

For this equipotential

$$\begin{aligned}\zeta &= e^{2\pi(1-\lambda)\psi + \lambda\pi j} \\ &= q e^{\lambda\pi j} \quad . \quad . \quad . \quad . \quad . \quad . \quad (119)\end{aligned}$$

From equation (108)

$$\frac{dz}{dq} = \frac{\gamma}{\pi}\,\frac{q e^{\lambda\pi j} - c}{q\,[(q e^{\lambda\pi j} - a)\,(q e^{\lambda\pi j} + 1)]^{\frac{1}{2}}} \quad . \quad . \quad (120)$$

Writing $\qquad dz = e^{j\theta'} ds$

the slope of the boundary is given by

$$\theta' = \text{arc tan}\,\frac{q \sin \lambda\pi}{q \cos \lambda\pi - c} - \tfrac{1}{2}\,\text{arc tan}\,\frac{q \sin \lambda\pi}{q \cos \lambda\pi - a} - \tfrac{1}{2}\,\text{arc tan}\,\frac{q \sin \lambda\pi}{q \cos \lambda\pi + 1} \qquad (121)$$

This is a maximum when

$$\frac{(1 + c)\,(q^2 + c)}{q^2 + 1 + 2q \cos \lambda\pi} = \frac{(c - a)\,(ac - q^2)}{q^2 + a^2 - 2qa \cos \lambda\pi} \qquad (122)$$

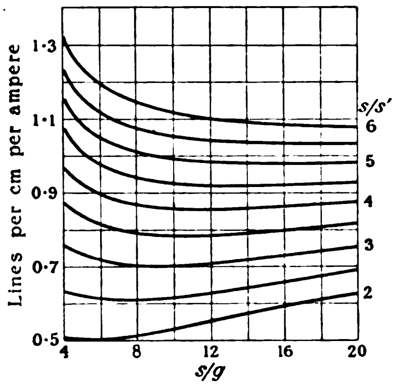

FIG. 39.

and the maximum value of θ' is, by assumption, connected with the angle θ of the lip by the relation

$$\theta + \theta' = \pi \quad . \quad . \quad . \quad . \quad (123)$$

For particular values of the constants, and of the angle θ, equations (121), (122) and (123) determine λ.

The calculation indicated is, however, more intricate than the solution warrants, in view of the lack of exact correspondence between assumed and actual boundaries.

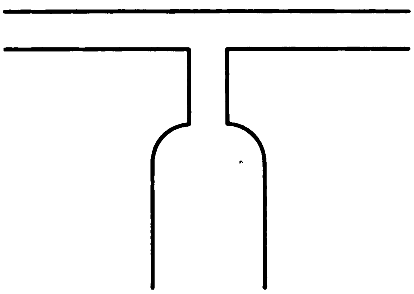

FIG. 40.

It cannot, however, lead to much, if any, greater deviation from the actual boundary to deduce λ, by a similar process of reasoning, from the problem next to be discussed. The connection between λ and the maximum slope of the equipotential line is readily shown in this case to be given by

$$\tan \frac{\lambda\pi}{2} = \frac{s - s'}{s + s'} \tan \theta \quad . \quad . \quad . \quad (124)$$

The additional flux is then determined from equation (116) with p deduced from equations (109), (110) and (111). Fig. 39 gives this flux for the case in which $\theta = 20°$.

In the preceding problem the tips of the slot are supposed brought to about as sharp an edge as mechanical considerations render practicable. In some cases, however, the parallel sides of the mouth are made of appreciable depth, as in Fig. 40, and the field between the sides attains sensibly the normal value corresponding to the distance between them. Consider first the

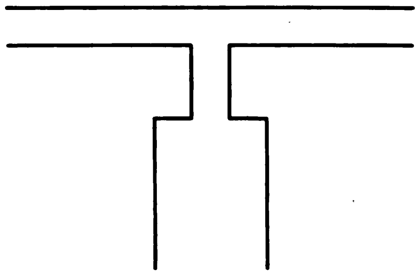

FIG. 41.

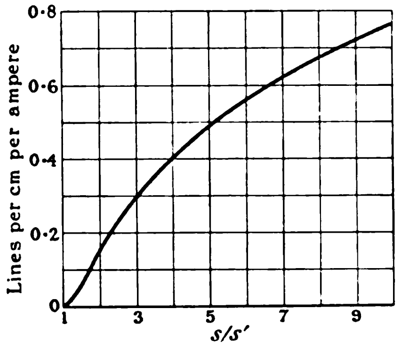

FIG. 42.

rectangular slot, shaped as in Fig. 41. There are here three regions in which the field may be described as normal, viz. the slot, the mouth and the gap, and two regions of transition, one between slot and mouth, the

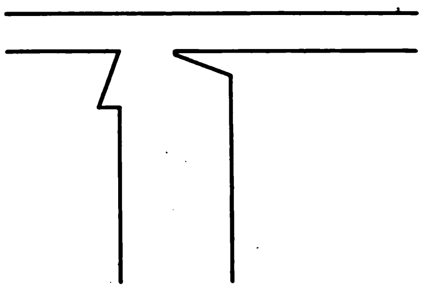

FIG. 43.

other between mouth and gap. For the first of these the additional flux is $\tfrac{1}{2}N$ given by equation (103) (see Figs. 26 and 42); for the second the additional flux is given by equation (117) and Figs. 32 and 33.

For a rounded slot, like that of Fig. 40, one of the equipotential lines might be taken as boundary; but the slots usually employed do not approximate to the shape of these lines, and the square-ended slot is the

better representation. In most cases, accordingly, it is sufficient to assume an equivalent square-ended slot.

Another form of slot, which has its use on occasion, is the unsymmetrical semi-closed slot, shaped as shown in Fig. 43. It is probably sufficient in this case to consider the slot to be bounded as shown in Fig. 44, thus assuming the extra flux due to the bluntness of the overhanging lip in Fig. 43, as compared with Fig. 44, to be sensibly compensated by the reduced flux due to the presence of the recess on the opposite side of the slot.

The transformation in this case may be written

$$z=\frac{g}{\pi}\int\left(\frac{\zeta+c}{\zeta-a}\right)^{\frac{1}{2}}\cdot\frac{\zeta-b}{\zeta+1}\cdot\frac{d\zeta}{\zeta}$$

$$=\frac{g}{\pi}\left\{\operatorname{arc\,cosh}\frac{2\zeta+c-a}{c+a}+\frac{s}{g}\operatorname{arc\,cos}\frac{(c-a)\zeta-2ca}{(c+a)\zeta}\right.$$

$$\left.-\operatorname{arc\,cosh}\frac{(2-c+a)(\zeta+1)-2(1+a)(1-c)}{(c+a)(\zeta+1)}\right\} \quad (125)$$

where -1, $-c$, a, b are in ascending order of magnitude.

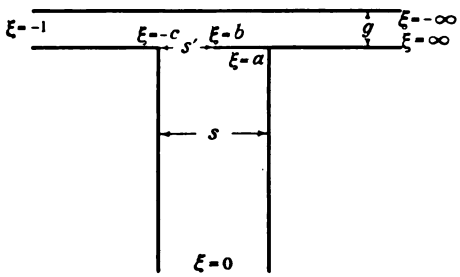

Fig. 44.

When ζ lies between -1 and ∞ the flux function ψ is given by

$$\frac{\zeta^2}{\zeta+1}=e^{2\pi\psi} \quad . \quad . \quad . \quad . \quad (126)$$

The constants in equation (125) are connected with the dimensions of the slot by the equations

$$\frac{s}{g}=b\left(\frac{c}{a}\right)^{\frac{1}{2}} \quad . \quad . \quad . \quad . \quad . \quad (127)$$

$$(1+b)\left(\frac{1-c}{1+a}\right)^{\frac{1}{2}}=1 \quad . \quad . \quad . \quad (128)$$

$$\frac{s'}{g}=\frac{1}{\pi}\left\{\operatorname{arc\,cosh}\frac{2b+c-a}{c+a}+\frac{s}{g}\operatorname{arc\,cos}\frac{(c-a)b-2ca}{(c+a)b}\right.$$

$$\left.-\operatorname{arc\,cosh}\frac{(2-c+a)(1+b)-2(1+a)(1-c)}{(c+a)(1+b)}\right\} \quad (129)$$

When ζ is large, real and positive :—

$$x=\frac{g}{\pi}\left\{2\pi\psi_1+\log\frac{4}{c+a}+\frac{s}{g}\operatorname{arc\,cos}\frac{c-a}{c+a}\right.$$

$$\left.-\operatorname{arc\,cosh}\frac{2-c+a}{c+a}\right\}$$

When ζ is small, real and positive :—

$$y=\frac{g}{\pi}\left\{\operatorname{arc\,cos}\frac{c-a}{c+a}-\frac{s}{g}\left(-\pi\psi_0+\log\frac{4ca}{c+a}\right)\right.$$

$$\left.-\operatorname{arc\,cos}\frac{2ac+c-a}{c+a}\right\}$$

Whence

$$\psi_1-\psi_0=\frac{x-s'}{2g}+\frac{-y}{s}+\frac{s'}{2g}$$

$$+\frac{1}{2\pi}\left\{\log\frac{(c+a)^3}{64c^2a^2}-\left(\frac{s}{g}-\frac{2g}{s}\right)\operatorname{arc\,cos}\frac{c-a}{c+a}\right.$$

$$\left.+\operatorname{arc\,cosh}\frac{2-c+a}{c+a}-\frac{2g}{s}\operatorname{arc\,cos}\frac{2ac+c-a}{c+a}\right\} \quad (130)$$

The flux accordingly may be reckoned as filling the slot at the appropriate normal density, and the gap to the mouth of the slot at its appropriate normal density with the addition, per unit length of core, of N, given by

$$N=\frac{s'}{2g}+\frac{1}{2\pi}\left\{\log\frac{(c+a)^3}{64c^2a^2}-\left(\frac{s}{g}-\frac{2g}{s}\right)\operatorname{arc\,cos}\frac{c-a}{c+a}\right.$$

$$+\operatorname{arc\,cosh}\frac{2-c+a}{c+a}$$

$$\left.-\frac{2g}{s}\operatorname{arc\,cos}\frac{2ac+c-a}{c+a}\right\} \quad . \quad (131)$$

In many cases $s/s'=2$, and although this does not simplify the equations from which the constants are derived, it reduces the results to functions of a single variable, such as s/g, and enables them to be expressed in a single curve. Fig. 45 gives the curve for this case.

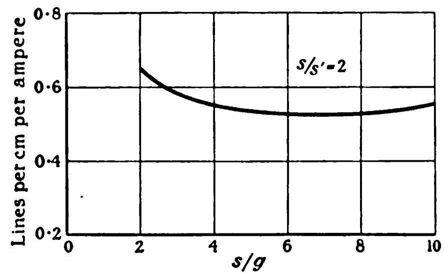

Fig. 45

In the foregoing the slots have been assumed to be opposed to plane equipotential surfaces, but in most cases in which the reactance of the embedded conductors is of importance there are slots in both opposing surfaces. The reactance then varies, being a minimum when slot is opposed by slot, and a maximum when slot is opposed by tooth. Since the variation takes place principally in the field outside the slot, it is sufficient for practical purposes to consider the case in which the opposing slots are rectangular and of widths equal to those of the mouths of the actual slots. The curve of variation, as the slots are displaced relatively, might be deduced by means of the transformation given in Section 4, but, for the purpose in view, it is probably sufficient to establish a formula giving the extent of the variation.

If s' is the width of the mouth of the slot containing the conductors whose reactance is required, and s_1 that of the opposing slot, the transformation

$$z=\frac{g}{\pi}\int\frac{[(\zeta-a)(\zeta+c)]^{\frac{1}{2}}d\zeta}{\zeta(\zeta+b)}$$

$$=\frac{g}{\pi}\left\{\operatorname{arc\,cosh}\frac{2\zeta+c-a}{c+a}+\frac{s'}{2g}\operatorname{arc\,cos}\frac{(c-a)\zeta-2ac}{(c+a)\zeta}\right.$$

$$\left.+\frac{s_1}{2g}\operatorname{arc\,cos}\frac{2(c-b)(a+b)+(a+2b-c)(\zeta+b)}{(a+c)(\zeta+b)}\right\} \quad (132)$$

in which $-c$, $-b$, 0, a, are in ascending order of magnitude, and in which

$$\frac{s'}{2g}=\frac{\sqrt{(ac)}}{b} \quad . \quad . \quad . \quad . \quad . \quad (133)$$

$$\frac{s_1}{2g}=\frac{\sqrt{[(a+b)(c-b)]}}{b} \quad . \quad . \quad . \quad (134)$$

converts the half-plane of ζ into the plane of z, bounded

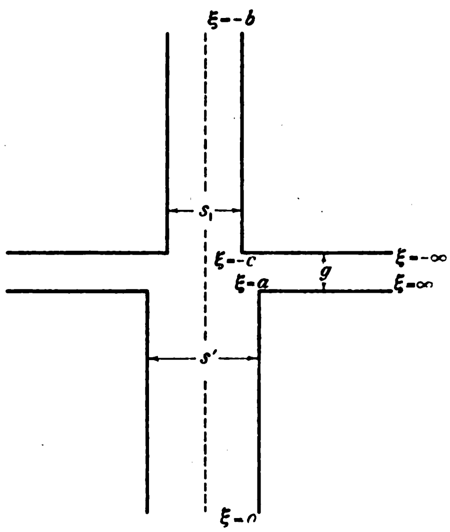

FIG. 46.

as in Fig. 46. The flux function ψ is given on the real axis of ζ by

$$\zeta=e^{2\pi\psi} \quad . \quad . \quad . \quad . \quad . \quad . \quad (135)$$

When ζ is large, real and positive :—

$$x=\frac{g}{\pi}\left\{2\pi\psi_1+\log\frac{4}{c+a}+\frac{s'}{2g}\operatorname{arc\,cos}\frac{c-a}{c+a}\right.$$

$$\left.+\frac{s_1}{2g}\operatorname{arc\,cos}\frac{a+2b-c}{c+a}\right\}$$

When ζ is small, real and positive :—

$$y=\frac{g}{\pi}\left\{\operatorname{arc\,cos}\frac{c-a}{c+a}-\frac{s'}{2g}\left(-2\pi\psi_0+\log\frac{4ac}{c+a}\right)\right.$$

$$\left.+\frac{s_1}{2g}\operatorname{arc\,cosh}\frac{2ac+b(c-a)}{b(c+a)}\right\}$$

Whence

$$\psi_1-\psi_0=\frac{x-\frac{1}{2}s'}{2g}+\frac{-y}{s'}$$

$$+\frac{1}{2\pi}\left\{\log\frac{(c+a)^2}{16ca}+\frac{s'}{2g}\left(\pi-\operatorname{arc\,cos}\frac{c-a}{c+a}\right)\right.$$

$$+\frac{2g}{s'}\operatorname{arc\,cos}\frac{c-a}{c+a}-\frac{s_1}{2g}\operatorname{arc\,cos}\frac{a+2b-c}{c+a}$$

$$\left.+\frac{s_1}{s'}\operatorname{arc\,cosh}\frac{2ac+b(c-a)}{b(c+a)}\right\} \quad . \quad (136)$$

The additional flux in this case is accordingly

$$N=\frac{1}{2\pi}\left\{\log\frac{(c+a)^2}{16ca}\right.$$

$$+\frac{s'}{2g}\left(\pi-\operatorname{arc\,cos}\frac{c-a}{c+a}\right)+\frac{2g}{s'}\operatorname{arc\,cos}\frac{c-a}{c+a}$$

$$-\frac{s_1}{s'}\left[\frac{s'}{2g}\operatorname{arc\,cos}\frac{a+2b-c}{c+a}\right.$$

$$\left.\left.-\operatorname{arc\,cosh}\frac{2ac+b(c-a)}{b(c+a)}\right]\right\} \quad . \quad . \quad (137)$$

Writing $\lambda=(c/a)^{\frac{1}{2}}$, equations (133) and (134) give

$$\frac{s'}{2g}\lambda=\frac{c}{b};\quad \frac{s'}{2g}\lambda^{-1}=\frac{a}{b}$$

$$\left(\frac{s_1}{2g}\right)^2=\left(\frac{s'}{2g}\lambda^{-1}+1\right)\left(\frac{s'}{2g}\lambda-1\right)$$

$$=\left(\frac{s'}{2g}\right)^2-1+\frac{s'}{2g}(\lambda-\lambda^{-1}) \quad . \quad (138)$$

Equation (138) gives λ, and the additional flux may be written

$$N=\frac{1}{\pi}\left\{\log\left[\tfrac{1}{2}(\lambda+\lambda^{-1})\right]\right.$$

$$\left.+\frac{s'}{2g}\operatorname{arc\,tan}(\lambda)+\frac{2g}{s'}\operatorname{arc\,tan}(\lambda^{-1})\right\}$$

$$-\frac{1}{2\pi}\frac{s_1}{s'}\left\{\frac{s'}{2g}\operatorname{arc\,cos}\frac{4g^2+s'^2-s_1^2}{2gs'(\lambda+\lambda^{-1})}\right.$$

$$\left.-\operatorname{arc\,cosh}\frac{4g^2+s'^2+s_1^2}{2gs'(\lambda+\lambda^{-1})}\right\} \quad (139)$$

Equation (139) gives the minimum additional flux, and the maximum is given by equation (117). The variation sought is therefore

$$N'=\frac{1}{\pi}\left\{\log\left[\left(\frac{s'}{2g}+\frac{2g}{s'}\right)\Big/(\lambda+\lambda^{-1})\right]\right.$$

$$+\frac{s'}{2g}\left[\operatorname{arc\,tan}\frac{2g}{s'}-\operatorname{arc\,tan}\lambda\right]$$

$$\left.+\frac{2g}{s'}\left[\operatorname{arc\,tan}\frac{s'}{2g}-\operatorname{arc\,tan}\lambda^{-1}\right]\right\}$$

$$+\frac{1}{2\pi}\cdot\frac{s_1}{s'}\left\{\frac{s'}{2g}\operatorname{arc\,cos}\frac{4g^2+s'^2-s_1^2}{2gs'(\lambda+\lambda^{-1})}\right.$$

$$\left.-\operatorname{arc\,cosh}\frac{4g^2+s'+s_1^2}{2gs(\lambda+\lambda^{-1})}\right\} \quad (140)$$

APPENDIX 1.

On the Transformation of Schwarz and Christoffel (Section 3, Page 1116).

The powerful and beautiful method of transformation associated with the joint names of Schwarz * and Christoffel † is used in most of the problems discussed herein, and, although well known to mathematicians, the reasoning on which it is based is not readily available in explicit form to English readers. It is discussed fully in Sir J. J. Thomson's "Recent Researches in Electricity and Magnetism," ‡ which has, however, long been out of print. It is treated slightly in Dr. J. H. Jean's "Electricity and Magnetism," § where, however, it is introduced as a transformation in which one equipotential can be any linear polygon. The apparent restriction of the boundary to a single equipotential is an unnecessary one, which would exclude all the problems discussed in the present paper. It is, in effect, removed in a later Section, dealing with successive transformations; but although this procedure offers no difficulty to the expert, it is perhaps confusing to those less exclusively occupied with mathematics, who may, nevertheless, be quite competent to understand the method. It may, therefore, not be considered inappropriate to attempt the elucidation of the matter here.

It is expedient at the outset to state the general problem in mathematical language, in order to show the aim of the investigation. Briefly, we seek a certain function of the co-ordinates, designated a potential function, which satisfies Laplace's equation within a certain region, and which has certain properties on the boundaries of the region. A knowledge of this function determines the whole solution. In two dimensions Laplace's equation takes the form:

$$\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2} = 0$$

Now the real or the imaginary part of any function of the complex variable, $x + jy$, satisfies this equation, and it is only necessary to find the form of the function appropriate to the boundary conditions. In most of the problems herein discussed the potential distribution at the boundary is known, having a constant value over one portion and another constant value over the remainder. Sometimes, as in the case of Fig. 4, the potential assumes certain constant values on portions of the boundary, and its conjugate function, which we designate the "flux function," assumes constant values on other portions.

If (x, y) are the co-ordinates of a point, and any function of the complex variable, $z = x + jy$, be formed, it is itself a complex quantity, and may be written in the form, $\zeta = F(z) = \xi + j\eta$. If (ξ, η) be taken as the co-ordinates of a point in a new plane, a problem in the plane of (x, y), involving certain boundaries, yields a problem in the plane of (ξ, η), with corresponding transformed boundaries. From the relation:

$$d\zeta = F'(z)dz$$

it is apparent that $d\zeta$, in the neighbourhood of any point, is dz multiplied by the modulus of $F'(z)$ and turned through a certain angle—the argument of $F'(z)$. Infinitesimal areas about a point accordingly transform into similar areas. The potential and flux functions, ϕ and ψ, are, as already remarked, conjugate. Thus $\phi + j\psi$ is a function of z and, therefore, of ζ. ϕ and ψ accordingly remain possible potential and flux functions on transformation. By means of such transformation

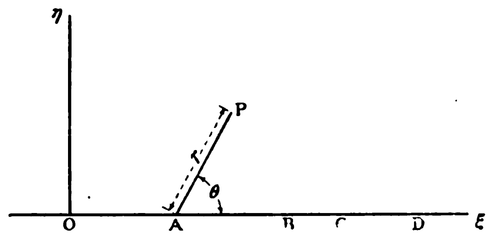

Fig. 47.—Plane of ζ.

an intricate problem can often be made to depend on a simpler one.

The transformation of Schwarz and Christoffel is a geometrical one, transforming the whole region on the positive side of the real axis in one plane (called herein the plane of ζ, where $\zeta = \xi + j\eta$, see Fig. 47), into a region bounded by any required rectilinear polygon in the transformed plane (called herein the plane of z, where $z = x + jy$, see Fig. 48). Here the word "polygon" should be interpreted as any continuous recti-

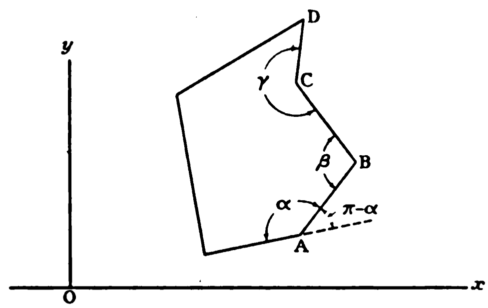

Fig. 48.—Plane of z.

linear figure which does not cross itself, closed either in finite regions or by means of the line at infinity, and the region bounded by it as the region on one side of the boundary.

Consider the transformation

$$\frac{dz}{d\zeta} = A(\zeta - a)^{(\alpha/\pi)-1}(\zeta - b)^{(\beta/\pi)-1}(\zeta - c)^{(\gamma/\pi)-1} \quad (141)$$

in which A is a constant, real or complex, $a, b, c \ldots$ are real constants, representing the distances OA, OB, OC . . . in Fig. 47, and $\alpha, \beta, \gamma, \ldots$ are real constants, representing the internal angles of the polygon in Fig. 48. It will be noted that $dz/d\zeta$ becomes either zero or infinity at a singular point, implying that an

* Crelle, 1869, tome 70.
† *Annali di Matematica* (2), 1867, tome 1.
‡ Oxford, 1893, ch. 3.
§ Cambridge University Press, 1923, ch. 8, par. 322 *et seq.*

infinitesimal $d\zeta$ at such a point gives rise to an infinitesimal dz of higher or lower order.

Now at any point P (see Fig. 47)

$$\begin{aligned}\zeta - a &= \xi - a + j\eta \\ &= r(\cos\theta + j\sin\theta) \\ &= re^{j\theta} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (142)\end{aligned}$$

When ζ is on the real axis, the argument of $\zeta - a$ is zero, or a multiple of π, but as we are only concerned with changes in the argument we may take it as zero when $\zeta - a$ is positive, and as π when $\zeta - a$ is negative, the passage through A from $\zeta > a$ to $\zeta < a$ being viewed as the limit of a passage in a small semi-circle, drawn about A in the region under consideration, in which the argument θ increases from 0 to π.

Now, the argument of a product being the sum of the arguments of its factors, it follows that along the real axis of ζ, the argument of $dz/d\zeta$ in equation (141) (and therefore that of dz, since $d\zeta$ is real), only changes when ζ passes through one of the points A, B, C . . . Accordingly dz maintains a constant direction between consecutive singular points in Fig. 47, and the transformed figure corresponding to the real axis of ζ is a rectilinear polygon. In passing through a singular point (e.g. $\zeta = a$) the argument of $\zeta - a$ is diminished by π, and that of $(\zeta - a)^{(\alpha/\pi)-1}$ is diminished by $[(\alpha/\pi) - 1]\pi$, i.e. increased by $\pi - \alpha$. The change in direction of the boundary at A in Fig. 48 is therefore $\pi - \alpha$, and α is the value of the internal angle at A in the transformed figure; and so generally.

The transformation required is accordingly

$$z = A\int(\zeta - a)^{(\alpha/\pi)-1}(\zeta - b)^{(\beta/\pi)-1}(\zeta - c)^{(\gamma/\pi)-1} \ldots d\zeta \quad (143)$$

in which α, β, γ, . . . are the internal angles of the polygon; a, b, c, . . . are real quantities which have to be determined so as to give correct proportions to the figure, but of which three may be given arbitrary values *; and A is a constant determining the size and orientation of the figure.

The boundary having thus been determined, the appropriate field depends on the particular problem, for the same boundary transformation may be used in different problems.† In most of the problems discussed, the potential function is required to be such as gives a certain distribution of potential on the bounding polygon; in order to determine this, a potential function is sought in terms of ζ, which gives the required distribution on corresponding portions of the boundary (i.e. the real axis), in the plane of ζ; and this function, transformed into z co-ordinates, gives the solution of the problem. In most of the problems considered, the field in the plane of ζ may be taken as that due to a current of electricity passing through one of the singular points at right angles to the plane, thus causing a constant difference of magnetic potential between the portions of boundary on the two sides of the singular point. If ϕ is the potential function and ψ the flux function, the field is determined by an equation of the form

$$\phi + j\psi = Cj\log(\zeta - a) \quad . \quad . \quad . \quad (144)$$

* In the problems discussed, however, two only of the points have been chosen arbitrarily, the origin being one, but the line at infinity has been localized as the third condition.

† See Section 10, page 1128.

in which C is real. If r is the modulus and θ the argument of $\zeta - a$, the equation may be written

$$\phi + j\psi = C(j\log r - \theta) \quad . \quad . \quad . \quad (145)$$

The radial lines, θ = constant (in particular $\theta = 0$ and $\theta = \pi$), are equipotential, and the circles, r = constant, are lines of flux. It may be mentioned that, except in one case (see Fig. 20), the transformed source is at infinity. The field in the plane of ζ may take other forms, that determined by equation (39) for instance, in which two equipotential sections of the boundary are isolated and separated by flux lines.

As an example of the use of the method, consider the first problem discussed in Section 6 (see Fig. 15). Starting from $\zeta = -\infty$, z follows the y axis until $\zeta = -1$ (a figure chosen arbitrarily), where the polygonal boundary has an internal angle $\frac{1}{2}\pi$. It then follows the x axis to infinity ($\zeta = 0$), here doubles back on itself (internal angle zero), until the point A is reached ($\zeta = a$), where it again doubles back (internal angle 2π), and proceeds to infinity. Equation (143) accordingly gives

$$z = A\int(\zeta + 1)^{\frac{1}{2}-1}(\zeta - 0)^{0-1}(\zeta - a)^{2-1}d\zeta \quad (146)$$

which is equation (45).

The field on this case is required to make the line between A and infinity at one potential, and the rest of the boundary at another. Equation (144), with $a = 0$, is of the form of equation (46), in which, however, an immaterial constant has been added to make one section of the boundary of zero potential.

One other matter may be mentioned, having reference to the practice, of which frequent use is made, of taking one line of the boundary to infinity and returning by a parallel line. The angle between these sides is zero and the corresponding factor in equation (143) is $(\zeta - a)^{-1}$. In order to find the change in z as ζ passes through A, proceed to a point indefinitely near to A; then, passing to the other side by a semi-circle drawn in the region under consideration, as already explained, the increment of z is

$$\begin{aligned}\delta z &= A(a - b)^{(\beta/\pi)-1}(a - c)^{(\gamma/\pi)-1} \ldots \int(re^{j\theta})^{-1}d(re^{j\theta}) \\ &= A(a - b)^{(\beta/\pi)-1}(a - c)^{(\gamma/\pi)-1} \ldots \int_{\pi}^{0} j\,d\theta \\ &= -A(a - b)^{(\beta/\pi)-1}(a - c)^{(\gamma/\pi)-1} \ldots j\pi \quad . \quad . \quad (147)\end{aligned}$$

This then is the distance between the parallel sides. Much use is made of equation (147) in the course of the paper, e.g. in equations (12), (17), (109), (110), (127), (128), (133) and (134).

APPENDIX 2.

ATTRACTION BETWEEN POLAR SURFACES (SEE SECTION 1, PAGE 1116.)

The strictures made concerning the practicability of using the method of conjugate functions where there is no natural limit to the field, apply to problems involving the integral flux, such as that of the inductance of the

coil producing the field. Problems which merely involve change in flux may be quite appropriate for treatment. Thus, if the difference of potential between the members in Fig. 1 be maintained constant, this difference, multiplied by the rate of increase of flux with movement of a member, and divided by 8π, is the mechanical force tending to produce the movement. If, for instance, Fig. 1 represents the edge of the poles of a contactor, or plunger electromagnet, the force of attraction between the poles is readily obtained. The appropriate transformation and field function are given in equations (95) and (96), whilst equation (98) gives ψ under the pole. When ψ is large and negative :—

$$x_1 = \frac{\gamma}{\pi} e^{-\pi\psi_1}$$

or

$$\psi_1 = -\frac{1}{\pi} \log \frac{\pi x_1}{\gamma}$$

whence $$\psi - \psi_1 = -\frac{x}{\gamma} + \frac{1}{\pi} \log \frac{\pi x_1}{\gamma} + \text{const.}$$

This is the total flux between the points x and x_1 with unity difference of potential between the polar

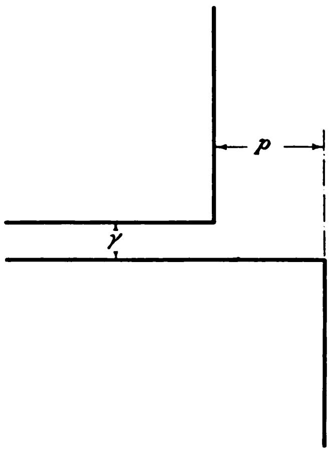

FIG. 49.

surfaces. The attraction between the members, if ϕ_0 is their difference of potential, is accordingly

$$-\frac{\phi_0}{8\pi} \cdot \frac{d}{d\gamma}[\phi_0(\psi - \psi_1)] = \frac{\phi_0^2}{8\pi}\left(-\frac{x}{\gamma^2} + \frac{1}{\gamma\pi}\right)$$

$$= \frac{\phi_0^2}{8\pi\gamma^2}\left(-x + \frac{\gamma}{\pi}\right) \quad (148)$$

Here $-x$ is the distance under the pole, measured from the edge, and $\phi_0^2/(8\pi\gamma^2)$ is the force per unit area. The attraction of the plunger is accordingly the same as if the pole were increased by a rim of width γ/π all round, and the normal flux density ϕ_0/γ maintained throughout the area so increased.

A similar transformation, devised to deal with the case of overhanging poles (Fig. 49), was used by the author in a note * on "Magnetic Centering of Dynamo-electric Machinery," in a somewhat similar manner. The attraction between such poles is readily found to be equivalent to adding to the smaller a rim of width

$$\frac{\gamma}{\pi} + \frac{p}{\pi} \operatorname{arc\,cot} \frac{p}{\gamma} \quad . \quad . \quad . \quad . \quad (149)$$

* *Minutes of the Proceedings of the Institution of Civil Engineers*, 1911-12, vol. 187, p. 311.

APPENDIX 3.

CALCULATION OF GAP COEFFICIENT (SEE SECTION 3, PAGE 1118).

As an example of a calculation approximately applicable to given conditions, take the case in which $t/s = 1$ and $2g/s = 1$. Equation (8) gives $\sigma = 0 \cdot 2794$; and from equation (25)

$$\frac{F'}{F} = 1 \cdot 7206 \quad . \quad . \quad . \quad . \quad (150)$$

whence the modulus of F,

$$k \operatorname{sn} \alpha = \sin 15° \; 16 \cdot 4' = 0 \cdot 2634 \quad . \quad . \quad (151)$$

Equation (16) gives $\operatorname{sn} \alpha = 0 \cdot 7071$, and accordingly $k = 0 \cdot 3726$ approx. Sn α is, however, not quite the most convenient starting point for the calculation, and it appears to give a better approximation to the actual case to modify equation (16), making

$$\sin \frac{\pi\alpha}{2K} = \left[1 + \left(\frac{s}{2g}\right)^2\right]^{-\frac{1}{2}}$$

or

$$\tan \frac{\pi\alpha}{2K} = \frac{2g}{s} \quad . \quad . \quad . \quad . \quad . \quad (152)$$

A preliminary calculation for $\operatorname{sn} \alpha$ with $k = 0 \cdot 3726$ gives $\operatorname{sn} \alpha = 0 \cdot 72$, whence $k = \sin 21° \; 30' = 0 \cdot 3665$.

$$K = 1 \cdot 6280 \; ; \; K' = 2 \cdot 4404 \; ; \; q = e^{-\pi(K'/K)} = 0 \cdot 00901$$

whence $$\frac{\pi}{2} \frac{\alpha}{K} = \frac{\pi}{4}; \quad \alpha = \frac{K}{2} = 0 \cdot 8140$$

$$\Theta(\alpha) = 1 - 2q \cos\left(\pi\frac{\alpha}{K}\right) + 2q^4 \cos\left(2\pi\frac{\alpha}{K}\right) \ldots$$
$$= 1 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (153)^*$$

$$H(\alpha) = 2\left[q^{\frac{1}{4}} \sin\left(\frac{\pi\alpha}{K}\right) - q^{\frac{9}{4}} \sin\left(\frac{3\pi\alpha}{K}\right) + \ldots\right]$$
$$= 0 \cdot 4357 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (154)^*$$

$$\Theta'(\alpha) = \frac{2\pi}{K}\left[q \sin\left(\frac{\pi\alpha}{K}\right) - 2q^4 \sin\left(2\frac{\pi\alpha}{K}\right) + \ldots\right]$$
$$= 0 \cdot 03477 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (155)^*$$

$$\operatorname{sn} \alpha = \frac{H(\alpha)}{k^{\frac{1}{2}}\Theta(\alpha)}$$
$$= 0 \cdot 7198 \quad . \quad . \quad . \quad (156)\dagger$$

$$\operatorname{cn} \alpha = 0 \cdot 6942 \quad . \quad . \quad . \quad . \quad (157)$$

$$\operatorname{dn} \alpha = 0 \cdot 9646 \quad . \quad . \quad . \quad . \quad (158)$$

$$\frac{\operatorname{sn} \alpha \operatorname{dn} \alpha}{\operatorname{cn} \alpha} = 1 \cdot 00 \quad . \quad . \quad . \quad . \quad . \quad (159)$$

$$Z(\alpha) = \frac{\Theta'(\alpha)}{\Theta(\alpha)}$$
$$= 0 \cdot 03477 \quad . \quad . \quad . \quad (160)\ddagger$$

* *Vide* Cayley's "Elliptic Functions," 2nd edn., par. 388.
† *Ibid.*, par. 387. ‡ *Ibid.*, par. 210.

Hence, from equation (19) :—

$$\frac{2g}{s} = 1\cdot0004 \quad . \quad . \quad . \quad . \quad . \quad (161)$$

and from equation (20) :—

$$\frac{t}{s} = 0\cdot9997 \quad . \quad . \quad . \quad . \quad . \quad . \quad (162)$$

Again,

$$k \operatorname{sn} a = 0\cdot2638 \quad . \quad . \quad . \quad . \quad . \quad (163)$$

$$F = 1\cdot5993 \quad . \quad . \quad . \quad . \quad . \quad (164)$$

$$F' = 2\cdot7503 \quad . \quad . \quad . \quad . \quad . \quad (165)$$

Hence, from equation (22) :—

$$\frac{G}{g} = 1\cdot1622 \quad . \quad . \quad . \quad . \quad . \quad . \quad (166)$$

The formula of (10), for the dimensions given by (161) and (162), yields

$$\frac{G}{g} = 1\cdot161$$

APPENDIX 4.

Calculation of Fringe Flux at Pole-Tip (see Section 6, Page 1122).

The process of computing the curves of Fig. 17 was as follows :—

(1) A number of suitable values of the constant a were determined by drawing a curve between x/γ and a, where x is deduced from equation (45), with $\zeta = a$ and $\lambda = 0$.

(2) With each of these values of a and for a few values of λ, q was determined from equation (52).

(3) The corresponding radius of curvature was determined from equations (49) and (51).*

(4) The radius of curvature was plotted, against λ as abscissa, for each of the selected values of a.

(5) The value of x/γ corresponding to the extreme tip was determined, from equations (45), (47) and (52), for each value of a and of λ.

(6) This value of x/γ was plotted, against λ as abscissa, for each of the selected values of a.

(7) The fringing effect d/γ as given by equation (55) was determined for each value of a and of λ.

(8) The fringing was expressed as an equivalent addition to the pole-face, by subtracting the result given above by (7) from that given by (5).

(9) The fringing so expressed was plotted, against λ as abscissa, for each of the selected values of a.

(10) By cross-plotting, for each required value of the radius of curvature, and for each value of a, the corresponding values of x/γ and of the fringing coefficient $(x - d)/\gamma$ were determined.

(11) The fringing coefficient was plotted against x/γ as abscissa, for each required value of radius of curvature.

* In this connection it may be noted that $q^2 + 2q\cos\lambda\pi + 1 = (1 + a)^2$.

THE CIRCLE DIAGRAMS OF THE THREE-PHASE SHUNT COMMUTATOR MOTOR.*

By A. H. M. Arnold, Ph.D., Student.

(*Paper first received 5th November, 1925, and in final form 23rd February, 1926.*)

Summary.

A simplified mathematical theory of the circle diagrams of the three-phase shunt commutator motor is developed from the theory of the standard polyphase induction motor. Sources of error in the theory are outlined, and the theoretical circles are then compared with test-results. Formulæ are developed for the slip, torque and mechanical power. The improvement in performance of the motor, which may be obtained by an unsymmetrical setting of the brushes, is described fully, and an approximate formula for the circle diagrams under these conditions is given. The capabilities of the motor as a generator are briefly discussed.

In the Appendix, phenomena occurring in the operation of the motor at synchronous speed are noted, with particular reference to the effect of errors in the brush settings.

Table of Contents.

List of Symbols Used.

Φ = mutual flux.

E_1 = E.M.F. induced in primary (rotor) phase winding.

E_2 = E.M.F. induced in secondary (stator) phase winding.

E_L = E.M.F. induced in lap winding between the half brushes of one phase, when these half brushes are separated 180 electrical degrees. This is termed the maximum lap winding E.M.F. or maximum "injected" E.M.F.

aE_L = lap winding E.M.F. or "injected" E.M.F. for an angle of brush separation of β electrical degrees.

$$a = \frac{k_{wl\beta}}{k_{wl}} \cdot \frac{\beta}{180}$$

(A curve, obtained experimentally, showing the relation between β and a is given in Fig. 3.)

n_1 = number of turns per phase in primary (rotor) winding.

n_2 = number of turns per phase in secondary (stator) winding.

n_l = number of turns per phase in lap (secondary) winding for a brush separation of 180 electrical degrees.

k_{w1} = breadth factor of primary winding.

k_{w2} = breadth factor of secondary (stator) winding.

k_{wl} = breadth factor of lap winding for a brush separation of 180 electrical degrees.

$k_{wl\beta}$ = breadth factor of lap winding for a brush separation of β electrical degrees.

n_{e1} = effective primary turns per phase $= n_1 \times k_{w1}$.

n_{e2} = effective secondary (stator) turns per phase $= n_2 \times k_{w2}$.

$$n = \frac{n_l \times k_{wl}}{n_2 \times k_{w2}}$$

$p = an$.

s = slip (defined on page 1142).

I_2 = secondary phase current (common to lap and stator windings).

I = primary (rotor) phase current.

I_m = magnetizing and hysteresis phase current.

$I_1 = I - I_m$ (vectorial subtraction).

R_1 = primary phase winding resistance.

R_2 = secondary phase resistance. This is the sum of the stator resistance, the brush contact resistance and the resistance of that part of the lap winding between the half brushes of the phase.

X_1 = primary phase winding leakage reactance at supply frequency.

X_2 = stator phase winding leakage reactance at supply frequency.

V = supply phase pressure.

P = mechanical power of the motor.

T = mechanical torque of the motor. (If pressures are in volts and currents in amperes, the torque will be in synchronous watts.)

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

T_m = maximum torque of the motor for a given brush position.

s_m = slip for maximum torque.

$$\left.\begin{aligned} \theta &= \text{vector angle between } E_2 \text{ and } I_2 \\ 180^\circ - \psi &= \text{vector angle between } V \text{ and } I_2 \\ \phi &= \text{vector angle between } V \text{ and } I_1 \\ \gamma &= \text{vector angle between } V \text{ and } I \end{aligned}\right\}\text{(see Fig.4).}$$

(i.e. phase angle of supply voltage and supply current.)

ρ = vector angle between E_L and I_1.

η = angle between centre-line of brush gear and centre line of secondary winding. (For symmetrical brush positions, $\eta = 0$.)

$\left.\begin{matrix} x \\ y \end{matrix}\right\}$ = co-ordinates of extremity of I_2 vector measured from O_1 as origin (see Fig. 6).

$\left.\begin{matrix} x_1 \\ y_1 \end{matrix}\right\}$ = co-ordinates of extremity of I_1 vector measured from O_1 as origin (see Fig. 6).

$\left.\begin{matrix} a \\ b \end{matrix}\right\}$ = co-ordinates of centre of secondary circle, measured from O_1 as origin.

$\left.\begin{matrix} a_1 \\ b_1 \end{matrix}\right\}$ = co-ordinates of centre of primary circle, measured from O_1 as origin.

r = radius of secondary circle.

r_1 = radius of primary circle.

Introduction.

In writing this paper much assistance has been derived from two papers * which explain the general theory of the motor fully and clearly.

It will be assumed in order to avoid, as far as possible, needless repetition, that the reader has access to the second of these two papers, but no knowledge of the German paper, as such parts of it as are necessary will be reproduced in the present paper.

The symbols used by Dr. Teago in his paper have been retained as far as possible, but certain new symbols are required for the mathematical solution of the diagrams, and in some cases the meanings of the symbols have been slightly altered. Full definitions are given of all the symbols used, and it is hoped that this will prevent confusion.

Dr. Teago's paper describes the general principles on which the motor operates. The present paper shows how the performance of the motor may be predetermined with reasonable accuracy and simplicity from the design data.

The Development of the Vector Diagram of the Three-Phase Shunt Commutator Motor from the Vector Diagram of the Induction Motor.

The standard vector diagram for one phase of the three-phase induction motor is shown in Fig. 2. This diagram is really two diagrams drawn about the same origin, the diagram of primary vectors and the diagram of secondary vectors. If it is desired to transfer a secondary vector to the primary diagram, it must be reduced to its equivalent primary value, by means of the transformation ratio of the motor. This is the ratio of effective primary turns to effective secondary turns per phase winding. Owing to the space distribution of the conductors of each phase winding, the M.M.F. produced by all the conductors of one phase winding is less than the algebraic sum of the individual M.M.F.'s of each conductor. Thus the effective turns are less than the actual turns. This is taken account of by means of a breadth factor, as follows:—

Effective primary turns (n_{e1}) = actual primary turns (n_1) × primary breadth factor (k_{w1}).

Effective secondary turns (n_{e2}) = actual secondary turns (n_2) × secondary breadth factor (k_{w2}).

$$\text{Transformation ratio} = \frac{n_{e1}}{n_{e2}} = \frac{n_1}{n_2} \times \frac{k_{w1}}{k_{w2}}.$$

Equivalent primary value of secondary current = (n_{e2}/n_{e1}) secondary current.

Equivalent primary value of secondary voltage = (n_{e1}/n_{e2}) secondary voltage.

Equivalent primary value of secondary resistance (or reactance) = $\left(\frac{n_{e1}}{n_{e2}}\right)^2$ secondary resistance (or reactance).

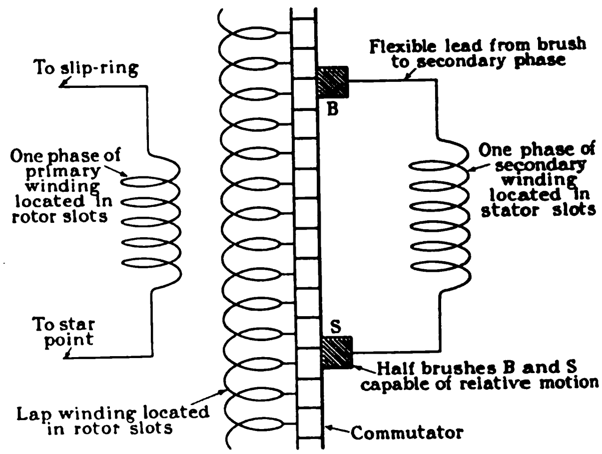

Fig. 1.—Diagram of windings.

If $n_{e1} = n_{e2}$ then the secondary vector diagram becomes identical in size and shape with the reduced secondary diagram, although its orientation about the origin will vary relatively to the primary diagram according to the position of the rotor. In practice it is always assumed that $n_{e1} = n_{e2}$, and the secondary diagram is drawn in such a position that it coincides with the reduced secondary diagram. If in the actual motor considered the ratio n_{e1}/n_{e2} is not unity, then the true values of vectors in the secondary circuit may be obtained from the diagram as follows.

True value of secondary current = (n_{e1}/n_{e2}) × value shown on diagram.

True value of secondary voltages = (n_{e2}/n_{e1}) × value shown on diagram.

True value of secondary resistances = $\left(\frac{n_{e2}}{n_{e1}}\right)^2$ × value shown on diagram.

Fig. 1 shows diagrammatically the windings for one phase of the three-phase shunt commutator motor. In this motor the transformation ratio is very much more

* H. K. Schrage: "Ein Neuer Drehstrom-Kommutatormotor Mit Nebenschluss-Regulierung Durch Bürstenverschiebung," *Elektrotechnische Zeitschrift*, 1914, vol. 35, p. 89; and F. J. Teago: "Test-Results Obtained from a Three-Phase Shunt Commutator Motor" *Journal I.E.E.*, 1922, vol. 60, p. 328.

complicated owing to the existence of two secondary windings, the stator winding and the lap winding. This gives rise to three different transformation ratios, two of which vary as the brush position is varied. The E.M.F. induced in the stator winding has a transformation ratio of effective primary turns per phase to effective stator winding turns per phase. The E.M.F. induced in the lap winding has a transformation ratio of effective primary turns to effective lap turns per phase, and the effective lap turns per phase will obviously depend on the amount of brush separation. The secondary current, which is common to both lap and stator windings, has a transformation ratio of effective primary turns to the vector sum of effective stator winding turns and effective lap winding turns. For symmetrical brush positions, the vector sum will

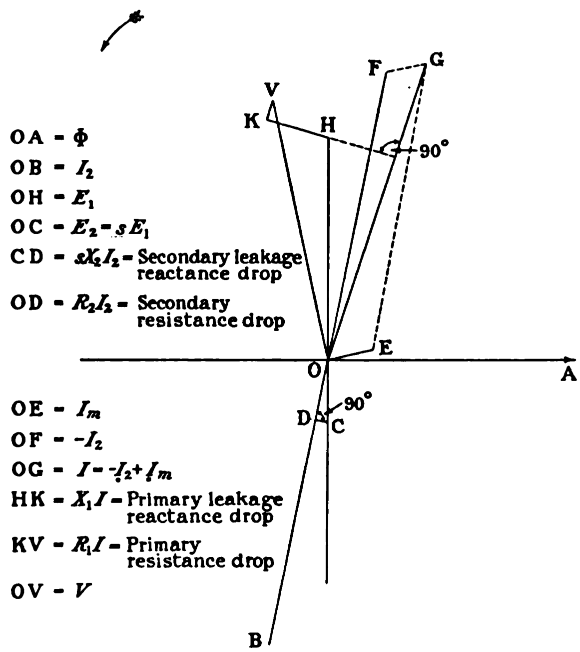

FIG. 2.—Induction motor vector diagram.

be identical with the algebraic sum. This ratio is also dependent on the brush separation; it will be high at sub-synchronous speeds, since the stator winding turns and lap winding turns oppose each other, and will be low at super-synchronous speeds, since they act together. In drawing the vector diagram for this motor it is assumed that the ratio of effective primary turns to effective stator winding turns is unity, but it should be noted that this will not make the secondary vector diagram identical with the reduced secondary vector diagram. If in an actual case this ratio is not unity, then all the vectors in the secondary diagram, as drawn, must be transformed by means of this ratio to get the true values, as in the case of the induction motor. In solving the diagram it must now be remembered that the lap E.M.F. vector and the secondary current vector are not reduced to their primary values; but this difficulty may be overcome by a very simple artifice. Two new ratios are required for this. The first ratio, which may be called the lap winding ratio (denoted in this paper by n), is the ratio of effective lap winding turns, when the brushes are separated the maximum amount, i.e. 180 electrical degrees, to effective stator winding turns. This is a constant for a given machine. The second ratio is the ratio of effective lap winding turns for an angle of brush separation of β electrical degrees to the effective lap winding turns for maximum brush separation (denoted by a in this paper). This is an independent variable, depending on the brush position.*

Fig. 3 shows the variation of a with the brush separation. In order to reduce the lap E.M.F. vector to the primary circuit it must be multiplied by $1/(an)$, and in order to reduce the secondary current vector to the primary circuit it must be multiplied by $(1 \pm an)$. It is thus seen that n and a are not used separately, and the only advantage in keeping them separate is that, whereas n may be different in different machines, and is therefore a detail of design, a can always be varied between 0 and ± 1, for any machine.† In the vector

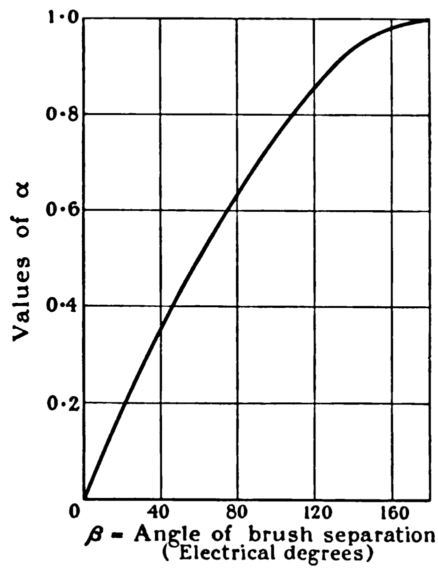

FIG. 3.—Relation between a and angle of brush separation.

diagram, the lap E.M.F. vector and the secondary current vector are drawn in the secondary diagram and reduced to the primary diagram.

The treatment is slightly more complicated when the brush positions are unsymmetrical, but it is explained in the section dealing with unsymmetrical brush positions.

THE CIRCLE DIAGRAMS WITH SYMMETRICAL BRUSH POSITIONS.

The following assumptions are made in Dr. Teago's paper and are retained in the present paper:—

(1) All currents and voltages vary harmonically with time.

(2) The rotating wave of flux is distributed round the rotor circumference according to a sine law.

(3) There is no leakage between the primary winding and the lap winding. These two windings are located in the same slots and it is reasonable to think that the

* Schrage in his paper combines these two ratios in one, but Dr. Teago uses a in the sense defined above, and it was thought better to retain his definition.

† Definitions of signs are given later.

leakage between them must be very small. In order to simplify the diagram, this assumption is subsequently further modified.

(4) The secondary leakage reactance drop is proportional to the product of the stator ampere-turns and the slip. Slip is defined as: (synchronous speed — actual speed)/synchronous speed, synchronous speed being that rotor speed which causes the primary magnetic field to become stationary with respect to the secondary (stator) winding.

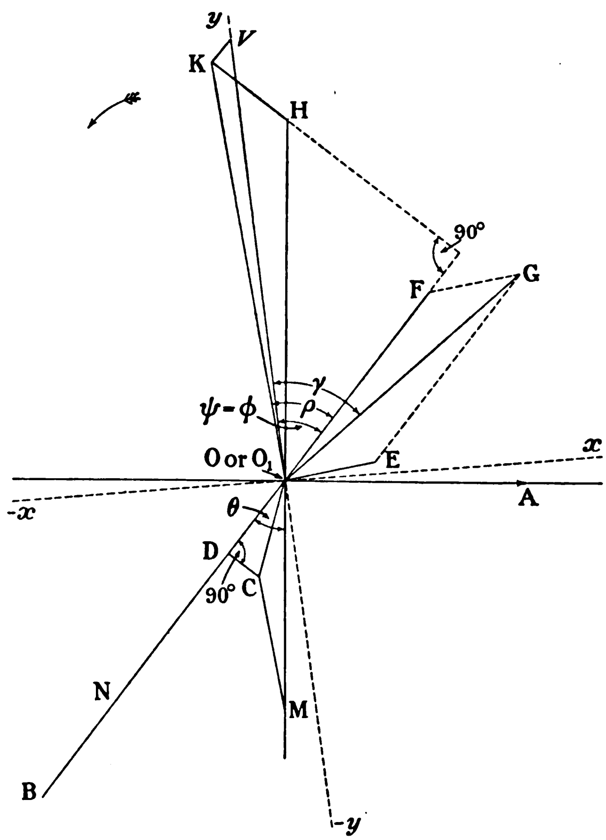

FIG. 4.—Three-phase shunt commutator motor vector diagram with symmetrical brush position.

OA = Φ.
OB = I_2 (proportional to stator ampere-turns).
BN = pI_2 (proportional to lap ampere-turns).
ON = $I_2 - pI_2$ = primary value of I_2.
OE = I_m.
OF = $-[I_2 - pI_2] = I_1$.
OG = $\dot{\text{OF}} + \dot{\text{OE}} = \dot{I}_1 + \dot{I}_m = I$ (vectorial addition).
OH = E_1.
HK = $X_1 I_2$ = primary reactance drop.
KV = $R_1 I_1$ = primary resistance drop.
OV = V.
MC = aE_L = lap E.M.F.
OK = $\frac{E_L}{n} = \frac{MC}{an}$ = primary value of lap E.M.F.
OM = $E_2 = sE_1$.
OC = resultant secondary voltage.
CD = sX_2I_2 = secondary leakage reactance drop.
OD = R_2I_2 = secondary resistance drop.
$\angle$MOD = θ; $\angle$ 180° − VOB = ψ; $\angle$ VOF = ϕ $\angle$VOG = γ; $\angle$KOF = ρ.
(For symmetrical brush positions, $\psi = \phi$.)

(5) The R.M.S. magnetizing current is constant in value.

It follows from the third assumption that the primary leakage reactance drop is proportional to the vector sum of the primary and lap ampere-turns. In order to simplify the mathematical solution of the vector diagram, this assumption is further modified by regarding the magnetizing current as flowing in a coil in parallel with the motor, and neglecting the resistance and leakage reactance drops due to it, as is done in the case of the induction motor. This is justifiable from a practical point of view since the errors involved are more than counterbalanced by the gain in simplicity, and the value of a strictly accurate method is destroyed by the uncertainty of the data of the motor. With this assumption the primary leakage reactance drop is proportional to the stator ampere-turns, since these are equal and opposite to the vector sum of the primary and lap ampere-turns. Fig. 4 shows the vector diagram based on these assumptions.

It is also assumed that $n_{e1} = n_{e2}$, and appropriate values are given to the secondary vectors in accordance with this assumption (see page 1140).

The following quantities are assumed to be constant: X_1, X_2, R_1, R_2, V, n, and the supply frequency.

Also, let $(X_1 + X_2) = X$.

In order that one mathematical solution may serve for sub-synchronous and super-synchronous speeds, the following conventions as to signs will be adopted.

s = slip. This is positive below synchronous speed and is negative above synchronous speed.

a is positive when the angle of brush separation is such that the stator and lap ampere-turns oppose each other, and is negative when the angle of brush separation is such that the stator and lap ampere-turns act in the same direction.

It should be noted that although a varies as the brushes are moved, it is an independent variable which may be kept constant at will. In the solution of the diagram it is assumed constant, but of course any value between -1 and $+1$ may be assigned to it for a particular solution.

Since n is a constant, it follows that p changes sign with a.

EQUATIONS FOR CIRCLE DIAGRAMS.

It should be noted that the diameter of the secondary circle will vary relatively to the diameter of the primary circle when the brush position is altered.

From Fig. 4 we get

$$sE_1 = I_2R_2 \cos\theta + sI_2X_2 \sin\theta + aE_L \cos(\rho - \theta) \quad (1)$$

$$s = \frac{I_2R_2 \sin\theta - aE_L \sin(\rho - \theta)}{I_2X_2 \cos\theta} \quad . \quad . \quad (2)$$

$$(E_L/n) \sin(\rho - \theta) = X_1I_2 \cos\theta \quad . \quad . \quad (3)$$

$$(E_L/n) \cos(\rho - \theta) = E_1 + X_1I_2 \sin\theta \quad . \quad (4)$$

From equations (2) and (3) we obtain

$$s = \frac{R_2}{X_2} \tan\theta - p\frac{X_1}{X_2} \text{ (where } p = an) \quad . \quad . \quad (5)$$

From equations (1), (4) and (5),

$$E_1 = \frac{I_2R_2X_2}{\{R_2 \sin\theta - pX \cos\theta\}} \text{ [where } X = X_1 + X_2]$$

$$\cos\theta = \frac{V\cos\psi - R_1I_1}{E_1}; \quad \sin\theta = \frac{V \sin\psi - X_1I_2}{E_1}$$

$$\therefore I_2 = \frac{V}{X}\left\{\frac{R_2 \sin\psi - pX\cos\psi}{R_2 - p(1-p)R_1}\right\} \quad . \quad . \quad (6)$$

Transforming equation (6) to Cartesian co-ordinates, with O_1 as origin and $O_1V_1 = V$ as the axis of y (see Fig. 4),

$$\text{let}\quad \left\{\begin{matrix} -I_2 \sin\psi = x \quad \text{and} \quad I_1 \sin\psi = x_1 \\ -I_2 \cos\psi = y \quad \text{and} \quad I_1 \cos\psi = y_1 \end{matrix}\right\}$$

[I_1 and I_2 are assumed to be positive.]

Then

$$\left[x + \frac{VR_2}{2X\,\{R_2 - p(1-p)R_1\}}\right]^2 + \left[y - \frac{Vp}{2\{R_2 - p(1-p)R_1\}}\right]^2 = \frac{V^2\left\{\left(\frac{R_2}{X}\right)^2 + p^2\right\}}{4\{R_2 - p(1-p)R_1\}^2}$$

which is the equation of a circle, with centre at (a, b) and radius r,

$$\text{where}\quad a = -\frac{VR_2}{2X\{R_2 - p(1-p)R_1\}}$$

$$b = \frac{Vp}{2\{R_2 - p(1-p)R_1\}}$$

$$r = \left[\frac{VR_2}{2\{R_2 - p(1-p)R_1\}}\right]\left[\frac{1}{X^2} + \left(\frac{p}{R_2}\right)^2\right]^{\frac{1}{2}}$$

Since $I_1 = -I_2(1-p)$ in magnitude and direction, therefore, the free end of the vector I_1 travels round a circle, the centre of which is (a_1, b_1) and radius r_1.

$$a_1 = -a(1-p) = \frac{VR_2(1-p)}{2X\{R_2 - p(1-p)R_1\}}$$

$$b_1 = -b(1-p) = \frac{-Vp(1-p)}{2\{R_2 - p(1-p)R_1\}}$$

$$r_1 = r(1-p) = \left[\frac{VR_2(1-p)}{2\{R_2 - p(1-p)R_1\}}\right]\left[\frac{1}{X^2} + \left(\frac{p}{R_2}\right)^2\right]^{\frac{1}{2}}$$

If the origin is displaced by an amount equal to the magnetizing current in magnitude and opposite in direction, the I_1 circle becomes the I circle or supply current circle, and the power factor at any point may be determined by measuring the angle which the I vector to that point makes with OV, where O is the new origin, and OV the new axis of y.

If $p = 0$, the case corresponds to that of an induction motor, and

$$a_1 = -a = \frac{V}{2X};\quad b_1 = -b = 0$$

$$r_1 = r = \frac{V}{2X}$$

Sources of Error in the Preceding Theory.

The theory is subject to all the errors which occur in the theory of the simple induction motor. In actual machines, fluxes, voltages and currents do not vary harmonically. The amount of error involved cannot be easily determined, but probably this will not be serious up to full load, although considerable distortion of the circle diagram will probably occur at heavy overloads.

The assumption of constant primary reactance involves another error. In this theory the primary leakage is assumed to be produced by the primary and lap ampere-turns. As the number of turns in the lap winding depends on the brush position the primary reactance will also be dependent on this.

The most serious source of error occurs in assuming the secondary resistance to be constant. This was found to be so serious that a partial correction has been made in the circles drawn, but as the resistance

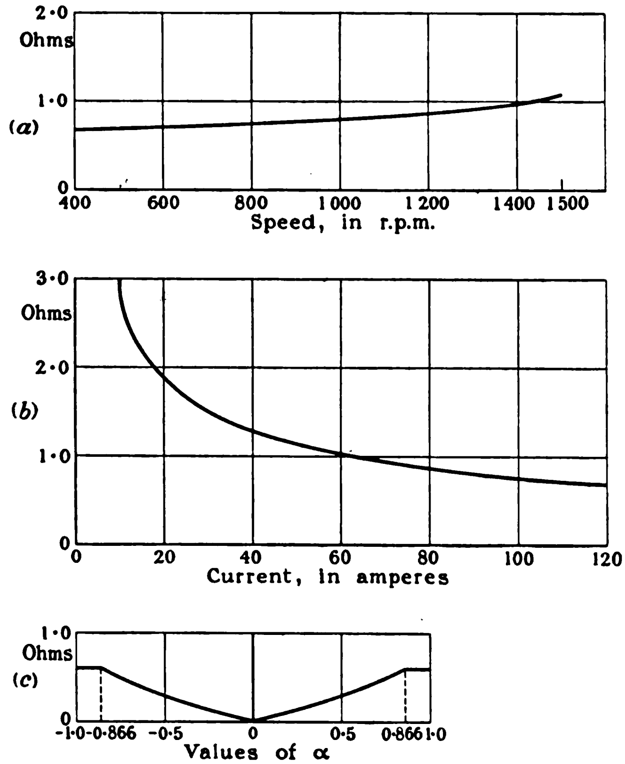

FIG. 5.—Secondary resistance (in terms of the primary), Stator resistance = 0·5 ohm.

(a) Relation between brush contact resistance and speed. Constant current = 86 amperes.
(b) Relation between brush contact resistance and current. Constant speed = 1 000 r.p.m.
(c) Relation between lap winding resistance and α.

varies with current it was not possible to make a complete correction.

The secondary resistance may be divided into three parts, the stator winding resistance, the brush contact drop, and the lap winding resistance. The stator resistance in the machine tested was found to be 0·5 ohm (in terms of the primary) and this is fairly constant, the only variation being due to eddy currents which depend on the frequency of the secondary current. The brush contact drop is shown by Fig. 5 [(a) and (b)]. It varies both with current and with speed. The lap winding resistance per phase depends on the number of turns included. When the angle of brush separation exceeds 120°, the apparent lap winding resistance per phase does not increase any further as the currents of different phases flowing in the same conductors par-

tially cancel out. The apparent resistance of the lap winding per phase is shown in Fig. 5 (c) on the assumption that all three phases are carrying currents.

In drawing the theoretical circle diagrams the value of secondary resistance used has been chosen for full-

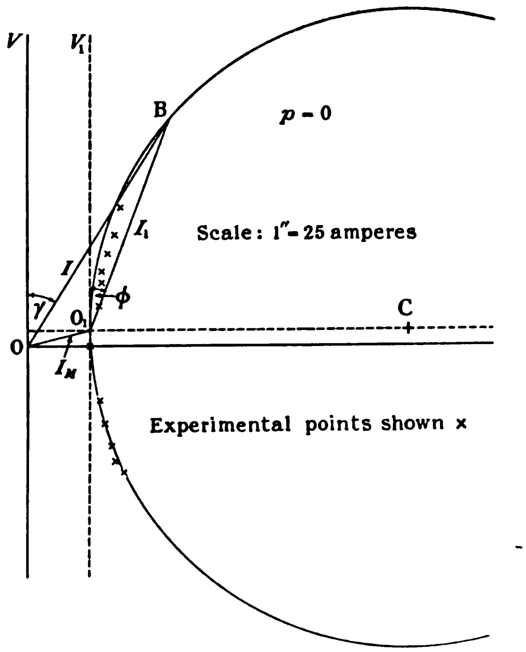

FIG. 6.

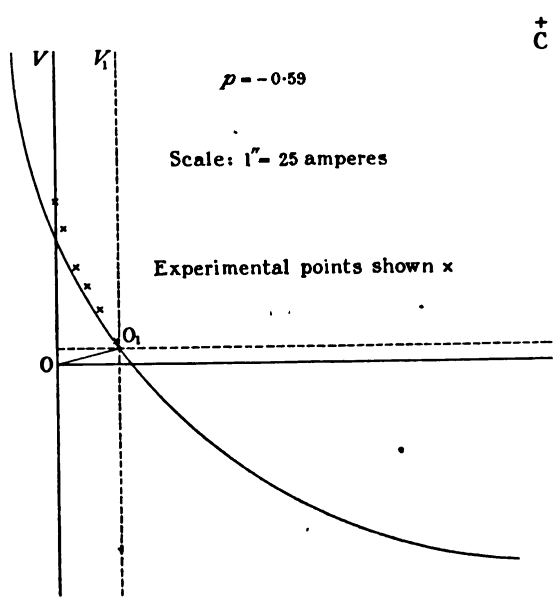

FIG. 7.

load current. It follows, therefore, that the value will be incorrect for all other currents.

Test-results, obtained at a reduced voltage, showed considerable distortion of the circle diagram at heavy overloads up to standstill, and this was no doubt mainly due to the change in the secondary resistance, although the other errors mentioned would also contribute their effects.

The brush contact resistance was found to be negligible in the primary resistance, owing to the much higher resistance of the windings.

THE THEORETICAL CIRCLE DIAGRAMS FOR THE MOTOR TESTED.

The motor tested was the same one as that on which Dr. Teago carried out his experiments. The following

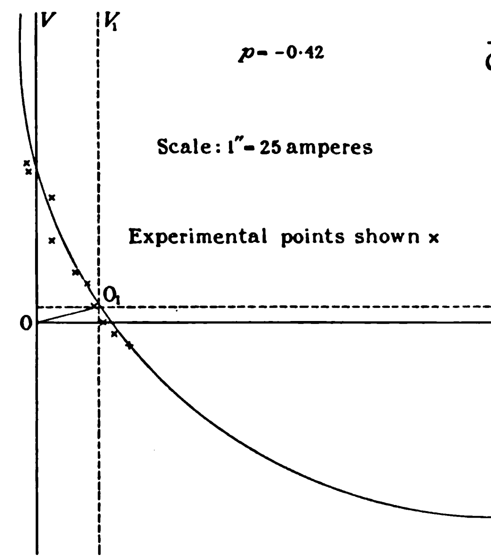

FIG. 8.

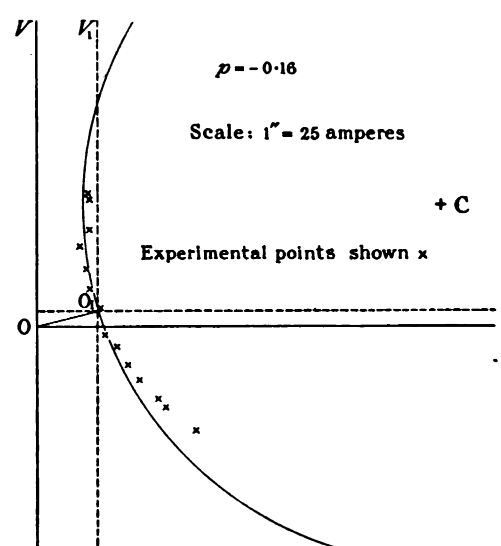

FIG. 9.

particulars of the machine were used in determining the theoretical circle diagrams.

Primary volts = 400 (phase voltage = 230).
Full-load secondary current = 86 amperes.

No-load current (magnetizing current) = 8 amperes at 0·2 power factor.

(This value was the mean of a number, measured experimentally, over the whole speed range of the motor.)

Synchronous speed = 1 000 r.p.m.

Turns per phase in primary winding = 288 = n_1.

Breadth factor of primary winding = 0·96 = k_{w1}.

Turns per phase in stator winding = 60 = n_2.

Breadth factor of stator winding = 0·83 = k_{w2}.

Transformation ratio (a = 0) $= \dfrac{288 \times 0\cdot 96}{60 \times 0\cdot 83} = 5\cdot 55$.

Turns per phase in lap winding for a brush separation of 180 electrical degrees = 54 = n_l.

Breadth factor of lap winding for a brush separation of 180 electrical degrees = 0·55 = k_{wl}.

(This low value was due to the coils being short-pitched.)

$$n = \frac{54 \times 0\cdot 55}{60 \times 0\cdot 83} = 0\cdot 6 \text{ and } p = an = 0\cdot 6a.$$

Primary resistance = R_1 = 0·42 ohm.

Secondary resistance = R_2 (see Fig. 5).

Primary and secondary reactance = $X_1 + X_2 = X$ = 2·8 ohms.

The values of R_1, R_2 and X were determined experimentally and are all reduced to the primary.

From these particulars the positions of the centres and the diameters of the circles for seven values of a have been calculated. These are shown in Table 1, and the circles are drawn in Figs. 6–12. The value of R_2 used in each case was obtained from the curves in Fig. 5 for full-load secondary current.

a_1 and b_1 are measured from O_1. OO_1 = the no-load current.

TABLE 1.

a	p	Full-load speed (motoring)	a_1	b_1	r_1	Value of R_2 used in each case
		r.p.m.	amps.	amps.	amps.	ohms
−0·98	−0·59	1 500	56	41	69	2·2
−0·70	−0·42	1 300	51	34	61	1·8
−0·27	−0·16	1 100	45	14	47	1·5
0	0	950	41	0	41	1·3
0·27	0·16	800	36	−11	37	1·5
0·70	0·42	500	25	−16	30	1·8
0·95	0·57	300	19	−17	25	1·8

The actual calculations involved are given below for one case. The other six were worked out similarly.

Case I. $a = -0\cdot 98$.

$p = 0\cdot 6a = -0\cdot 59$; $R_2 = 2\cdot 2$ ohms.

$V = 230$ volts; $X = 2\cdot 8$ ohms; $R_1 = 0\cdot 42$ ohm.

From the equations on page 1143 :—

TEST-RESULTS.

A large number of test-points were obtained for the seven brush positions, of which the theoretical circle diagrams have been worked out. These are plotted in Figs. 6–12, and their agreement with the theoretical circles may be seen to be reasonably close.

The most serious discrepancies occur when $p = 0\cdot 42$ (see Fig. 11). Here the agreement is good for motoring, but the generation is unexpectedly poor. Experiments carried out at a quarter of the standard voltage confirmed this result for points further round the circle, and so far it has been found impossible to assign any

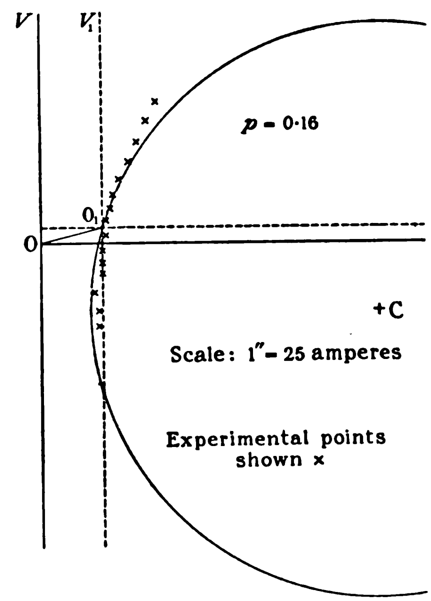

FIG. 10.

satisfactory reasons for it. It is hoped that further work on this motor may reveal the cause. All the other circles, when obtained at a quarter of the standard voltage, were very much distorted. It is believed that this distortion is mainly due to the change in the secondary resistance. The object of obtaining points at a quarter voltage was to find the shape of the circle diagram beyond the normal working range of the motor.

A certain amount of error was caused by the angles between half brushes not being the same for all three phases, due to faulty setting in erecting the motor. Although this caused considerable out-of-balance currents in the secondary windings, the primary currents were balanced.* These out-of-balance currents would increase the copper losses and would possibly be respon-

* See also F. J. TEAGO, *loc. cit.*, p. 334, Table 1.

$$a_1 = \frac{VR_2(1-p)}{2X\{R_2 - p(1-p)R_1\}} = \frac{230 \times 2\cdot 2 \times 1\cdot 59}{5\cdot 6\{2\cdot 2 + (0\cdot 59 \times 1\cdot 59 \times 0\cdot 42)\}} = \frac{805}{5\cdot 6 \times 2\cdot 59} = 56 \text{ amperes.}$$

$$b_1 = \frac{-Vp(1-p)}{2\{R_2 - p(1-p)R_1\}} = \frac{230 \times 0\cdot 59 \times 1\cdot 59}{2 \times 2\cdot 59} = 41 \text{ amperes.}$$

$$r_1 = \left[\frac{VR_2(1-p)}{2\{R_2 - p(1-p)R_1\}}\right]\left[\frac{1}{X^2} + \left(\frac{p}{R_2}\right)^2\right]^{\frac{1}{2}} = \left[\frac{230 \times 2\cdot 2 \times 1\cdot 59}{2 \times 2\cdot 59}\right]\left[\frac{1}{(2\cdot 8)^2} + \left(\frac{0\cdot 59}{2\cdot 2}\right)^2\right]^{\frac{1}{2}} = 69 \text{ amperes.}$$

sible for part of the discrepancies between test-results and the theoretical curves.

Figs. 6–12 show theoretical circle diagrams (with symmetrical brush positions); line voltage = 400 (phase voltage = 230), frequency = 50 cycles per sec.

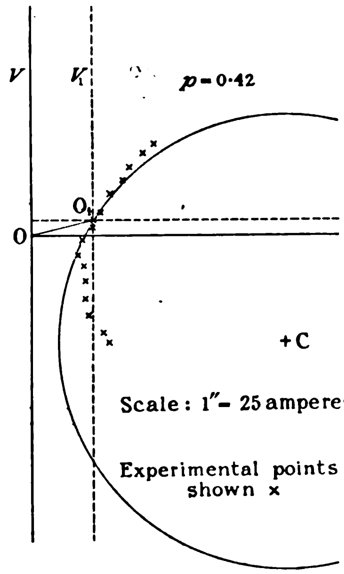

FIG. 11.

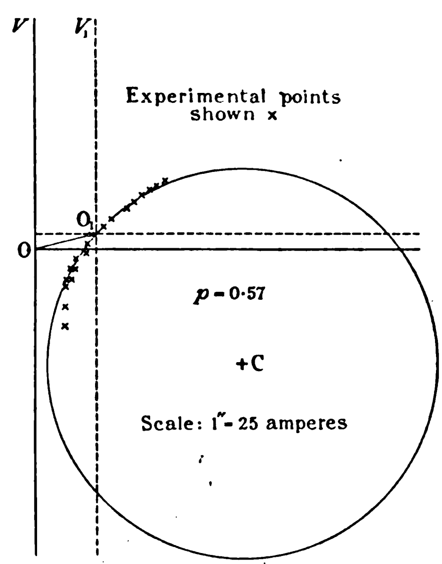

FIG. 12.

In these figures :—

OO_1 = no-load (magnetizing) current.
$O_1B = I_1$.
$OB = I$ = primary current.
$VOB = \gamma$ = angle of lag of primary current.
a_1 and b_1 are the co-ordinates of C with respect to O_1 as origin.

RELATION BETWEEN SECONDARY CURRENT AND SLIP, AND RELATION BETWEEN TORQUE, MECHANICAL POWER AND SLIP, WITH SYMMETRICAL BRUSH POSITIONS.

By eliminating ψ and retaining s in equations (1) to (6) on page 1142, the following equations may be obtained:—

$$I_2 = \frac{(s-p)V}{\sqrt{[s^2X^2 + \{R_2 + (1-p)(s-p)R_1\}^2]}}$$

Mechanical power

$$= P = I_2^2 R_2 \left\{\frac{1-s}{s-p}\right\}$$

$$= \frac{(1-s)(s-p)V^2R_2}{[s^2X^2 + \{R_2 + (1-p)(s-p)R_1\}^2]}$$

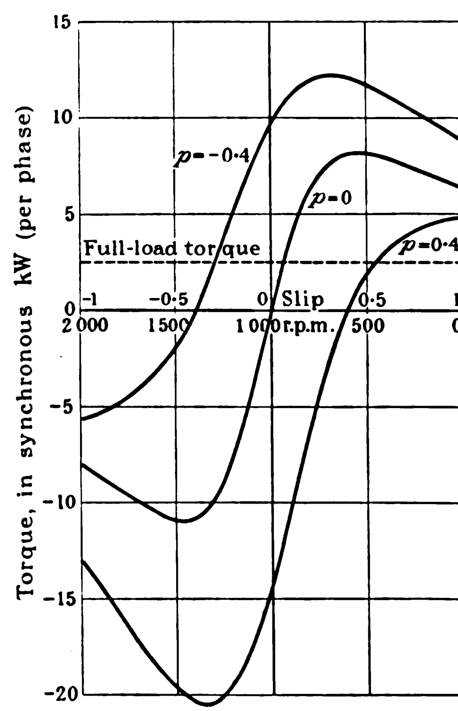

FIG. 13.—Theoretical torque/speed curves.

The mechanical or shaft power is the output when motoring, and the input when generating. Both it and the shaft torque are positive in these equations when the machine is motoring, and negative when the machine is generating.

Electrical power is the input when motoring, and the output when generating.

$$\text{Torque} = T = \frac{(s-p)V^2R_2}{[s^2X^2 + \{R_2 + (1-p)(s-p)R_1\}^2]}$$

synchronous watts.

By differentiating, the expression for maximum torque may be obtained,

$$T_m = \frac{\pm \frac{1}{2} R_2 V^2}{+\sqrt{[\{R_1^2(1-p)^2 + X^2\}\{p^2X^2 + R_2^2\}]} \pm \{pX^2 + R_2R_1(1-p)\}}$$

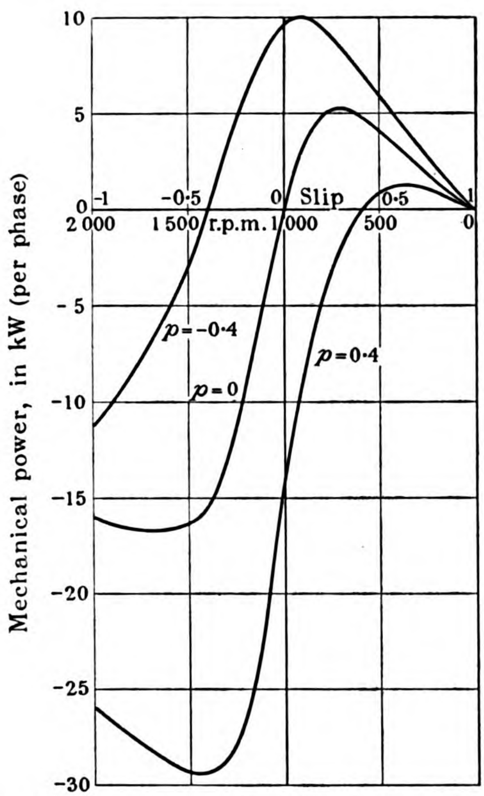

FIG. 14.—Theoretical mechanical-power/speed curves.

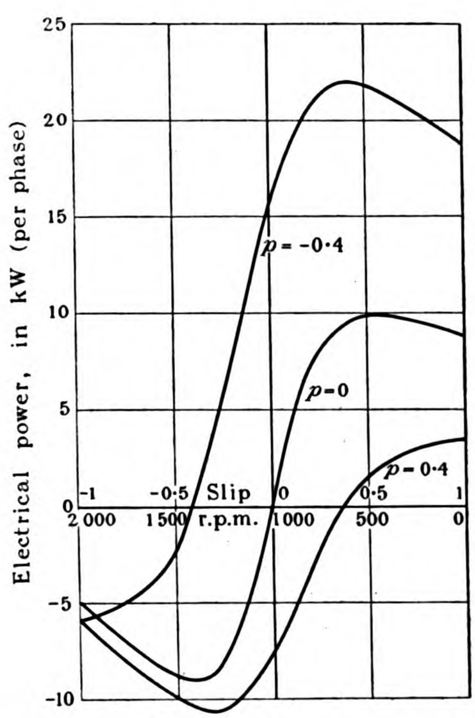

FIG. 15.—Theoretical electrical-power/speed curves.

Slip for maximum torque

$$s_m = p \pm \sqrt{\left[\frac{R_2^2 + p^2X^2}{R_1^2(1-p)^2 + X^2}\right]}$$

Where two signs are given, the top one refers to the motoring zone, and the lower one to the generating zone.

If $p = 0$, these equations reduce to the induction motor case.

$$I_2 = \frac{sV}{\sqrt{[s^2X^2 + \{R_2 + sR_1\}^2]}}$$

$$T = \frac{sV^2R_2}{[s^2X^2 + (R_2 + sR_1)^2]}$$

$$T_m = \frac{\pm V^2}{2[+\sqrt{\{R_1^2 + X^2\}} \pm R_1]}$$

$$s_m = \frac{\pm R_2}{+\sqrt{[R_1^2 + X^2]}}$$

Lack of time prevented the accurate verification of these formulæ by test-results. The theoretical curves for the motor tested are shown in Figs. 13–15, and the test-results obtained indicated the general shape to be correct. Test-curves obtained by the A.S.E.A. Co. also showed a similarity to these theoretical curves.

EFFECT OF DISPLACING THE BRUSH GEAR BODILY THROUGH AN ANGLE η.

By means of unsymmetrical brush positions, considerable improvements may be effected in the performance of the motor. These are outlined later. The solution of the vector diagram will be given first. In order to simplify the treatment, the primary resistance will be neglected, and the results are therefore only approximate.

The angle η will be considered positive if it causes the injected E.M.F. to lag on the primary supply pressure, and negative if it leads on the primary supply pressure.

The vector diagram is given in Fig. 16, the lettering being the same as for Fig. 4. Note that K and V coincide as a result of assuming the primary resistance to be negligible.

The injected E.M.F. will now lag behind the primary supply pressure by the angle η. The lap ampere-turns have a space advance of η over the stator ampere-turns and this is shown in Fig. 16 by an equivalent time-phase advancement. The following equations may now be derived from Fig. 16 :—

$$V = \frac{E_L}{n}$$

$$\cos\theta = \frac{V}{E_1}\cos\psi\,; \quad \sin\theta = \frac{V\sin\psi - X_1I_2}{E_1}$$

$$s = \frac{I_2R_2\sin\theta - aE_L\sin\{(\psi-\eta)-\theta\}}{I_2X_2\cos\theta}$$

$$sE_1 = I_2R_2\cos\theta + sX_2I_2\sin\theta + aE_L\cos\{(\psi-\eta)-\theta\}$$

From these equations it may be proved that :—

$$I_2^2R_2X + I_2V\{pX\cos(\psi-\eta) - R_2\sin\psi\} - pV^2\sin\eta = 0$$

which is the equation of a circle.

Transforming to Cartesian co-ordinates with O_1 as origin and O_1V_1 as axis O_1y

$$-I_2 \sin\psi = x \quad \text{and} \quad I_1 \sin\phi = x_1$$
$$-I_2 \cos\psi = y \quad \text{and} \quad I_1 \cos\phi = y_1$$

$$\left\{x + \tfrac{1}{2}V\left(\frac{1}{X} - \frac{p \sin\eta}{R_2}\right)\right\}^2 + \left\{y - \frac{pV\cos\eta}{2R_2}\right\}^2 = \frac{V^2}{4}\left\{\frac{p^2}{R_2^2} + \frac{2p\sin\eta}{R_2X} + \frac{1}{X^2}\right\}$$

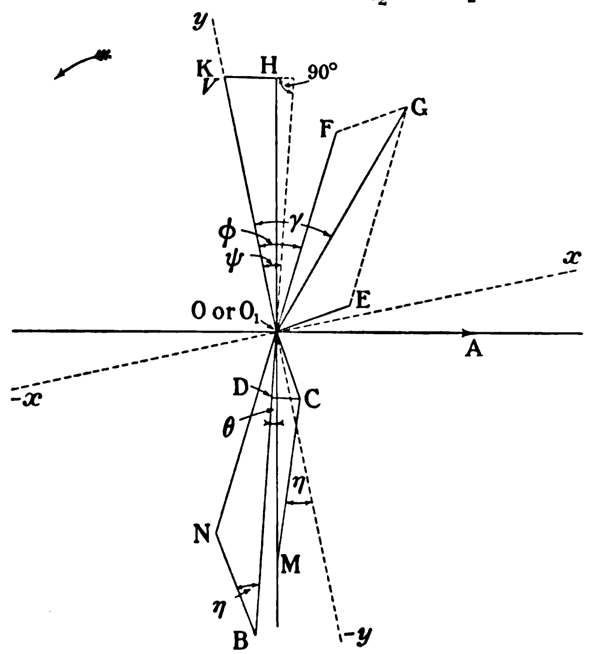

FIG. 16.—Vector diagram with unsymmetrical brush position.

This is the circle diagram equation of the secondary current.

$$\text{Centre}\begin{cases} a = -\tfrac{1}{2}V\left(\dfrac{1}{X} - \dfrac{p\sin\eta}{R_2}\right) \\ b = \tfrac{1}{2}V\left(\dfrac{p\cos\eta}{R_2}\right) \end{cases}$$

$$\text{Radius} = r = \tfrac{1}{2}V\sqrt{\left[\frac{p^2}{R_2^2} + \frac{2p\sin\eta}{R_2X} + \frac{1}{X^2}\right]}$$

$$x_1 = I_1\sin\phi = I_2\sin\psi - pI_2\sin(\psi - \eta)$$
$$y_1 = I_1\cos\phi = I_2\cos\psi - pI_2\cos(\psi - \eta)$$

$$\therefore x_1^2 + y_1^2 + x_1\left\{V\left(\frac{p\sin\eta}{R_2} + \frac{p\cos\eta}{X} - \frac{1}{X}\right)\right\} + y_1\left\{V\left(\frac{p\sin\eta}{X} + \frac{p\cos\eta}{R_2} - \frac{p^2}{R_2}\right)\right\} = \frac{pV^2\sin\eta(1 - 2p\cos\eta + p^2)}{R_2X}$$

This is the circle diagram equation of I_1

$$\text{Centre}\begin{cases} a_1 = \tfrac{1}{2}V\left\{\dfrac{1}{X} - p\left(\dfrac{\sin\eta}{R_2} + \dfrac{\cos\eta}{X}\right)\right\} \\ b_1 = -\tfrac{1}{2}V\left\{p\left(\dfrac{\sin\eta}{X} + \dfrac{\cos\eta}{R_2}\right) - \dfrac{p^2}{R_2}\right\} \end{cases}$$

$$\text{Radius} = r_1 = \tfrac{1}{2}V\sqrt{\left[(1 - 2p\cos\eta + p^2)\left\{\frac{1}{X^2} + \frac{p^2}{R_2^2} + \frac{2p\sin\eta}{R_2X}\right\}\right]}$$

This circle is identical with the primary current circle, if the origin be displaced by an amount equal to the magnetizing current and opposite in direction. If η does not exceed about 15° it may be assumed that $\sin\eta = \eta$ and $\cos\eta = 1$. Then :—

$$a_1 = \left\{\frac{V}{2X}(1 - p) - \frac{\eta pV}{2R_2}\right\}$$
$$b_1 = -\left\{\frac{Vp}{2R_2}(1 - p) + \frac{\eta pV}{2X}\right\}$$
$$r_1 = \tfrac{1}{2}V(1 - p)\sqrt{\left[\frac{1}{X^2} + \frac{p^2}{R_2^2} + \frac{2p\eta}{R_2X}\right]}$$

In this form it is easy to see the effect of η, since those terms containing η disappear when $\eta = 0$.

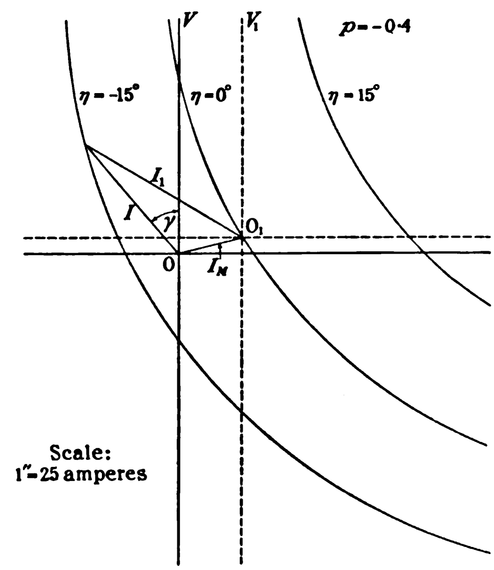

FIG. 17.—Theoretical circle diagrams.

Brush gear displaced by the angle η. Super-synchronous speed. $p = -0 \cdot 4$; line voltage = 400; frequency = 50 cycles per sec.

It is interesting to note that if $p = 0$ the η terms disappear, thus showing that an unsymmetrical brush position has no effect on the circle diagram, for zero brush separation. This is, of course, what one would expect.

In Figs. 17 and 18 the theoretical circles for the motor tested are drawn with $\eta = 15°$, 0° and $-15°$ for both sub-synchronous speed and super-synchronous speed. The general trend of these curves was verified experimentally, but lack of time prevented the careful verification of them.

From these it may be seen that at sub-synchronous speeds a positive angle η advances the time phase of the primary current relative to the supply voltage OV, while at super-synchronous speeds a negative angle η has the same effect.

Expressions for the torque, mechanical power and slip are not reproduced as the mathematics involved is very cumbersome, but the general effect on the performance may easily be arrived at by the following line of argument. The effect of displacing the brush

gear is to cause the injected E.M.F. to alter its phase, and this in turn alters the phase of the resultant secondary E.M.F. and the secondary current.

At sub-synchronous speeds the secondary current is lagging behind the flux with symmetrical brush position (Fig. 4), and a positive angle η will bring it into phase with the flux. It will then have a minimum value for a given torque so that the efficiency will be higher than with the symmetrical setting, while the maximum torque will be increased considerably. The power factor of the primary current will also be considerably improved, although not to unity power factor. If improvement to unity power factor is desired, η must be increased still further, so that the secondary current leads on the flux. By this means the secondary current may be made to supply the magnetizing component.

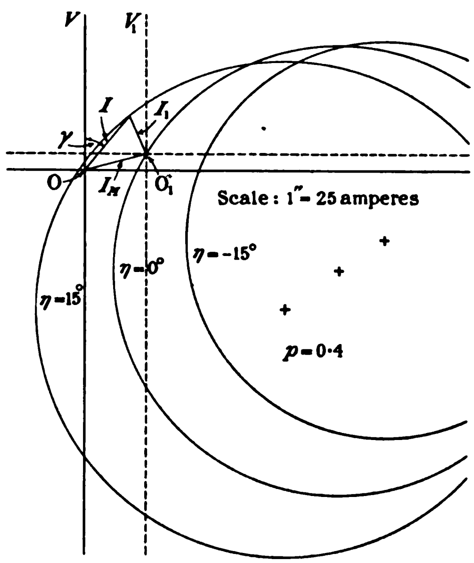

FIG. 18.—Theoretical circle diagrams.

Brush gear displaced by the angle η. Sub-synchronous speed. $p = -0\cdot4$; line voltage = 400 ; frequency = 50 cycles per sec.

As the stator and lap ampere-turns are opposed to each other at sub-synchronous speeds the effective turns will be small, and the secondary current will have to lead by a large amount in order to supply the magnetizing component. This will involve, for a given torque, an increased secondary current and, therefore, a lower efficiency. It is not, therefore, advisable to improve the power factor at sub-synchronous speeds much beyond that point at which the secondary current begins to lead on the flux.

In most machines the power factor may be brought up to 0·8, even at the lowest speeds, without much loss of efficiency.

At super-synchronous speeds the secondary current is generally leading the flux with symmetrical brush position, and the motor therefore operates near unity power factor.

The power factor may be brought actually to unity without much loss of efficiency, as the stator and lap ampere-turns act together, and therefore a comparatively small lead of the secondary current on the flux will supply the magnetizing component. Alternatively, the maximum torque and the efficiency may be raised by bringing the secondary current into phase with the flux. There is not much advantage to be gained by this, as the maximum torque is already high at super-synchronous speeds.

It should be noted that at sub-synchronous speeds maximum efficiency will occur practically when the secondary current is in phase with the flux, since the primary copper losses are small. At super-synchronous speeds the primary copper losses are greater, and the secondary current may have a correspondingly greater lead on the flux for maximum efficiency. Although in most machines unity power factor operation will entail a slight drop from maximum efficiency at super-synchronous speeds, it will be negligible for practical purposes.

Thus by suitable brush movements the performance of the motor may be improved at all speeds. By unsymmetrical gearing the double movement may be obtained by moving one wheel, and this has the advantage that the makers fix the setting; but to get the best performance under all conditions it is necessary to have two wheels, one to separate the half-brushes and the other to displace the gear bodily.

Generation.

It is well known that the lower half of the circle diagram of the induction motor represents a generating zone, and generation is obtained by driving the motor above synchronous speed.

In the three-phase shunt commutator motor also, the lower portion of the circle diagram represents a generating zone, and generation takes place when the motor is driven above the speed at which, for a given brush position, it would operate as a motor. By choosing a suitable brush position, therefore, generation may be obtained for a large range of speed, and the amount of generation may be controlled within wide limits.

The circle diagrams in Figs. 6–12 and the performance curves in Fig. 15 for symmetrical brush positions, indicate that for all positive values of p the amount of generation may be varied up to approximately the same maximum, although the power factor improves considerably as p increases. When p becomes negative the maximum generation falls off slowly, while the power factor of generation falls off very rapidly as p increases negatively.

The circles in Fig. 17 show, however, that even for large negative values of p regeneration at unity power factor may be obtained by displacing the brush gear bodily, and in this case the magnetizing current can be supplied by the secondary for a lower copper loss, since the lap and stator ampere-turns act together, and the fall in efficiency is small and may be non-existent or even negative.

Generation may, therefore, be obtained at all speeds above a certain minimum speed, at unity power factor, high efficiency, and controllable as to amount.

Conclusions.

A study of this paper will show that the three-phase shunt commutator motor is capable of operating either

as a motor or a generator at unity power factor and high efficiency over a speed range of about 3 to 1. This speed range may be increased further by special design and by a sacrifice of output. It has a starting torque of twice full-load torque with a starting current of only $1\frac{1}{2}$ times full-load current in the primary circuit and twice full-load current in the secondary circuit. No starting gear is required, except a three-pole switch. Its chief limitation, as already pointed out in Dr. Teago's paper, is commutation, and this prevents motors of very large sizes being built.

It is hoped that the theory put forward in this paper will be easier to understand and apply than Schrage's owing to the elimination of advanced mathematics; while the divergencies of test-results from theory are pointed out, and some of the possible causes suggested. The author regrets that he was unable to verify more fully the torque/speed and power/speed curves, and also the circle diagrams with unsymmetrical brush positions. The results are put forward, however, in the hope that they may provide a starting point for other investigators.

Thanks are due to the Faculty of Engineering and Prof. E. W. Marchant for permission to publish the results, and also to Dr. Teago for his valuable help and advice, both in the experimental work and in the preparation of the paper.

APPENDIX.

List of Symbols and Notation Used in the Appendix.

Total number of conductors in lap (secondary) winding $= z$.

Current in phase 1 of secondary winding $= i_1$.
Current in phase 2 of secondary winding $= i_2$.
Current in phase 3 of secondary winding $= i_3$.
Current in any conductor $= i$.
Angle between half brushes in phase 1 $= \psi_1$.
Angle between half brushes in phase 2 $= \psi_2$.
Angle between half brushes in phase 3 $= \psi_3$.
Where no particular phase is referred to, and ψ_1, ψ_2, and ψ_3 are assumed equal, the letter ψ without suffix is used.

Let $\eta_2 = \psi_1 - \psi_2$
and $\eta_3 = \psi_1 - \psi_3$

η_2 and η_3 are angles of error in the angles between half brushes.

Let the maximum rate of cutting flux by a conductor $= \Phi$ lines per sec.

Let $E_1 =$ injected E.M.F. in phase 1.
$E_2 =$ injected E.M.F. in phase 2.
$E_3 =$ injected E.M.F. in phase 3.
$\theta =$ angle between any conductor and the axis of maximum flux (i.e. NO in Fig. 19 = axis of maximum flux).
$\beta_1 =$ angle between centre line of brush gear of phase 1 and the axis of maximum flux.
$\beta_2 =$ angle between centre line of brush gear of phase 2 and the axis of maximum flux.
$\beta_3 =$ angle between centre line of brush gear of phase 3 and the axis of maximum flux.
$r_1 =$ combined resistance of stator and lap winding and brush contact resistance of phase 1.
$r_2 =$ combined resistance of stator and lap winding and brush contact resistance of phase 2.
$r_3 =$ combined resistance of stator and lap winding and brush contact resistance of phase 3.

All angles are in radians unless expressly stated otherwise.

Operation at Synchronous Speed.

The operation of this motor at synchronous speed is accompanied by some interesting phenomena. At this

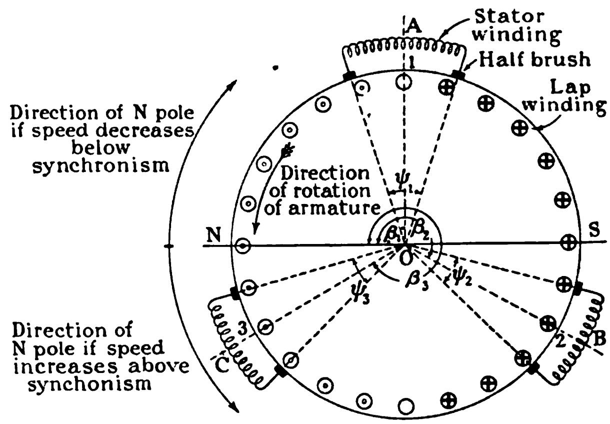

Fig. 19.—The particular case of synchronous speed.
$\angle NOA = \beta_1$; $\angle NOB = \beta_2$; $\angle NOC = \beta_3$

speed the stator winding E.M.F. is zero, and the secondary current is therefore produced entirely by the lap winding E.M.F. Moreover, since the magnetic field is now stationary in space, the secondary current will be direct current. It also follows that the secondary currents will be different in the different phases since the lap winding E.M.F.'s cannot be the same in all three phases, and their actual values will depend on the relative positions of the field and the brushes. In Fig. 19 is shown a diagram of the lap winding, from which a formula for the torque is developed.

Average rate of cutting flux by lap conductors of phase 1

$$= \frac{1}{\psi_1}\int_{\beta_1-\frac{1}{2}\psi_1}^{\beta_1+\frac{1}{2}\psi_1} \Phi \cos\theta d\theta$$

$\therefore$ injected E.M.F. in phase 1

$$= E_1 = 2\Phi \cos\beta_1 \cdot \frac{\sin \frac{1}{2}\psi_1}{\psi_1} \cdot \frac{z\psi_1}{\pi}$$

$$= \frac{2}{\pi} z\Phi \cos\beta_1 \sin \tfrac{1}{2}\psi_1$$

This assumes a breadth factor of unity. Up to full load at synchronous speed the angles ψ_1, ψ_2 and ψ_3

are all small angles, and the effect of phase difference in the E.M.F.'s of different conductors between two half brushes is negligible. It is also justifiable to assume that $\sin \frac{1}{2}\psi_1 = \frac{1}{2}\psi_1$ for the same reason.

Then $\qquad E_1 = (z\Phi\psi_1/\pi) \cos \beta_1$

and $\qquad i_1 = E_1/r_1 = z\Phi\psi_1 \cos \beta_1/(\pi r_1)$

Torque produced by phase 1 is proportional to $\Phi \cos \beta_1 \times i_1$.

$\therefore$ torque produced by phase 1 is proportional to $z\Phi^2\psi_1 \cos^2 \beta_1/(\pi r_1)$.

Similarly torque produced by phase 2 is proportional to $z\Phi^2\psi_2 \cos^2 \beta_2/(\pi r_2)$.

Similarly torque produced by phase 3 is proportional to $z\Phi^2\psi_3 \cos^2 \beta_3/(\pi r_3)$.

$\therefore$ total torque ($= T$) is proportional to

$$\frac{z\Phi^2}{\pi}\left\{\frac{\psi_1}{r_1}\cos^2 \beta_1 + \frac{\psi_2}{r_2}\cos^2 \beta_2 + \frac{\psi_3}{r_3}\cos^2 \beta_3\right\} \quad . \quad (7)$$

In the ideal machine :—

$$r_1 = r_2 = r_3 = r\,; \quad \psi_1 = \psi_2 = \psi_3 = \psi$$

and

$$\beta_2 = \beta_1 + \frac{2\pi}{3}, \quad \beta_3 = \beta_1 + \frac{4\pi}{3}$$

so that the above expression then reduces to

$$T \propto \frac{1 \cdot 5 z\Phi^2}{\pi} \cdot \frac{\psi}{r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

or

$$T \propto \frac{z\Phi^2}{2\pi r} \cdot 3\psi \quad . \quad . \quad . \quad . \quad . \quad . \quad (8a)$$

i.e. the torque is the same for a given brush setting, when the motor reaches synchronous speed, whatever position the field comes to rest in, but the currents in the three phases are respectively

$$\frac{z\Phi\psi}{\pi r}\cos \beta_1\,; \quad \frac{z\Phi\psi}{\pi r}\cos\left(\beta_1 + \frac{2\pi}{3}\right)$$

and

$$\frac{z\Phi\psi}{\pi r}\cos\left(\beta_1 + \frac{4\pi}{3}\right)$$

and the torques produced are proportional to $\Phi^2 \cos^2 \beta_1$, $\Phi^2 \cos^2 \{\beta_1 + (2\pi/3)\}$ and $\Phi^2 \cos^2 \{\beta_1 + (4\pi/3)\}$. Both the current and the torque of any one phase are therefore dependent on the position of the brushes of that phase relative to the magnetic field. From this investigation it would appear that as the total torque is uniform the motor would not in practice operate for more than an instant at exactly synchronous speed, and that, therefore, the unbalanced currents in the three phases would be of no importance. If, however, the angles ψ_1, ψ_2 and ψ_3 are not exactly equal, the total torque of the motor varies according to the relative position of the brushes and the magnetic field. This is very likely to be the case in practice, since on normal loads at synchronous speed the angles ψ_1, ψ_2 and ψ_3 are very small, and slight errors in setting the brushes become of considerable importance.* The setting here referred to is the manufacturer's setting, and is not within the control of the operator, as the amount of brush separation is.

From equation (1) if it is assumed that $r_1 = r_2 = r_3 = r$, $\beta_1 = \beta_2 + (2\pi/3)$, and $\beta_3 = \beta_1 + (4\pi/3)$, the total torque is proportional to

$$\{(\psi_1+\psi_2+\psi_3)+\tfrac{1}{2}(\eta_2+\eta_3)\ \cos\ 2\beta_1+\tfrac{1}{2}\sqrt{3}(\eta_3-\eta_2)\ \sin\ 2\beta_1\}$$

The first term in this expression is independent of the position of the magnetic field, the second and third are dependent on it, and it follows that for a given brush-setting the motor can operate against a varying torque (within limits) by a movement of the field, without departing permanently from synchronous speed. In effect this constitutes a locking action and the motor may operate for considerable periods at exactly synchronous speed, with resultant unequal heating of the phase windings and greater total heating. In the motor tested it was found that the variation in external torque possible without bringing the motor out of synchronism, for a constant brush-setting, was about 30 per cent of full-load torque. The values of η_2 and η_3, determined by measurement, were $\eta_2 = 2$ electrical degrees and $\eta_3 = 2\frac{1}{2}$ electrical degrees. The currents in the three phases were widely different while running at synchronous speed. In one case they were 106 amperes, 61 amperes, and 0 amperes respectively.

A similar investigation has been carried out to find the effect of inequality in the angles between centre lines of pairs of half brushes, and it was found that although this also caused a similar locking action at synchronous speed, the effect was not nearly so large (for the same error in degrees) as inequalities in the angles between half brushes.

It may also easily be seen that these errors will cause a periodic torque variation at speeds close to synchronism, which will result in corresponding speed oscillations. Thus operation close to synchronous speed will be unsatisfactory owing to speed oscillations, and operation at exactly synchonous speed will be unsatisfactory owing to the unbalanced currents. The importance of very careful setting of the brushes, therefore, need hardly be emphasized. As these out-of-balance currents are not reflected into the primary, the ordinary user would not suspect their presence until the motor gave trouble due to overheating.

* In the motor tested, these angles were found to differ by about 2 electrical degrees (two-thirds of a geometrical degree).

A CRITICAL RÉSUMÉ OF RECENT WORK ON DIELECTRICS.*

[REPORT (REF. L/T14) PREPARED BY MR. L. HARTSHORN, B.SC., AT THE NATIONAL PHYSICAL LABORATORY, AND RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.†]

PREFACE.

During recent years, electrical engineers throughout the world have come to realize that progress in the industry is largely retarded by the limitations and uncertainties of the insulating materials at its disposal.

Accordingly, although the Association is not yet in possession of adequate funds for a general attack upon the problem, it has decided to do all it can with available funds to prepare the ground. As a first step; the work of preparing a critical résumé of modern work on dielectrics was put into the hands of the National Physical Laboratory.

The object is to give a critical review of modern work and theories upon the subject of dielectric phenomena, extending over the past ten years.

This résumé is now being published for the advancement of the industry.

CONTENTS.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† The symbols adopted by the International Electrotechnical Commission have been substituted for those used in the original copy of the Report.

CONTENTS—*continued.*

I. DIELECTRICS IN GENERAL—POWER LOSS.

(*a*) *The ideal dielectric—Electric polarization or displacement.*

In the early days of electrical science all substances were divided into two classes—*Conductors* and *Insulators*. The characteristic property of a conductor is that "when a charge of electricity is communicated to any part of that substance, the electricity is rapidly transferred from places of high to places of low potential till the potential of the whole becomes the same" (Maxwell).*

The transference is not equally rapid for all substances, but is slower the greater the resistance of the substance or the smaller its conductance. Substances in which such a transference of electricity does not take place were called insulators. All bodies whose insulating power is such that when they are placed between two conductors at different potentials the electromotive force acting on them does not immediately distribute their electricity so as to reduce the potential to a constant value, were called by Faraday *Dielectrics*. Consider now a slab of dielectric bounded by two conducting planes A and B. The arrangement forms a condenser. If now one of the plates A or B be earth connected and the other be given a charge Q, then its potential will be raised to V, where

$$V = \frac{Q}{C}$$

C being a constant called the capacity of the condenser. The + charge Q on A induces an equal negative charge on B, and the two plates exert a force of attraction on each other. These actions of one plate on the other are considered to be exerted by means of the medium between them, i.e. the dielectric which is considered to be in a state of stress called *electric polarization*, the term polarization † signifying that any elementary portion of the dielectric has acquired equal and opposite properties on two opposite sides. In order to form a mental picture of the polarization of the dielectric we often imagine it crossed by lines of force, or lines of induction starting from the positive charge on A and ending on the negative charge on B.

Faraday discovered that the capacity of a condenser depends not only on the size and distance apart of the plates, but also on the nature of the dielectric medium. He defined the ratio of the capacity of a condenser with any given dielectric medium to the capacity of a condenser of the same size and form with air as dielectric as the *specific inductive capacity* of the dielectric.

Consider again the slab of dielectric bounded by the two conducting plates A and B. Let the plates, originally earth connected, be connected to a source of e.m.f. such as to maintain a difference of potential V between the plates. Immediately on connecting up, the condenser becomes charged with a quantity of electricity $Q = VC$, i.e., a charge $+Q$ flows * from the source of e.m.f. into A, an equal and opposite charge flows into B, and the dielectric becomes polarized. The charge Q flowing into the condenser is given by

$$Q = \epsilon C_a V$$

where V = potential difference between the plates,
ϵ = specific inductive capacity of the dielectric,
C_a = capacity of the plate condenser AB with air as dielectric.

If the dielectric is a "perfect" one, then when the charge Q has flowed into the condenser, equilibrium is reached and no further transfer of electricity takes place. There is now a potential gradient in the dielectric. It is subjected to the action of an electromotive force V acting from A to B and it is in a state of polarization. Maxwell conceived this polarization to consist in what he called an *electric displacement* produced by the electromotive force. He considered that although electricity cannot flow through a dielectric it can be displaced a certain amount within it, the displacement being in the same direction as, and proportional to, the e.m.f. producing it. The displacement is measured by the quantity of electricity crossing the unit of area, and this is a measure of the electric polarization. Thus electromotive force is considered to produce electric displacement just as mechanical force produces the displacement of an elastic body. Pursuing the analogy Maxwell called the ratio

$$\frac{\text{e.m.f.}}{\text{displacement produced}} = \text{coefficient of electric elasticity.}$$

* CLERK MAXWELL: "Electricity and Magnetism," vol. i, p. 48.

† In the text, polarization is used in the purely qualitative sense defined here. It is also sometimes used quantitatively as follows: The ether is supposed to permeate all matter, and thus the total displacement in the dielectric medium of any material condenser due to the application of an electric force F may be regarded as consisting of the part

$$\frac{1}{4\pi} \cdot \frac{F}{v^2}$$

in the ether, together with the part

$$\frac{\epsilon - 1}{4\pi} \cdot \frac{F}{v^2}$$

in the material, all the quantities being expressed in electromagnetic units. This part in the material is called the polarization of the material. Thus

$$\text{Polarization} = P = \frac{\epsilon - 1}{4\pi} \cdot \frac{F}{v^2} = a\frac{F}{v^2} \text{ (say)}$$

where $\epsilon = 1 + 4\pi a$.

a may be called the dielectric susceptibility. It is found that P may be interpreted as the electric moment per unit volume of the material. It is thus exactly analogous to the Intensity of Magnetization.

* It is probably more accurate to speak only of the motion of negative electricity, since in conductors and perfect dielectrics the electron is probably the only carrier of electricity. The argument, however, is in no way affected by such a change.

This coefficient varies inversely as the specific inductive capacity.

In the case considered, the total electric displacement across any cross-section of the dielectric between A and B is Q. Thus in charging the condenser, at the same time as the quantity of electricity Q flows from the source of e.m.f. along the connecting wire to A, a quantity of electricity Q crosses every cross-section of the dielectric from A towards B and a quantity Q flows out of B leaving it with a charge $-Q$. Thus the flow of electricity can be regarded as continuous round the whole circuit.

When the electromotive force is removed, the displacement disappears. Thus, suppose the condenser is discharged by joining the plates A and B by a wire. The quantity of electricity Q flows from A along the wire to B, whilst the polarization of the dielectric disappears. The displacement has subsided, a quantity of electricity Q crossing each cross-section of the dielectric from B towards A. Thus we have motion of electricity in the opposite direction to that in charging round the whole circuit.

Thus, says Maxwell,* whatever electricity may be, and whatever we may understand by the movement of electricity, the phenomenon which we have called electric displacement is a movement of electricity in the same sense as the transference of a definite quantity of electricity through a wire is a movement of electricity, the only difference being that in the dielectric there is a force which we have called electric elasticity which acts against the electric displacement and forces the electricity back when the electromotive force is removed; whereas in the conducting wire the electric elasticity is continually giving way, so that a current of true conduction is set up, and the resistance depends not on the total quantity of electricity displaced from its position of equilibrium, but on the quantity which crosses a section of the conductor in a given time.

Our ideas of the nature of electricity and its movement have crystallized out very considerably since Maxwell's time. A conductor is now regarded as a substance containing free electrons, i.e. electrons capable of moving about freely in the interstices between the atoms. When an electromotive force is applied to such a body there is a general drift of the electrons in the direction of the e.m.f. (or rather in the opposite direction since the electron is a negative charge) and this drift constitutes the conduction current. When the e.m.f. is removed the conduction current merely ceases.

A perfect dielectric is regarded as containing no free electrons. All its electrons are bound by forces of attraction to the positive nuclei of the atoms. Thus when an e.m.f. is applied to a dielectric there can be no general drift of the electrons, i.e. no conduction current. The electrons are, however, displaced somewhat from their equilibrium position against the action of the force of attraction binding them to their positive nuclei. The amount of the displacement is proportional to the force, and when the e.m.f. is removed the electrons immediately return to their equilibrium position under the action of the restoring force.

* Clerk Maxwell: "Electricity and Magnetism," vol. i, p. 64.

(b) *Conduction in dielectrics.*

It was very early realized that no substance could be regarded as a perfect insulator or dielectric, i.e. whenever an e.m.f. is applied to any actual dielectric, in addition to the sudden movement of electricity constituting the electric displacement or polarization of the dielectric, there was also a very feeble conduction current. Thus in order to specify the behaviour of any dielectric under the action of an e.m.f. we must have a knowledge of two constants:—

(i) A constant determining the electric displacement. The specific inductive capacity or dielectric constant ϵ serves this purpose.

(ii) A constant determining the conduction current—the specific conductivity σ, or the specific resistance ρ.

Suppose we have a slab of dielectric of area A and thickness l. Let an e.m.f. E be applied to its opposite faces. Then at the instant of applying the e.m.f. we shall have an electric displacement D given by

$$D = \frac{\epsilon}{4\pi v^2} F \text{ (in electromagnetic C.G.S. units)}$$

where F = electric intensity $= \dfrac{E}{l}$

v = velocity of light.

The total movement of electricity is thus

$$Q = D \times A = \epsilon \frac{A}{4\pi l} \times \frac{1}{v^2} \times E$$

In addition to this sudden displacement of electricity there will be a conduction current of amount

$$i_0 = \frac{A\sigma E}{l} = A\sigma F$$

which will persist as long as the e.m.f. is applied. If now the e.m.f. is reduced to zero, the electric displacement vanishes, i.e. there is a sudden rush of charge in the opposite direction and the conduction current ceases.

We regard the conduction current in such cases as due to the fact that the dielectric must contain a comparatively small number of free electrons in addition to the bound electrons pertaining to the electric displacement. Similarly it seems reasonable to suppose that a conductor contains a certain number of bound electrons in addition to its free electrons, and thus we may expect conductors to show dielectric properties to a certain extent, though these may be difficult to detect. In fact, it is not possible to draw a hard and fast line between conductors and dielectrics.

(c) *Dielectrics in practice.*

In practice dielectrics are used almost exclusively on account of their property of withstanding electric stress; they may be subjected to the action of large voltage gradients without allowing the passage of electricity through them. There is, of course, the small conductor current already referred to. This is usually termed the leakage current and is kept as small as possible. In

the perfect dielectric the only effect of the voltage gradient is to produce an electric displacement in the dielectric, which disappears when the voltage gradient is removed. A certain amount of energy is expended on the dielectric in producing the displacement and the dielectric gives up the same amount of energy when the electric field is removed. Thus when the perfect dielectric is placed in an alternating field, energy is alternately stored up and given back by the dielectric and there is no net loss of power.

All the dielectrics used in practice fall far short of the ideal of withstanding the voltage gradient with no net loss of power, and a great amount of research work has been done with the object of finding out the cause of the defects usually met with. In the following pages an attempt will be made to trace the course of these investigations up to their present stage. The defects of commercial dielectrics may be classed as follows:—

(i) *Leakage.*—The leakage current may become excessive, leading to a considerable loss of power.

(ii) *Breakdown.*—The electric elasticity of the dielectric gives way completely if it is subjected to a voltage gradient greater than a certain critical value.*

(iii) *Power loss in alternating fields.*—When used in alternating fields many dielectrics dissipate a considerable amount of power which causes a rise in temperature of the dielectric. This power loss is much greater than can be accounted for by the leakage current. It will be considered in detail later.

(*d*) *Quantities measured.*

In order to know how any dielectric will behave in practice we usually determine certain constants of the material.

Consider first the constants necessary to determine the leakage current. The current passing through the body of the dielectric is determined by the *volume resistivity* of the material, which is defined as the resistance between two opposite faces of a centimetre cube. In the case of solid dielectrics, however, the leakage current is found to consist of two parts, one flowing through the body of the material and the other flowing over the surface through a very thin film of moisture or other conducting material. This surface leakage current is determined by the *surface resistivity*,† which may be defined as the resistance between two opposite edges of a surface film one centimetre square. It is often convenient to express the total resistance between two conductors separated by a solid dielectric. This is called the *leakage resistance* ‡ or the *insulation resistance*. It is a function of both the volume and surface resistivities and the relative importance of the two varies enormously in different cases. The reciprocal of the leakage resistance gives the *leakage conductance*.

The power of the material to resist breakdown is usually specified by means of its *dielectric strength*, which is the voltage gradient just sufficient to cause breakdown.

* It must not, however, be imagined that the electrical breakdown of an insulator is in all cases strictly analogous to the mechanical breakdown of an elastic solid [see page 118 (g)].

† CURTIS: *Bulletin Bureau of Standards*, 1915, vol. 11, p. 378.

‡ *Ibid.*, p. 379.

The power dissipated in the dielectric when it is subjected to the action of an alternating field may be specified in a number of ways. Any system of conductors and dielectrics may be regarded as a condenser, and in dealing with the problem of dielectric losses it is convenient to suppose that we are simply dealing with a condenser, though actually the insulating material in any piece of electrical equipment may constitute the "condenser."

A condenser in which the dielectric is a vacuum dissipates no power when subjected to alternating voltage. It is a "perfect" condenser. If voltage of sine wave-form

$$v = V_0 \sin \omega t$$

is applied to such a condenser, the current is given by

$$i = V_0 C_0 \omega \cos \omega t$$

where C_0 is the capacity of the condenser. Thus the current leads the voltage by 90°, which must be the case since no power is dissipated. Such a condenser can only be obtained in practice by using a gas as the dielectric. When any solid or liquid dielectric is used,

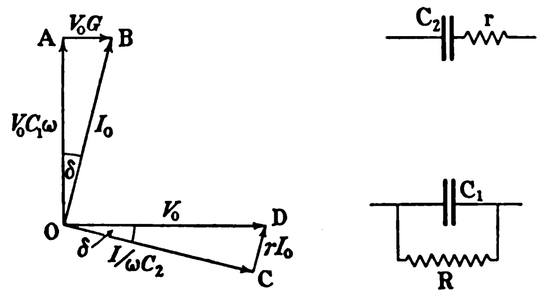

FIG. 1.—Power loss vector diagram illustrating effective series and shunt capacities.

a certain amount of power is always lost as heat in the dielectric. Thus the current no longer leads the voltage by exactly 90°, but by a slightly smaller angle (90° − δ), where δ may be called the "*loss angle*" of the condenser, or since δ is independent of the form of the condenser, the loss angle of the dielectric. If I and V are the effective current and voltage, the power loss is obviously given by

$$\text{Power loss} = W = IV \times \sin \delta,$$

i.e. Power factor = sin δ.

Such a condenser is usually regarded as being equivalent to a perfect condenser of capacity C_1 shunted by a very high resistance R $\left(\text{or conductance } G = \frac{1}{R}\right)$ the power loss being represented by that dissipated by the resistance. It may also be regarded as a perfect condenser of capacity C_2 in series with a small resistance r, which is the cause of the power loss.

Fig. 1 shows the vector diagram of an imperfect condenser and its equivalent circuits. In one case the current I_0 is regarded as consisting of two components, OA = $V_0C_1\omega$ being the current in the perfect condenser of capacity C_1 and therefore at right angles to the

applied voltage V_0, and AB $= V_0 G$ the component due to the shunt conductance G and thus in phase with V_0. Alternatively, the voltage V_0 is regarded as consisting of the two components OC:—

$$\mathrm{OC} = \frac{I_0}{\omega C_2}$$

due to the capacity C_2 and thus 90° out of phase with the current I_0, and CD the voltage drop in the series resistance r and thus in phase with the current I_0.

It is to be noted that the capacities C_1 and C_2 are not identical. We have

$$C_1 = \frac{I_0}{V_0\omega}\cos\delta \text{ — the equivalent shunt capacity.}$$

$$C_2 = \frac{I_0}{V_0\omega}\cdot\frac{1}{\cos\delta} \text{ — the equivalent series capacity.}$$

Also $$\tan\delta = \frac{G}{C_1\omega} = rC_2\omega.$$

Thus the two capacities are only the same when $\cos\delta$ is sensibly unity, i.e. when δ is very small. When this is the case we also have approximately

$$\text{Power factor} = \sin\delta = \delta = \tan\delta.$$

The wave-form of the current obtained when voltage of sine wave-form is applied to a dielectric has been directly determined in a number of cases by Thornton.* He found that in all cases the phase difference between current and voltage was somewhat less than 90°, as is indicated above, but that in certain cases the current wave was also distorted. In such a case it is no longer possible to find a combination of perfect condenser and resistance which represents exactly the behaviour of the condenser, though by ignoring the distortion we may represent it approximately in this manner. Fig. 2 shows the current and voltage wave-forms in two typical cases:—

1. In which there is no distortion, and
2. In which distortion occurs.

The quantity of electricity (Q) in the condenser at any instant may be found by integrating the current wave up to that instant, and thus a curve may be plotted showing the variation of Q during the cycle. If now Q is plotted against the corresponding values of V we obtain the figures shown at (c) and (d) corresponding to the two cases (a) and (b). The resemblance of these to magnetic hysteresis loops is obvious, and thus the power loss is sometimes regarded as due to "dielectric hysteresis." The power loss per cycle is, of course, determined by the area of the loop obtained. As will be shown later, the resemblance between the phenomena of power losses in dielectrics in alternating fields and hysteresis losses in iron in alternating magnetic fields is only superficial. The magnetic cycle depends very little on frequency, whereas the electric cycle depends entirely on frequency, i.e. at zero frequency there seems to be no loop but a straight line only. On this account many writers † deprecate the use of the term hysteresis in connection with the phenomena of power losses in dielectrics. Sometimes the loops are referred to as "cycles of viscosity," * but in the present state of our knowledge it is probably best not to use any term which assumes that the loss arises from any particular source.

The meaning of the term "capacity" as applied to a condenser in which there are power losses requires some attention. In the case in which there is no distortion in the current wave we have

$$v = V_0 \sin\omega t$$
$$i = I_0 \cos(\omega t - \delta)$$
$$Q = \frac{I_0}{\omega}\sin(\omega t - \delta) = Q_0 \sin(\omega t - \delta).$$

In this case the QV loop is an ellipse. Capacity is usually defined as the ratio Q/V, and for a perfect condenser the ratio is constant. Fig. 2 shows, however, that in the case considered, the ratio takes all values

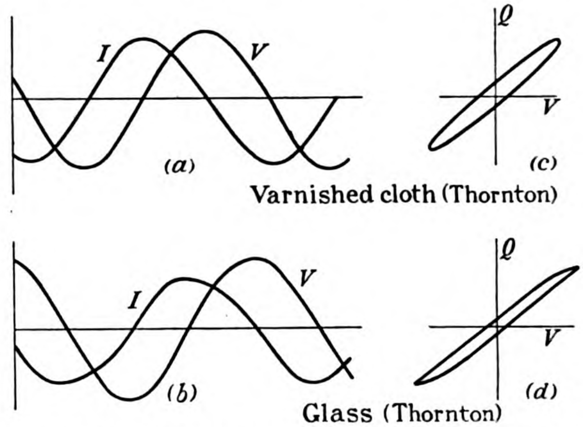

FIG. 2.—Distorted and undistorted waves with corresponding QV loops.

from $-\infty$ to $+\infty$ during a cycle. In such a case two definitions † of capacity have been used :—

1. The ratio $\frac{Q}{V}$ at the instant when Q has its maximum value. This is equal to

$$\frac{Q_0}{V_0\cos\delta} = \frac{I_0}{V_0\omega}\cdot\frac{1}{\cos\delta}$$

i.e. the equivalent series capacity.

2. The ratio $\frac{Q}{V}$ at the instant when V has its maximum value. This is equal to

$$\frac{Q_0\cos\delta}{V_0} \quad\text{or}\quad \frac{I_0}{V_0\omega}\cos\delta$$

i.e. the equivalent shunt capacity.

If β represents the angle between the axis of the ellipse and the V axis, then

$$\tan 2\beta = \tan 2\alpha\cos\delta$$

where $\alpha = \arc\tan\frac{Q_0}{V_0}$.

* THORNTON: *Proc. Phys. Soc.*, 1912, vol. 24, p. 301.
† See for example SCHWEIDLER: *Ann. der Physik*, 1907, vol. 24, p. 711.

* J. GRANIER: *Bulletin de la Société Française des Électriciens*, 1923 vol. 3, p. 355, or J. GRANIER: *Rev. Gén. de l'Électricité*, 1921, vol. 10, p. 219.
† H. JORDAN: *E.T.Z.*, 1911, p. 127.

Thus as the loss angle increases, the axis of the ellipse approaches the V axis.

If we had a dielectric which possessed a certain small conductivity but was otherwise perfect, it would possess a QV loop as shown above. In this case it is obvious that the equivalent shunt capacity, i.e. definition (2), would give the true value, and thus we shall in all cases use this value when obtaining the effective capacity of a condenser at any particular frequency. The value may vary considerably with frequency, and as each value determines a value of the "dielectric constant" of the material, it becomes doubtful whether we are entitled to speak of the material as possessing a "dielectric constant." On this account the value of ϵ calculated from the effective capacity of a condenser under alternating voltage is often called the *permittivity* of the dielectric under the conditions of the test.

Summarizing, when dealing with any dielectric system subjected to alternating voltages, it is of importance to know

1. The effective capacity C.
2. The loss angle δ.

The power loss is given by

$$W = IV \sin \delta$$

where I and V are effective values ; or, since

$$C = \frac{I}{V\omega} \times \cos \delta$$

$$W = V^2 \times \omega \times C \times \tan \delta.$$

The loss angle δ is independent of the size of the condenser and depends only on the nature of the dielectric, but the loss W and capacity depend on the size and shape of the system, and to compare different materials we must consider the permittivity ϵ given by

$$\epsilon = \frac{C}{C_0}$$

C_0 being the capacity of a condenser of the same size and shape as C, but with air as dielectric. We then have

$$W = V^2 \times \omega \times \epsilon \times \tan \delta \times C_0$$

Thus the power loss in any material is proportional to the product of ϵ and $\tan \delta$.

Suppose we are dealing with a parallel-plate condenser of area A and thickness d.

Then

$$C_0 = \frac{A}{4\pi d} \times \frac{1}{v^2} \text{ absolute electromagnetic units}$$

$$= \frac{A}{3 \cdot 6\pi d} \times 10^{-12} \text{ farads}$$

$$\therefore W = \frac{10^{-12}}{3 \cdot 6\pi} \times \omega\epsilon \tan \delta \times \frac{A}{d} V^2 \text{ watts.}$$

If now we regard the energy dissipation as occurring uniformly throughout the dielectric we may write

$$\text{Power loss per cm}^3 = \frac{10^{-12}}{3 \cdot 6\pi} \omega\epsilon \times \tan \delta \left\{\frac{V}{d}\right\}^2.$$

The voltage gradient is V/d volts per cm. If we put g = voltage gradient in kilovolts per mm, we obtain

$$\text{Power loss per cm}^3 = 55 \cdot 5\epsilon \times \tan \delta \times f \times g^2 \times 10^{-6} \text{ watts}$$

where f = frequency.

Many workers* have expressed their results in an equation of this form. Others have expressed the power loss by means of the equivalent conductance G given by

$$W = V^2 G$$

$$= V^2 \frac{A\sigma}{d} = \left\{\frac{V}{d}\right\}^2 \sigma A d$$

σ is then called the "alternating-current conductivity" † of the dielectric. In this case we see that

Power loss per cm^3 = σ × (voltage gradient in volts/cm)^2.

$$\text{Also } \sigma = \frac{10^{-12}}{3 \cdot 6\pi} \times \omega\epsilon \times \tan \delta = \frac{10^{-12}}{1 \cdot 8} f \times \epsilon \times \tan \delta$$

Obviously σ may be regarded as the "specific power loss" of the material in question.

II. Dielectric after-effect—Absorption.

(a) *The anomalous properties of dielectrics.*

On the "ordinary" electromagnetic theory a dielectric is characterized by two quantities, the dielectric constant ϵ and the conductivity. In actual practice, the behaviour of dielectrics is found to be not solely determined by these quantities. All solid and liquid dielectrics show certain properties which seem to be quite independent of ϵ and σ, and these are usually referred to as their anomalous or abnormal properties. The power loss occurring in alternating fields is in practice the most important of these anomalies. The phenomena of "residual charge" and "absorption" are also of great importance. There is an intimate connection between these phenomena and the power loss with alternating current, and as "absorption" may be regarded as the more fundamental phenomenon, it will now be considered in some detail.

(b) *The polarization of dielectrics in constant fields.*

Consider the usual parallel-plate condenser with a perfect dielectric. Suppose initially the plates are connected together and to earth, and then at a given instant they are connected to a source of constant e.m.f. E. Current flows along the connecting wires into the condenser until it becomes charged with the quantity of electricity CE, where C is the capacity of the condenser. The current charging the condenser in this manner is termed the *normal charging current*. Its magnitude and duration depend on the resistance and inductance of the connecting wires and on the capacity of the condenser, being determined by the usual equation

$$L\frac{d^2 i}{dt^2} + R\frac{di}{dt} + \frac{i}{C} = 0$$

* Cf. F. W. Peek: *Gen. Elec. Rev.*, 1915, vol. 18, p. 1050. Also Minton: *Trans. A.I.E.E.*, 1915, vol. 34 (2), p. 1627.

† Cf. Fleming and Dyke: *Journal I.E.E.*, 1912, vol. 49, p. 323.

In practice R and L are usually very small, and the current has fallen to zero in a very small fraction of a second.

If the condenser possesses an appreciable conductance, then superposed upon this normal charging current there will be a constant leakage current. After the normal charging current has fallen to zero, this conduction current will continue to flow, so long as the e.m.f. is maintained. This will be referred to as the *normal conduction current*.

If now the e.m.f. be suddenly reduced to zero, the condenser discharges through the connecting wires giving the *normal discharge current* which extremely rapidly falls to zero, as did the normal charging current. The normal conduction current merely ceases the instant the e.m.f. is reduced to zero.

When the above experiment is made with any ordinary solid or liquid dielectric, the charging current is found to contain another component in addition to the normal charging and conduction currents. After the normal charging current has ceased (the time required for this can be calculated), a current, more or less rapidly decreasing with time, is observed to be flowing into the condenser. This current may continue to decrease for hours; cases have been observed in which the decrease has persisted for months.* Eventually either the current becomes too small to be detected or else a constant value is reached. This constant current is, of course, the normal conduction current. Thus the total current in charging consists of

1. The normal charging current $i_1(t)$.
2. The normal conduction current = constant = a.
3. *The anomalous charging current* or *absorption current* $i_2(t)$.

So that $$I = i_1(t) + a + i_2(t)$$

The charging current having continued until the steady state is reached, suppose now the e.m.f. is reduced to zero—the condenser is short-circuited. There is first the sudden rush of current in the opposite direction to the charging current, constituting the normal discharge current. In many cases after this has died down there is also observed an *anomalous discharging current* similar to the anomalous charging current but in the opposite direction. This also may persist for months. The condenser being short-circuited, there is no potential difference between its terminals, and thus no normal conduction current, during discharge. Thus the total current during discharge is given by

$$I' = i'_1(t) + i'_2(t).$$

The normal charge of the condenser is, of course, reversible so that, the circuit constants being the same in charge and discharge, we have

$$i'_1(t) = - i_1(t)$$

time being measured from the instant at which the charge and discharge respectively begin. In the case of most solid dielectrics we also find that

$$i'_2(t) = - i_2(t)$$

* SCHWEIDLER: *Ann. der Physik*, 1907, vol. 24, p. 759.

i.e. the abnormal charging current may also be regarded as being quasi-reversible. In such cases, the charge conveyed by the abnormal current is sometimes regarded as being "absorbed" by the dielectric during charge and liberated again during discharge. The term, though often convenient, can only be regarded as a very loose one. Many writers do, however, refer to these phenomena as *absorption phenomena*.

In other cases (generally with liquid dielectrics), although we find an anomalous charging current as described above, no anomalous discharge current is observed, or at any rate the anomalous discharge current is very small compared with the anomalous charging current.* It seems quite possible that we are dealing with quite different phenomena in the two cases, though the behaviour in charging is very similar. The normal charging current in the connecting wire corresponds to the production of a certain electric displacement in the dielectric, and the normal discharge current is merely the collapse of this displacement, the process being reversible. By analogy, when the anomalous current is quasi-reversible we may regard it as corresponding to an *anomalous displacement* in the dielectric. The normal conduction current is, of course, not reversible. Thus when the anomalous current is not reversible we may regard it as an *anomalous conduction* current. Thus for convenience we may assume there are two kinds of anomalies :—

1. Anomalous displacement.
2. Anomalous conduction.

It must not be taken that these terms imply any knowledge of the mechanism of the actions concerned.

The production of electric displacement by electric force has been compared with the production of deformation in an elastic body by mechanical force. Similarly anomalous electric displacement is analogous to elastic after-effect and the phenomena of fatigue in elastic bodies. On this account it is often termed dielectric after-effect.

(*c*) *The residual charge.*

The phenomena of anomalous displacement become much less simple when the condenser plates are not maintained at constant voltage, yet much work has been done under such conditions, i.e. having charged the condenser for a definite time, instead of discharging by joining the plates by a wire and so maintaining zero potential difference between them after the normal discharge is allowed to pass, one terminal of the condenser is left insulated. Under these conditions a charge of the same sign as before is observed gradually to build up on the condenser plates. This, of course, corresponds to the charge conveyed by the anomalous discharging current in the previous case. It rises to a maximum value and then slowly disappears (due no doubt to leakage). This is known as the *residual charge*.† It is obviously the same phenomenon that we have called anomalous displacement, but under

* SCHWEIDLER: *Ann. der Physik*, 1907, vol. 24, p. 753. Also TANK: *Ann. der Physik*, 1915, vol. 48, p. 349.
† CLERK MAXWELL: "Electricity and Magnetism," vol. 1, p. 380.

more complicated conditions. In the main we shall confine ourselves to the simple conditions.

(*d*) *Variation of capacity with time of charge and discharge.*

This again is seen to be another aspect of the phenomenon of anomalous displacement, though normal and abnormal conduction may play a part. The effect is observed when the capacity of a condenser is measured by means of a ballistic galvanometer or fluxmeter. The throw of the instrument is observed when the circuit is made or when the condenser is allowed to discharge through it. It is obvious that the quantity of electricity measured will include varying amounts carried by the anomalous current, depending on the time of swing of the instrument, the time during which the e.m.f. was applied, the time during which the condenser is left insulated and charged, the leakage resistance, and the law of decay of the anomalous current. In considering the results of such tests, it is obvious that the conditions must be known if the results are to be of any value.

The variation of capacity with frequency when the condenser is subjected to alternating voltage is also another aspect of the same phenomenon. It will be considered in detail later.

(*e*) *Methods of measurement.*

In the present section we shall confine ourselves to experiments in which the behaviour of the dielectric is

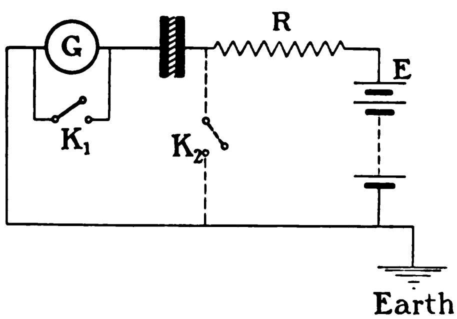

FIG. 3.—Measurement of anomalous current with series galvanometer.

studied whilst under the action of a constant electric force. The various methods used may be divided into two classes:

Those in which the current flowing into the condenser is measured as a function of time.

Those in which the total charge on the condenser or the total electric displacement or polarization is measured as a function of time.

(i) *Experiments in which the current is measured.*

In the methods of the first class we merely have to measure the current produced by a given voltage at various instants after the application of the voltage. The value of the current will depend enormously on the size of the condenser and the nature of the dielectric, but usually it becomes quite small in a very short time so that a sensitive galvanometer, or a still more sensitive instrument, is required.

1. The simplest possible case is shown in Fig. 3. This is the usual arrangement of galvanometer and battery used for insulation resistance measurements. The key K_1 short-circuits the galvanometer while the normal charging current passes. The galvanometer is used with various shunts so that a great range of current values can be measured. This arrangement is sufficient to measure the current until it decreases to something of the order 10^{-9} amperes.* What we measure in this case (assuming the galvanometer is short-circuited until the normal charging current has ceased) is $a + i_2(t)$. The variation of this with time is observed until it becomes constant. This constant value is a, and by subtracting it from each of the previous values we get $i_2(t)$. The discharge current is measured by closing the key K_2 (keeping K_1 closed until the normal discharge has ceased and then opening it). In this case there is no leakage current a and what we measure is simply $i_2'(t)$.

(The high resistance R protects the galvanometer against accidental short-circuits in charging, and also protects the battery when K_2 is closed. Its resistance is always small compared with the effective resistance of the dielectric.)

Measurements have been made in this way by many observers, including Schweidler,† on petroleum, toluol,

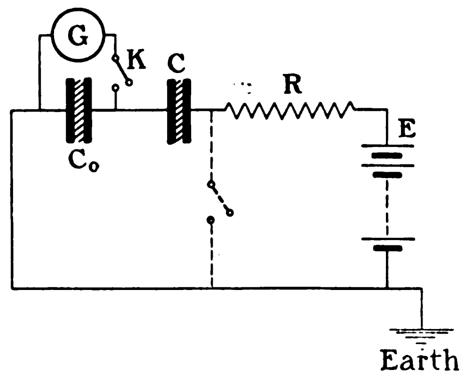

FIG. 4.—Measurement of anomalous current with ballistic galvanometer and condenser.

glass, mica and paraffined paper; Curtis,‡ on a very good range of solid dielectrics, examined chiefly volume resistivity and surface leakage; Wagner § on gutta percha, balata, rubber, ebonite, paraffin, fibrous materials, etc.; Lübben || on a large selection of the papers used in telephone cables.

2. For measuring the current when it has become smaller than 10^{-9} amps. the arrangement shown in Fig. 4 is sometimes convenient. The current through the dielectric C which is too small for the galvanometer G to detect is allowed to flow for a certain time Δt into the condenser C_0 (which is large compared with C).

* CURTIS: *Bulletin Bureau of Standards*, 1914, vol. 11, p. 363.
† SCHWEIDLER: *Ann. der Physik*, 1907, vol. 34, p. 711.
‡ CURTIS, *loc. cit.*
§ K. W. WAGNER: *Archiv. für Elektr.*, 1914, vol. 3, p. 67.
|| LÜBBEN: *Archiv. für Elektr.*, 1921, vol. 10, p. 283.

The key K is then closed and the charge ΔQ which has collected on C_0 is measured by the throw of the galvanometer. The mean current in the interval Δt is then given by

$$\frac{\Delta Q}{\Delta t}.$$

The circuit must be so arranged that the potential difference across C_0 is always small compared with the e.m.f. of the battery E. With this arrangement currents of 10^{-9} to 10^{-13} amps. are conveniently measured. It has been used by Curtis* and Schweidler.†

3. If still smaller currents have to be measured an electrometer may be used with advantage. The arrangement is shown in Fig. 5. The small current through C is allowed to charge up the electrometer for a time interval Δt. Let e be the potential reading indicated by the electrometer after this time. Let C_1 be the capacity of the electrometer and C_0 that of the shunting condenser. Then the charge which has flowed into the

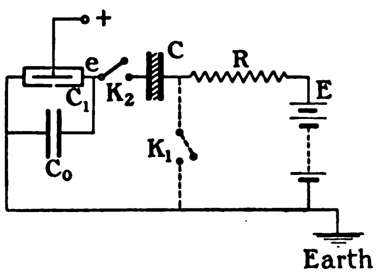

FIG. 5.—Measurement of anomalous current with electrometer.

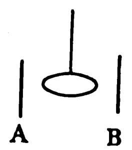

FIG. 6.—Thornton's polarization experiment.

electrometer and condenser is $(C_1 + C_0)e$ and then the mean current during the time Δt is

$$i = \frac{(C_1 + C_0)e}{\Delta t}.$$

As in the previous case, e must be kept small compared with E. Obviously the discharge current can also be measured with this arrangement. C_0 is chosen to give the most convenient sensitivity. Currents of 10^{-13} and 10^{-15} amps.* may be measured in this way. The method has been used by Curtis,‡ S. W. Richardson § (who made experiments on iceland spar, quartz and rock salt), and Tank.‖

4. In some cases it is desired to measure the charging current a small fraction of a second after applying the electromotive force. This cannot be done with the above circuits unless special arrangements are made for operating the switches. Arrangements for making such measurements have been described by Schweidler,¶ Jordan,** and Tank.‖ Jordan used a rotating commutator arrangement whereby the variations of the abnormal charging current in the first 2 seconds after applying the voltage could be explored. Tank used the circuit shown in Fig. 3 with a Helmholtz pendulum for opening the contacts K_1 and K_2 with time intervals of 0·0023 to 0·22 second. The electrometer then measures the total charge which has flowed in this small interval. One advantage of working with very small time intervals is that the abnormal charging current is then comparatively large, so that the leakage current is negligibly small compared with it. In all cases, of course, the effect of the leakage current must be taken into consideration.

(ii) *Experiments in which total charge or polarization is measured.*

1. A most ingenious method for making such measurements has been described by Thornton.* A sample of the dielectric to be studied is made up into the form of an ellipsoid. This is suspended by a quartz fibre between two parallel plates A and B, Fig. 6, between which a constant voltage is maintained. Thus the ellipsoid is situated in an electrostatic field and becomes polarized. If now the ellipsoid be made to execute small oscillations about its position of rest, the time of swing of these oscillations is obviously a function of the extent to which the ellipsoid has become polarized. The experiment is analogous to the oscillations of a magnet in a magnetic field. Thornton investigated the phenomenon mathematically and from the time of swing of the ellipsoid at any instant was able to deduce the value of

$$\epsilon = \frac{\text{Polarization}}{\text{Electric force}}$$

at that instant. The variation of ϵ with time and with the value of the electric force was investigated. The whole arrangement was in a vacuum and was carefully dried by phosphorous pentoxide.

2. H. A. Wilson † has used the arrangement shown in Fig. 7, by which the capacity of the sample C_2 is compared with that of an air condenser C_1. He gives the formula

$$\frac{C_2}{C_1} = \frac{\left(1 + a\frac{e}{V}\right)}{\left(1 - a\frac{e}{V} + \epsilon t\right)}$$

where a is a constant of the circuit and e is the electrometer reading. ϵt is a term representing the effect of conduction in the sample, t representing time. The reading e is taken at various times. When t is very large

$$\frac{C_2}{C_1}$$

becomes constant and thus ϵ may be found. Then using this value, the variation of

$$\frac{C_2}{C_1}$$

i.e. of C_2, may be found for the previous values of t.

(*f*) *Experimental results.*

When the results of different investigators are examined it is found that their conclusions are often

widely different. It seems not improbable that there are several different phenomena which it is almost impossible to separate, e.g. the true anomalous displacement, i.e. a phenomenon occurring within the molecule, effects of inhomogeneity of structure, and effects due to the migration of ions as in electrolysis.

Consider first the phenomena usually met with in the case of solid dielectrics, i.e. the reversible anomalous charge.

(i) It seems to be generally agreed that in such cases there is an anomalous charging current, which is comparatively large immediately after the voltage is applied, but which rapidly decreases with time. This current is found to be proportional to the applied voltage and to vary inversely as the thickness of the sample (i.e. it is proportional to the voltage gradient), the variation

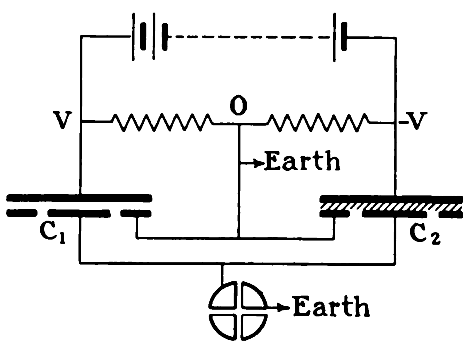

FIG. 7.—Wilson's circuit for measuring the variation of capacity with time.

with time being unaffected by change of voltage gradient.* Thus we may write :—

$$i_2(t) = \beta \times C_0 \times E \times \phi(t)$$

where β and the parameter of the characteristic time function $[\phi(t)]$ are constants of the material, and C_0 is the geometric capacity of the condenser.

(ii) Most observers also have found that after the dielectric has been charged until the anomalous current has become zero, and then discharged, the anomalous discharge current is given by

$$\begin{aligned} i_2'(t) &= -\, i_2(t) \\ &= -\,\beta \times C_0 \times E \times \phi(t). \end{aligned}$$

This was recently verified by Lübben † for telephone cable paper, but most observers in recent work have taken this for granted, and confined their attention either to charging current alone or the discharge current.

(iii) There seems to be some uncertainty as to the form of the time function $\phi(t)$. Many observers have found

$$\phi(t) = Bt^{-m}$$

where the constant $m < 1$. This law has been given by

* SCHWEIDLER : *Ann. der Physik*, 1907, vol. 24, p. 762.
† LÜBBEN : *Archiv. für Elektr.*, 1921, vol. 10, p. 291. Also SCHWEIDLER, *loc. cit.*

Hopkinson,* Schweidler,† Ashton,‡ Jordan,§ Lübben,‖ and others holding for various dielectrics, and there is no doubt that over a restricted time interval it is capable of representing the observed results in many cases. For values of t which are either very short or very long, it is doubtful whether it applies. Two difficulties stand in the way of its acceptance.

1. When $t = 0$, $\phi(t) = \infty$, which would mean an infinitely large initial current.

2. The total residual charge flowing into the condenser is given by

$$\int_0^\delta i_2(t)dt$$

where δ represents the time of charging, and

$$\int_0^\delta Bt^{-m}\,dt = \frac{B\delta^{1-m}}{1-m}$$

which is finite as long as δ is finite, but becomes infinite when $\delta = \infty$. This would mean that the residual charge increases indefinitely as long as the voltage is applied, whereas experiment shows that it reaches a finite limiting value.¶

In connection with (1) it is interesting to note that the experiments of Tank ** and Jordan,†† in which the current corresponding to very small values of t was measured, gave a law of the above form. It was anticipated that as t became smaller and smaller the current would approach a finite limiting value. Actually, although Tank was able to get down to $t = 0{\cdot}00033$, he was not able to obtain evidence of this. What actually happens as t gets smaller is that one gets into the region in which the normal charging current is large and thus the condenser is no longer under constant voltage. Over the range which could be investigated, no departure from the law was detected. The variation of capacity with time is obviously given by

$$C = C_0 + \int_0^t i_2(t)dt$$

and if $\quad i_2(t) = Bt^{-m}$

we have $\quad C = C_0 + \dfrac{B}{1-m}t^{1-m}$

H. A. Wilson ‡‡ gave as the result of his experiments the law

$$C = C_0[1 + B\log(1 + pt)]$$

This corresponds to an anomalous charging current of the form

$$i_2(t) = V\frac{dC}{dt} = \frac{VC_0Bp}{1+pt} = \frac{VC_0B}{t+1/p}$$

‡‡ H. A. WILSON : *Proc. Roy. Soc.* 1909, vol. 82, p. 409.

This may be written

$$i_2(t) = \frac{a}{t+b}$$

A formula of this form was also given by Trouton and Russ,* and Wilson pointed out that one set of observations of Schweidler's also obeyed this law. However, Schweidler's other observations do not correspond to it, and it does not seem to be capable of such wide application as the form $i_2(t) = Bt^{-m}$ although it gives a finite value for $i_2(t)$ when $t = 0$.

A most comprehensive and valuable set of measurements on commercial dielectrics has been made by K. W. Wagner.† He measured the anomalous discharge current after a charge of very long duration, using the simple galvanometer method [(*e.*)1]. He found that although the formula

$$i_2(t) = Bt^{-m}$$

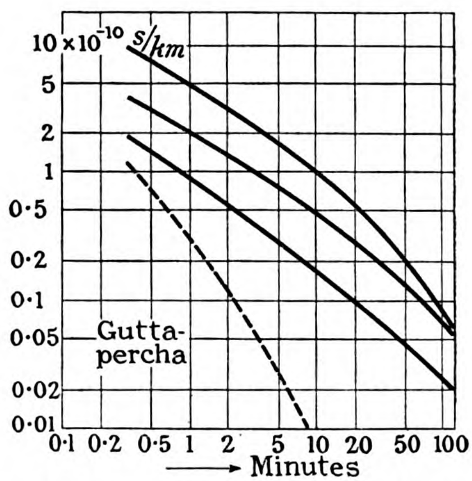

FIG 8.—Anomalous current as a function of time (gutta-percha).

could be applied in most cases over a limited time range, it did not fit all the results, expecially when the observations are extended over a long time. Typical curves are shown in Fig. 8. They are for gutta-percha (two samples) at various temperatures. For convenience $\log i_2(t)$ is plotted against $\log t$. The law $i_2(t) = Bt^{-m}$ would, of course, give a straight line of slope m

$$\log i_2 = -m \log t + \log B.$$

Actually, the line sooner or later becomes curved. These results of Wagner's illustrate the way in which the anomalous current is affected by temperature. The curves show (1) that the anomalous current, i.e. the "absorption," increases rapidly as the temperature rises; (2) that the variation with time is not so much affected by the change of temperature. These results are typical of dielectrics in general. Very similar results were given by Schweidler ‡ for glass. Schweidler stated that the law $i_2(t) = Bt^{-m}$ held approximately at all temperatures, but whereas B increased strongly with temperature, m was practically unaffected.

Wagner has given a formula which he considers more accurate than $i_2(t) = Bt^{-m}$, but as it is very complicated and arose out of theoretical considerations, discussion of it will be deferred until the theory is considered.

Various authors have given formulæ expressing the time variation of the discharge current with varying times of charge. In such cases we have introduced another variable and the formulæ become correspondingly more complicated. As no attempt has usually been made to connect these formulæ with other work, they will not be considered here.

Thornton * did not give any formula representing his results. He described the polarization produced by a constant field as consisting of three parts :—

1. A very rapid rise—the normal charge,
2. Then a slow charge at a uniform rate,
3. And finally an approach to saturation.

This does not seem to be consistent with the results of other observers. The point will be referred to later.

(iv) *Hopkinson's † Superposition Law.*

We have so far only considered the laws of the anomalous current under the condition of constant voltage. Consider now the case of a dielectric charged for a certain time τ with constant voltage and then discharged by short-circuiting. Suppose the anomalous charging current is given by

$$i_2(t) = f(t)$$

where t is reckoned from the instant at which the voltage was applied.

Then Hopkinson stated as the result of his experiments that the anomalous discharge current is given by

$$i_2'(t) = f(t) - f(t+\tau)$$

t now being reckoned from the instant at which the voltage is reduced to zero. Thus we may regard the current $i_2'(t)$ as consisting of two components, the first $f(t)$ being exactly similar in its time variation to the abnormal charging current but in the opposite direction, and the second $f(t+\tau)$ being merely a continuation of the abnormal charging current. It is as though the reduction of the voltage to zero, instead of annulling the effect of the initial application of the electrostatic field, merely superposes upon the current first produced, another one of the same time function but in the opposite direction. Thus the behaviour of any actual dielectric sample depends on the whole of its past history. (This brings out the importance of short-circuiting a sample for at least several hours before making any test on it, so as to allow the currents which have been started in it to die down.)

This is Hopkinson's Superposition Principle. Certain consequences of it are of particular interest.

‡ SCHWEIDLER: *Ann. der Physik*, 1907, vol. 24, p. 759.

* W. M. THORNTON: *Proc. Phys. Soc.*, 1910, vol. 22, p. 186.
† HOPKINSON: Original papers, vol. 2.

1. After charging for an infinite time, the anomalous discharge current is given by

$$\begin{aligned} i_2'(t) &= f(t) - f(t + \infty), \\ &= f(t), \text{ since } f(\infty) \text{ is zero}, \\ &= i_2(t)\,; \end{aligned}$$

$i_2(t)$ and $i_2'(t)$ are of course in the opposite direction.

2. In the case in which we charge for time τ and then discharge, we find

$$\int_0^\infty i_2'(t)dt = -\int_0^\tau i_2(t)dt$$

i.e. the total charge conveyed out of the condenser by the abnormal discharge current is equal to the charge carried into the condenser by the abnormal charging current in the time of charging τ. Measurements made by Ashton * on a cable are not in agreement with this. Results obtained by Ashton seem to indicate that quantity carried out during discharge is twice that carried in by $i_2(t)$. Thornton † quotes this result and explains it by saying that the charge goes in under constant voltage and comes out under decreasing voltage, and the energy of charge and discharge being the same, the "quantity" of discharge is double that of "charge." The case is, however, not so simple as this. In discharge the condenser is short-circuited, and therefore the potential difference between its terminals is very nearly zero, and thus only a very small percentage of the energy which goes into the condenser during the abnormal charge comes out of it, if it is discharged by short-circuiting (since the abnormal discharge current is known to be of the same order as the abnormal charging current).

The Superposition Principle has been extended to cover cases in which the voltage varies in any manner.‡ Suppose the applied p.d. is changed by a series of increments Δ_0E, Δ_1E, Δ_2E . . . at the instant 0, t_1, t_2, t_3 . . . . Then the resultant abnormal charging current may be considered as a superposition of the charging currents due to each of the increments, these component charging currents all being considered independent of each other. Thus the resultant current is given by

$$i_2(t) = \beta C[\Delta_0E\,.\,f(t) + \Delta_1E.f(t - t_1) + \Delta_2E.f(t - t_2) + \ldots]$$

If now the applied p.d. varies according to the function $E(t)$, then

$$i_2(t) = \beta C\int_{-\infty}^{t}\frac{dE(u)}{du}\cdot f(t-u)du.$$

If this generalized Superposition Principle be true, then if we charge a dielectric until the steady state is reached and then discharge it, then whether we discharge by short-circuiting or by slowly lowering the voltage the total quantity carried out by the residual discharge current is equal to the quantity carried in during charge. Suppose now we charge a condenser until it has absorbed a certain quantity of electricity consisting of normal charge q_N and residual charge q_R. Then the work done in charging is

$$W = \tfrac{1}{2}q_NV + q_RV$$

where V is the applied voltage. Suppose now the condenser is discharged by lowering the voltage by an infinite number of infinitesimal steps, allowing the steady state to be reached after each step. Then when the discharge is completed, the Superposition Principle requires that the residual charge released is equal to q_R. But the potential during discharge has fallen uniformly so that the energy given back by the condenser in discharge is

$$W_1 = \tfrac{1}{2}V(q_N + q_R).$$

Thus the net loss of energy in this case is $\tfrac{1}{2}q_RV$, i.e. half the energy required to store up the abnormal charge. As we have seen when we discharge by short-circuiting, the whole of this energy is lost. Thus it is evident that if the "absorption" current obeys the Superposition Principle a certain amount of energy is lost whenever the condenser is charged, unless it is charged and discharged infinitely slowly. The amount of this loss evidently depends on the total amount of charge "absorbed" and the rate of the charge and discharge. It is also obvious that when the condenser is subject to alternating voltage there will be a certain loss of energy in every half cycle, and that this energy loss is quite independent of any leakage resistance. The laws followed by the power loss when the voltage is of sine wave-form will be subsequently developed, continuing the present line of argument. Meanwhile, it is to be noted that the result obtained by Ashton and quoted by Thornton is contrary to the Superposition Principle and that both cannot be accepted. Ashton in his paper was by no means confident about the interpretation of the experiments, and being an isolated case the result cannot be accepted without further inquiry.

(v) *The internal e.m.f. of polarization.*

This is a quantity introduced by Curie * and measured by S. W. Richardson.† It merely represents another way of regarding this same phenomenon of the residual discharge current. Suppose an e.m.f. E is applied to a specimen for a given time and is then reduced to E'. If E' is greater than a certain value P then the "absorption" current continues in the same direction, but if $E' < P$ the absorption current is in the opposite direction. Richardson has called the critical value P the internal e.m.f. of polarization under the condition prevailing. He measured it by trial, using a potentiometer arrangement for varying the voltage.

It is interesting to see what P means. Applying the Superposition Principle to the case considered, the equation

$$i = E\,.\,f(t) - (E - E')\,.\,f(t - \delta)$$

gives the current after the reduction of voltage to E' at time δ. (Normal charges are not considered here.) Thus P is defined by

$$0 = E\,.\,f(t) - (E - P)\,.\,f(t - \delta) \text{ when } t = \delta$$

$$P = E\left[1 - \frac{f(t)}{f(t-\delta)}\right] \text{ where } t = \delta$$

i.e. $$P = E\left[1 - \frac{f(\delta)}{f(0)}\right].$$

* A. W. Ashton: *Phil. Mag.*, 1901, vol. 52, p. 501.
† W. M. Thornton, *loc. cit.*
‡ Schweidler: *Ann. der Physik*, vol. 24, p. 717, 1907.

* Curie: *Annales de Chimie*, 1889.
† S. W. Richardson: *Proc. Roy. Soc.*, 1916, vol. 92, p. 101.

Richardson states that P increases with the time of charging, very rapidly at first and more slowly afterwards. This is borne out by the above formula. He also states that in order to determine the true resistance of the specimen this e.m.f. must be taken into account. He writes

Charging current $= \frac{dQ}{dt} + \frac{E-P}{R}$, where $\frac{dQ}{dt}$ is the rate at which charge is accumulating, E is the applied e.m.f., and R the true resistance. He has determined R for quartz and iceland spar, using the definition, and of course obtains higher values than would be obtained by neglecting P. There is, however, another side to this question. The actual conduction current is i_c, say. If E is the applied voltage, then, neglecting P, the resistance is

$$\frac{E}{i_c} = R$$

and the power expended is

$$Ei_c = \frac{E^2}{R}.$$

If now we take Richardson's definition

$$R_1 = \frac{E-P}{i_c}$$

we can no longer write

$$\text{Power expended} = \frac{E^2}{R_1}$$

since the power expended is certainly equal to the product of applied voltage and conduction current. Thus from the point of view of energy dissipation the ordinary definition of resistance is more convenient, although it may not necessarily mean that the resistivity and the movement of electricity within the dielectric is uniform throughout the sample and determined by

$$\frac{RA}{l}$$

where A = cross-section, l = length, and R is resistance. R must be taken as merely a measure of the total power expended by the conduction current.

(*g*) *Absorption in alternating fields.*

We have seen that when a dielectric is subject to alternating voltage it is to be expected that the anomalous charging current will cause an increase in the apparent capacity, the amount of such increase depending on the time taken to complete a cycle, i.e. the frequency. Further, if this anomalous current obeys the Superposition Principle, there must be a certain loss of power also, depending on the frequency and quite independent of the conductor current. The relation between these effects and the behaviour of the dielectric under constant voltage was worked out by Schweidler.* We shall follow his reasoning. We have obtained the general equation for the anomalous current

$$i_2(t) = \beta C \int_{-\infty}^{t} \frac{dE(u)}{du} \cdot f(t-u)du$$

where $E(u)$ expresses the variation of the applied voltage with time, and $\beta Cf(t)$ is the anomalous current produced by the application of unit e.m.f. at the time $t = 0$.

If now the voltage is of sine wave-form, we have

$$E(u) = E_0 \sin \omega u$$

$$\frac{d}{du}E(u) = \omega E_0 \cos \omega u$$

$$\therefore \quad i_2(t) = E_0 \omega \beta C \int_{-\infty}^{t} \cos \omega u \,.\, f(t-u)du$$

$$= E_0[M \cos \omega t + N \sin \omega t]$$

where
$$M = \omega\beta C \int_0^{\infty} f(x) \,.\, \cos \omega x \,.\, dx$$

$$N = \omega\beta C \int_0^{\infty} f(x) \,.\, \sin \omega x \,.\, dx$$

and
$$x = (t-u)$$

This determines the abnormal current. Superposed upon this are the normal charging current $\omega E_0 C \cos \omega t$ and the normal conduction current $GE_0 \sin \omega t$. Thus the total current is

$$i = E_0[(\omega C + M) \cos \omega t + (G + N) \sin \omega t].$$

Thus the effective capacity is given by

$$C_{effective} = C + \frac{M}{\omega}$$

$$= C + \beta C \int_0^{\infty} f(x) \,.\, \cos \omega x \,.\, dx$$

Thus if
$$\frac{\Delta C}{C}$$

represents the fractional increase of capacity due to "absorption"

$$\frac{\Delta C}{C} = \beta \int_0^{\infty} f(x) \,.\, \cos \omega x \,.\, dx$$

Also, the power loss is given by—

$$\text{Power loss} = \frac{E_0^2}{2}(N + G)$$

i.e. if E is the effective voltage, the power loss due to "absorption" is

$$W_1 = E^2 \beta C \omega \int_0^{\infty} f(x) \sin \omega x \,.\, dx$$

Thus if the function $f(x)$ is known, both the power loss and the change of capacity with frequency can be calculated. It is worth noting that the power loss should be proportional to the square of the voltage if the Superposition Principle is true.

We have seen that our knowledge of the function $f(x)$ is not altogether satisfactory. The formula most usually given is

$$f(t) = Bt^{-m}$$

where m is a constant less than unity.

This leads to the formulæ

$$\frac{\Delta C}{C} = \beta \omega^{m-1} \Gamma(1-m) \cos \frac{(1-m)\pi}{2} = B' \omega^{m-1}$$

* SCHWEIDLER, *loc. cit.*

and

$$W_1 = E^2\beta C\omega^m \frac{\pi}{2\Gamma(m)\cos\dfrac{(1-m)\pi}{2}} = E^2 A\omega^m$$

A and B are obviously constant for a definite value of m, and a definite size of specimen. This result is of great importance as showing how the power loss varies with frequency. The tests made at the N.P.L. on varnished cloth have supplied a striking verification of these equations over a limited range of frequency.

For power loss due to leakage and absorption,

$$\tan\delta = \frac{1}{C\omega} \cdot \frac{G + A\omega^m}{1 + B'\omega^{m-1}}.$$

(*h*) *The irreversible anomalous current.*

This is usually considered a characteristic property of liquid dielectrics, though in certain cases it has been reported as existing in solids, e.g. paper. It is quite likely that in such cases an absorbed liquid was the cause of the phenomenon.

Comparatively little work has been done on this section of the subject in recent years, though it has an extensive literature published mostly before 1913. Schweidler in Graetz's Handbuch * has summarized the results obtained up to 1912 as follows :—

"The decrease of current with time is often very slow. In general the higher the applied voltage or field strength, the earlier is the final steady value of the current reached. If after the current has flowed for a long time under an applied voltage E_1, this is reduced to a smaller value E_2, then after the first decrease in current corresponding to the sudden drop in voltage, there follows an increase of current.

"The law generally given for the time variation of the anomalous current is :—

$$i_2(t) = Bt^{-m}$$

i.e. the same law as for the reversible anomalous current characteristic of solids.

"The usual assumption that the constant final value a of the charging current is a normal conduction current and that the variable part $i_2(t)$ is an anomalous current superposed upon it, is negatived by the fact that this constant final value shows a so-called deviation from Ohm's law. When different voltages are used the final value a, in géneral, is not proportional to E but increases more slowly than E; in many cases as the voltage is further and further increased a "saturation" value of the current is reached, as in the case of ionized gases. In a few cases, however, the opposite holds and the quotient a/E increases with increasing voltage.

"As in the case of electrolytic conduction, the current increases strongly with temperature.

"When the two electrodes are of different form the phenomenon is apt to show a dissymmetry with respect to the direction of flow of current."

A long list of references is given by Schweidler in support of these statements.

The most important recent work on the subject is that of Tank.† He examined a number of liquids, viz. carbon bisulphide, turpentine, resin oil, benzol, petroleum, and found that they all showed the same phenomenon. Under a constant applied voltage the liquids passed a current which can be represented *approximately* by the formula

$$i = Bt^{-m} \text{ where } o < m < 1.$$

The current was measured by the simple galvanometer circuit over the range $t = 1$ to 30 minutes. Although the current was not reversible there were in certain cases traces of back-effect. The phenomenon is considered to be due to conduction by ions and this conduction is considered not to be a characteristic property of the insulator itself, but to depend largely on impurities. The traces of back-effect found in certain cases were considered to be due to chemical polarization of the electrodes.

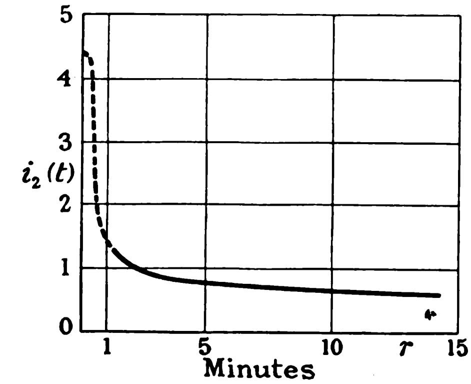

FIG. 9.—Variation of anomalous current with time in liquid dielectrics.

In the case of solids, which show the reversible anomalous phenomena, Tank found that the law $i_2(t) = Bt^{-m}$ held approximately, even when the time intervals were made as small as possible by means of the Helmholtz pendulum. When the liquids were examined in this way an important difference was noted. As the time t was made smaller and smaller the anomalous conduction current did not continue to increase at the rate indicated by the formula, but approached a constant value. The variations of the current with time appear to be as in Fig. 9. The experiments with short time intervals indicated a constant current. Those with $t > 1$ minute gave a variation

$$f(t) = Bt^{-m}$$

Unfortunately, it was not possible to investigate the intermediate portion of the curve. The dotted line in Fig. 9 indicates its probable course. Tank argued that when the current is alternating the conditions are such as correspond to the very small values of t, and to this alternating current the dielectric liquid will behave as if it has constant conductivity G. Thus the power loss will be given by V^2G and will be independent of the frequency. G must, of course, be calculated from the initial current when constant voltage is applied. Direct measurements of the power loss at 50 ∼ were found to agree with the value calculated from the constant-voltage experiments.

It seems, however, very doubtful whether we can

* GRAETZ : *Handbuch der Elektrizitat und des Magnetismus*, vol. 1, p. 237.
† TANK : *Ann. der Physik*, 1915, vol. 48, p. 307.

accept this as a law holding for liquid dielectrics. In the first place it assumes that the initial current is proportional to the applied voltage, and also that it does not depend on whether this voltage is increasing or diminishing so long as it is alternating at least several times per second. The results of previous observers quoted by Schweidler seem to indicate that neither of these assumptions is in general true.

On the whole the laws of the behaviour of liquid dielectrics under constant applied voltages do not as yet seem to be sufficiently generalized to enable us to state their connection with the power losses in alternating fields with any degree of exactness.

It seems to be the general opinion that—

(i) The anomalous phenomena in liquid dielectrics are due to conduction by ions.

(ii) That those phenomena depend enormously on impurities in the liquid.

(iii) If perfectly pure liquid dielectrics could be obtained they would probably be free from anomalous effects.

It is proposed to consider the ionic theory in detail later.*

III. The Methods of Measurement of Power Loss.

The methods of measuring the power dissipated in a dielectric when it is under the action of alternating voltage may be classified as follows :—

Wattmeter methods.

The power expended in any particular case may be directly measured by means of a wattmeter, either of the dynamometer or of the electrostatic type.

Calorimetric methods.

The quantity of heat generated in a given time in the dielectric as a result of the application of a known voltage to the condenser, is determined by placing the condenser in a calorimeter and making observations of rise in temperature.

Equivalent capacity and resistance methods.

The combination of perfect capacity and non-reactive resistance, which is equivalent to any particular condenser, is determined for the particular frequency chosen and the power factor or total power loss is then calculated as indicated in Section I. These methods may be divided into three classes :—

(i) Bridge methods—used mainly at power and telephonic frequencies.
(ii) Resonance substitution methods—widely used at radio frequencies.
(iii) Differential transformer methods.

Wave-form methods.

The actual wave-form and phase relationship of the applied voltage and current through the condenser are determined by means of an oscillograph of some type or other. The power factor or power loss is obtained from the records as indicated in Section I.

(*a*) *Wattmeter methods.*

The difficulties encountered in these methods depend on the fact that the power to be measured is usually quite small, and the power factor is also small. Thus a very sensitive wattmeter is necessary, and phase angle errors in the potential circuit are of great importance when a dynamometer is used. Allowance must also be made for the power expended in the current coil of the wattmeter, since this is also measured by the instrument. Rosa † has given a number of methods of using a dynamometer wattmeter for the measurement of dielectric losses. Fig. 10 (*a*) shows the connections for the simple deflection method, and Fig. 10 (*b*) is the corresponding vector diagram. OA represents the applied voltage V, OB represents i_p the current in the potential circuit, and thus α is the phase angle of this circuit, OG = i_c is the current in the current coil of the wattmeter, and therefore, in the condenser. If the current coil of the wattmeter had no resistance then OF would have represented the condenser current, where

$$\beta = \text{arc tan } rC\omega$$

and $\omega = \pi \times$ frequency,
r = resistance of wattmeter current coil,
C = capacity of condenser.

ϕ is the true phase angle of the condenser. The wattmeter reading is evidently proportional to ϕ' where

$$\phi = \phi' - \alpha + \beta$$

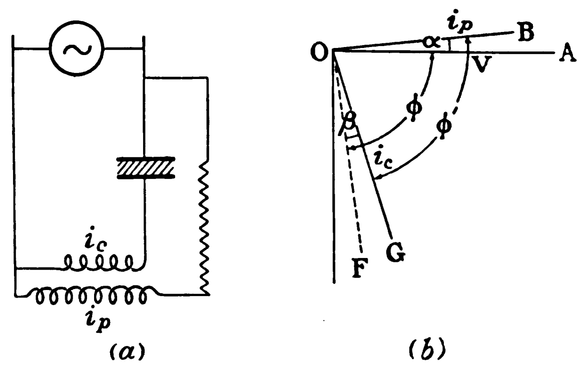

Fig. 10.—Vector diagram and connections of wattmeter.

Thus, in order to use this method, the corrections represented by α and β must be calculated from the constants of the wattmeter. It is difficult to obtain stability in an instrument which is made to have very great sensitivity, and thus Rosa has described a series of null methods in which such great stability is not necessary. In the simplest case a variable self-inductance is put in the potential circuit, and thus the angle α varied until ϕ' is 90°, i.e. the deflection is zero. Evidently the power factor (cos ϕ) can then be calculated from the known constants of the instrument and the added inductance. In other cases a compensating coil magnetically equivalent to the main wattmeter coil was wound over the latter. Current is passed through the compensating coil from a suitable shunt, or a transformer arrangement in the main circuit, and this auxiliary current adjusted until zero deflection is obtained as before. For details the original paper should be consulted. Rosa and Smith † have also described a resonance method using a dynamometer wattmeter. A

* Weissenberger: *Ann der Physik*, 1916, vol. 49, p. 481; Schrader: *Phys. Rev.*, 1921, vol. 17 (Ref. L/T2).

* Rosa: *Bulletin Bureau of Standards*, 1905, vol. 1, p. 383.
† Rosa and Smith: *Phys. Rev.*, 1899, vol. 8, p. 1.

self-inductance coil is placed in series or in parallel with the condenser under test, and the total power dissipated is measured by means of the wattmeter. These resonance methods are useful in special cases, e.g. in the series arrangement the voltage on the condenser may be very large, whilst the wattmeter only has to deal with small voltages.

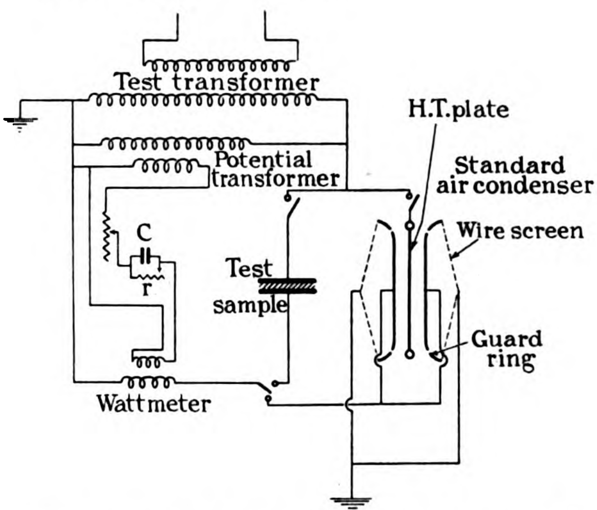

FIG. 11.—Shanklin's wattmeter method for power loss measurements.

In the majority of cases in which a dynamometer wattmeter has been used for dielectric loss measurements the instrument has been used deflectionally, and the phase-angle correction has been made by substituting an air condenser (assumed to be perfect) for the dielectric under test, and adjusting some part of the circuit

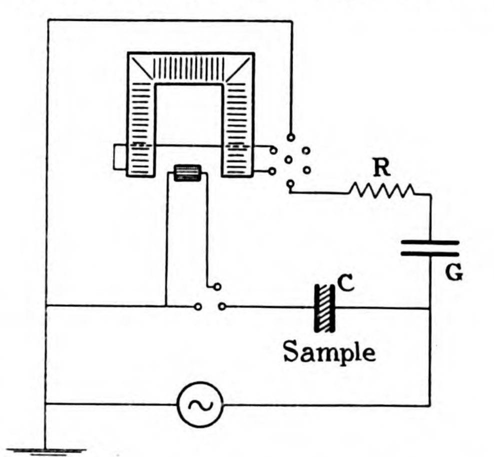

FIG. 12.—Tank's wattmeter method for power loss measurements.

until zero reading has been obtained on the wattmeter. The arrangement used by Shanklin * is shown in Fig. 11. The phase-angle compensating arrangement consists of a condenser C shunted by a variable resistance r, inserted in the potential circuit of the wattmeter. The standard air condenser is formed of three plates. The centre plate is at high voltage and is suspended from the ceiling by insulating cord. The outer plates are provided with guard rings, which are earthed, and all edges are rounded to avoid brush discharges. Air gaps up to 14 inches were used, the capacity being then 100 $\mu\mu$F. The power losses were considered negligible up to 60 000 volts. A similar arrangement is also used by Messrs. Brown Boveri,* but in this case the phase-angle adjustment was made by means of a variable self-inductance placed in the potential circuit of the wattmeter. In addition a correction was made for the effect of mutual inductance between the two wattmeter coils. For this purpose a special variometer was made, the coils of which were exactly the same as those of the wattmeter. This was connected in series with the wattmeter, in such a manner that the mutual inductance effect was in the opposite direction, so that if the variometer was turned in each case so that its reading was equal to the wattmeter reading, the mutual inductance effect would be compensated.† In order to get sufficient sensitivity an iron-cored wattmeter was used. Tank ‡ has also used a dynamometer with an iron core for dielectric loss measurements. In this case the instrument was a Sumpner dynamometer used as a wattmeter

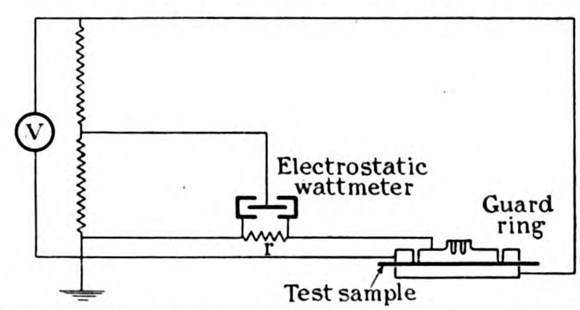

FIG. 13.—Rayner's electrostatic wattmeter method for power loss measurements.

(see Fig. 12). The auxiliary condenser G was adjusted so as to give resonance in the magnet circuit, and the accuracy of this adjustment was tested by substituting a perfect air condenser for the condenser under test, C, and adjusting until the deflection was zero. This arrangement is of course only for low voltages.

The electrostatic wattmeter has been used for the measurement of dielectric losses by a number of investigators, including Miles Walker,§ Skinner,|| Addenbrooke,¶ and Rayner.** The circuit used by Rayner is shown in Fig. 13. A guard-ring electrode was used so as to avoid measuring the losses due to ionization of the air at the edges of the electrode. The wattmeter was used with the voltage between needle and quadrants one half of that on the material under test. This avoids the correction for the energy loss in the current resistance *r*, which is necessary when the instrument is used in any other way. Measurements were made at voltages of the order 10 000.

** RAYNER: *Journal I.E.E.*, 1912, vol. 49, p. 3.

Skinner * has worked at voltages up to 70 000, using an electrostatic wattmeter filled with oil. In this case the quadrants were 16 inches diameter and 7·5 inches high, and the needle was provided with a bifilar suspension. The needle became unsteady when the voltage was raised above 70 000. In all these cases the electrostatic wattmeter has been used deflectionally. It may also be used as a null instrument,† though it does not appear to have been used to any extent in this way for dielectric loss measurements.

The wattmeter method has not been successfully applied at radio frequencies owing to the great difficulties encountered. Alexanderson ‡ has, however, used the voltmeter-ammeter method. His arrangement is shown in Fig. 14. The method is designed to work at high voltages, and for this purpose a special air-core transformer was used. The primary P was excited by means of a high-frequency alternator. The secondary is shown in three sections, S_1, S_2, S_3. These actually formed one long coil which was built up by connecting a number of flat coils in series. The secondary terminated in two

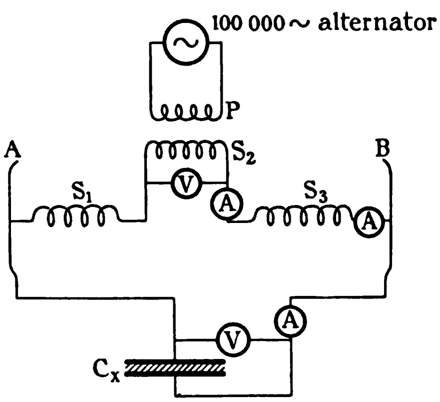

FIG. 14.—Alexanderson's method of measuring power loss at radio frequencies.

terminal shields, A and B, consisting of spirals of heavy copper wire. These are designed to avoid the production of large voltage gradients in the space occupied by the coils. The sample to be tested, C_x, was immersed in oil and connected across the terminal shields as shown. The actual power measurement was made by adjusting the secondary circuit to be in resonance, so that its power factor becomes unity, and then taking readings of current and voltage. Such a measurement was made with the sample disconnected, and then the sample was connected up and another set of observations taken. In each case, of course, resonance was obtained, so that the product volts × amperes gives the power dissipated in the circuit, including the transformer. The difference between the values obtained by the two sets of measurements was taken as the power dissipated in the dielectric. Exact details of the manipulation of the apparatus are not given. It is stated that the electrostatic voltmeter was often unreliable at high voltages, owing to corona. In such cases the voltage was calculated from the value of the current, self-inductance, and frequency.

(*b*) *Calorimetric methods.*

Calorimetric methods are not often used when accurate measurements of power loss or power factor are required, as the measurements are difficult, take a great deal of time, and require very specialized apparatus. As the actual power dissipated must be sufficient to cause a measurable rise of temperature, these methods are only suitable when the power loss is large, i.e. with high voltage gradients, or high frequency. For rough, comparative measurements, thermal methods are often very convenient, e.g. two similar condensers may be compared by subjecting them to the same voltage and noting the rise of temperature in each case. More accurate measurements have been made by Rosa and Smith * and Granier.† Rosa and Smith * used a continuous-flow calorimeter. The condensers were placed between copper sheets, to which were soldered coiled copper pipes, the whole being blackened. Water flowed through the pipes and so carried away the heat developed in the condensers. The calorimeter containing this arrangement was provided with triple walls, and the cooling correction was eliminated by heating the space between the walls electrically, so as to keep its temperature the same as that of the calorimeter, this equality of temperature being indicated by a differential air thermometer. The temperature of the water at inlet and exit was measured by accurate thermometers and the power dissipated as heat was calculated from the rate of flow of the water, and the difference between these two temperatures. The current and voltage were also measured and thus the power factor was calculated. These measurements were made at power frequencies, and the power dissipated was of the order of 10 watts. The power factors measured varied from about 0·5 per cent to 3 per cent. Granier † made measurements at high frequencies, 1 000 ~ to 300 000 ~. The dielectrics investigated were in the form of flexible sheets, which were wound on to a brass tube. Over the dielectric were wound :—

1. A layer of tin-foil to serve as the second electrode.
2. A coil of insulated wire of a few ohms resistance.
3. A layer of dry silk.

The whole was then placed in a vacuum flask in order to reduce the cooling correction to a minimum. The temperature-rise was measured by means of a thermometer inside the brass tube (and thus not in the electric field). In order to equalize the temperature, the tube was half filled with water or petrol. The procedure was as follows :—

High-frequency current was passed through the dielectric, and the current and voltage were measured (the current by means of a thermo-junction and galvanometer calibrated at 900 ~, and the voltage by an electrometer). The rise in temperature in a given time was noted. Direct current was now passed through the auxiliary coil wound over the dielectric, the value being so adjusted that the rise in temperature was practically the same at the same time. The current, voltage and actual temperature-rise were again noted. In the d.c. experiment let V_1, I_1 and Δt_1 be the voltage,

* ROSA and SMITH : *Phys. Rev.*, 1899, vol. 8, p. 79.
† GRANIER : *Bull. de la Soc. Française des Électriciens*, 1923, vol. 3, p. 333.

current and temperature-rise respectively. Let V_2, I_2, Δt_2 be the corresponding a.c. values. Then we have

$$\text{Power factor} = \frac{V_1 I_1 \times \Delta t_2}{V_2 I_2 \times \Delta t_1}$$

the time interval was, of course, the same for each experiment. The temperature-rise measured was 0·1 to 1 deg. C., and the power factors varied from 0·002 to 0·2.

(*c*) *Equivalent resistance and capacity methods.*

(i) *Bridge methods.*—These are used mainly at power and telephonic frequencies, though they can be used at radio frequencies.* A simple Wheatstone network is generally used (see Fig. 15). Here the test sample is in arm 1 of the bridge, and it is compared with a standard condenser in arm 2. The power factor of the material under test may be balanced by a variable resistance in series with the standard condenser, as in

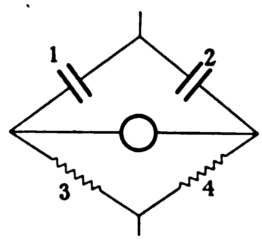

FIG. 15.—Wheatstone's bridge.

the Wien bridge, or if the power factor is very large, it may be convenient to place a variable resistance in parallel with the standard condenser. Another very convenient power-factor adjustment is that used in the Schering bridge, in which the ratio arms 3 and 4 are non-inductive resistances, and a variable capacity in parallel with arm 4 balances the power factor of arm 1 (Fig. 16). The ratio arms 3 and 4 may be non-inductive resistances, condensers, or inductances. In any case it is desirable that their phase angles should be equal. For the most precise measurements a symmetrical bridge is used, i.e. the ratio arms are equal, and a substitution method is employed.† In this way errors due to earth capacities and small residual errors in the phase angles of the ratio arms are avoided. The effects of earth capacities should be reduced to a minimum by earthing a suitable point on the bridge, or by using the Wagner earthing device. A general discussion of the various bridges, with practical details of earthing devices, etc., has been given by the author,‡ so that here only a few special cases will be considered. The Schering bridge § (Fig. 16), previously mentioned, may be considered as a typical case, since it is equally useful for power and telephonic frequencies, and for low and high voltages. The detector D may be a telephone or vibration galvanometer depending on the frequency.

* ENGLUND: *Proc. Inst. Rad. Eng.*, 1920, vol. 8, p. 326. HART: *Journal I.E.E.*, 1923, vol. 61, p. 697.
† GIEBE and ZICKNER: *Archiv. für Elektr.*, 1922, vol. 11, p. 109.
‡ HARTSHORN: *Beama Journal*, 1923, vol. 13, p. 89.
§ SCHERING: *Zeits. für Instr.*, 1920, vol. 40, p. 124; *Semm. Archiv. für Elektr.*, 1920, vol. 9, p. 30.

The ratio arms r_3 and r_4 are non-inductive capacity resistances whose impedances are very small compared with those of the capacities C_1 and C_2. Thus the point B of the bridge should be earthed, since then the detector will always be nearly at earth potential, and earth effects will not seriously affect it. On account of the high impedances of C_1 and C_2, the resistances r_3 and r_4 do not carry large currents, even when the voltage is very high, and thus no very special design is necessary, and further the bridge consumes very little power. The standard condenser C_2 has to withstand practically the whole applied voltage, and, by using a condenser of suitable design, measurements have been made on this bridge with voltages up to 100 kV. In this case the adjustments are made on r_3 and C_4, both of which are always nearly at earth potential and thus may be adjusted quite safely. A spark-gap across r_3 protects the system against damage

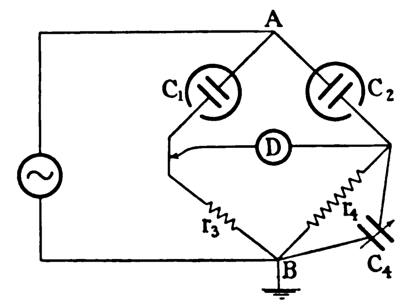

FIG. 16.—Schering bridge.

due to breakdown of the test condenser C_1. The equations of balance are

$$\tan \delta_1 = r_4 C_4 \omega$$
$$C_1 = \frac{r_4}{r_3} C_2 \cos^2 \delta = \frac{r_4}{r_3} C_2 \text{ (approx.)}$$

In practice it is convenient to keep r_4 constant, since then the bridge may be made direct reading for power factor, e.g. in work at 50∼, give r_4 a value of

$$\frac{1\,000}{\pi} \text{ ohms}$$

then $\tan \delta = 10^5 C_4$, and thus the power factor (approximately equal to $\tan \delta$) is equal to one-tenth of the reading of C_4 in microfarads. For fine adjustments of r_3 it is convenient to use a low-resistance slide wire between C_1 and r_3 as shown, the galvanometer being connected to the sliding potential point. This eliminates any trouble due to variable contact resistance. For measurements with low voltage at telephonic frequency it is often convenient to keep both r_3 and r_4 fixed and to vary the standard air condenser C_2. A modification * of the Schering bridge for dealing with large capacities (e.g. long lengths of cable) at high voltages has also been published. In this case the resistance r_3 may have to carry a large current, and since it must be capable of fine adjustment, its construction presents difficulties. In such cases the arrangement shown in

* SCHERING: *Zeits. für Instr.* 1924, vol. 44, p. 98.

Fig. 17 is used. The resistance r_3 is replaced by a parallel combination, consisting of a fixed small resistance n, a fixed resistance r, a slide wire S, and a variable resistance ρ. The galvanometer is connected to the sliding potential point as in the previous arrangement. Thus the small fixed resistance carries the greater part of the current, and the high resistances in parallel, which carry but a small current, are capable of fine adjustment quite conveniently. The formulæ for this arrangement are

$$C_1 = C_2 R_4 \frac{n + r + S + \rho}{n(\rho + \sigma)}$$

$$\tan \delta = \omega R_4 C_4 - \left[\frac{r + S - \sigma}{\rho + \sigma} R_4 \omega C_2\right]$$

The term in brackets is negligibly small, so that the original formula for tan δ holds.

Rosen * has used the Wien bridge for high-voltage measurements, the voltage being applied across the ratio arms. This necessitates special design of the

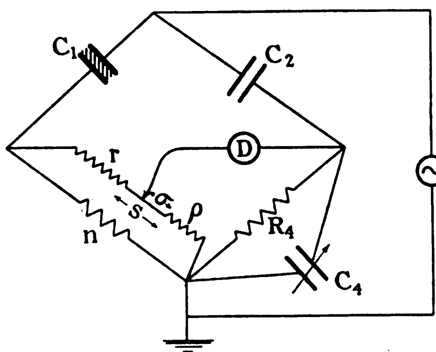

FIG. 17.—Schering bridge for high charging currents.

resistance arms which must carry heavy currents, but allows of the use of a low-voltage standard condenser.

In attempting to use bridge methods at radio frequencies, the difficulties encountered are considerably greater than at telephonic frequencies. A simple telephone receiver can no longer be used as a detector. It is necessary to use also an auxiliary heterodyne oscillator, with an amplifier to give the necessary sensitivity. Detecting arrangements on these lines are described by Englund † and Hart.‡ Hart varied the capacity in the heterodyne oscillator circuit, and listened for a change of frequency in the beat note, which must occur when the bridge is out of balance. Englund, on the other hand, obtained a beat note of constant frequency, and adjusted the bridge until the sound became of minimum intensity. Hart used the simple Wien bridge, with resistances formed of long straight wires, and a standard air condenser. The corner of the bridge at which the adjustments were made was earthed. The bridge described by Englund as being in use in the Western Electric Company's laboratories, has two equal ratio arms (non-reactive coils of 500 ohms). The third arm consists of a variable self-inductance in series with a standard variable air condenser, and the fourth arm is another non-reactive resistance. The coil and condenser in the third arm are adjusted to be in resonance at the frequency used, and thus the impedance of this arm becomes low, and the whole arrangement becomes a low-impedance bridge. Any given condenser is tested by substitution against the standard condenser.

The great advantage of bridge methods is that fluctuations in the applied voltage are of less consequence than in the other methods; the balance point is usually practically independent of the voltage.

(ii) *Substitution in a circuit adjusted to resonance.*—This method is the one generally used at radio frequencies on account of the simplicity of the circuit. General discussions of such methods are given by Dellinger * and Dye.† The arrangement of the measuring circuit is as shown in Fig. 18. L is a self-inductance, C a standard variable air condenser, C_x the condenser to be tested, r a non-inductive resistance, and A a current-indicating instrument, e.g. a thermo-junction and galvanometer. This circuit is loosely coupled to an oscillating circuit which supplies the power. In the simplest substitution method, the test condenser is

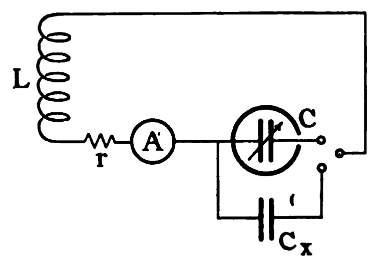

FIG. 18.—Power loss measurements at radio frequencies by simple substitution.

first placed in circuit, the resistance r being removed, and the resonance adjustment is made. The current reading is then noted, C_x is disconnected, and C substituted for it. The value of C is adjusted until resonance is again obtained, and the value of r is varied until the current is the same as before. The readings of r and C then give the equivalent series resistance and capacity of the test sample (assuming the standard condenser C is perfect). It is essential that the voltage induced in the measuring circuit should be the same before and after the substitution, and it is of the greatest importance that the capacity coupling between the generating and measuring circuits should not be altered in making the substitution. The difficulties of satisfying such conditions are generally considered to make this simple method rather inaccurate, though Schott ‡ favours this method for precision measurements. The resistances r usually consist of straight thin wires provided with thick copper terminal pieces, which dip into mercury cups. A series of such resistances all of the same length but of different resistances is convenient. For very fine adjustments of resistance, Schott used an arrangement like a variometer, the movable coil being wound of high-resistance wire, and short-circuited in

* ROSEN: *Proc. Phys. Soc.*, 1923, vol. 35, p. 235.

‡ SCHOTT: *Jahrbuch der Drahtlosen Teleg.*, 1921, vol. 18, p. 82.

itself. The effective resistance of this arrangement varies with the position of the moving coil, and thus a continuous fine adjustment of resistance is possible. It is necessary to calibrate the arrangement against the straight-wire standard resistances for each frequency used. As current indicator Schott used a thermo-junction and galvanometer, placed in a separate circuit (aperiodic), coupled with the measuring circuit. By means of a potentiometer arrangement the galvanometer deflection was reduced to zero for the required current. This arrangement was considered greatly to increase the sensitivity.

For accurate measurements this simple substitution method is not generally used, but the following procedure is adopted. C_x is inserted, the resonance adjustment made, and the current reading noted. This is repeated for various values of r, and from the observations, the total effective resistance of the circuit is calculated using the formula

$$I = \frac{E}{R + r}$$

where E is the induced e.m.f. (which is unaffected by changing r) and R is the effective resistance of the whole circuit excluding r. The standard condenser is now substituted for C_x and the experiment repeated. The difference between the two values of R gives the effective resistance of the test condenser, and its capacity is given by the reading of the standard condenser. Alterations of capacity coupling due to the substitution of the standard condenser will obviously cause no error when this method is used. It is important to avoid reaction between the measuring and generating circuits, and the resistances r and the detector should be connected to the shield side of the condenser which may be earthed.

Dielectric loss measurements by the substitution method at radio frequencies have also been made by Fleming and Dyke,* L. W. Austin,† G. E. Bairsto,‡ and Dellinger and Preston.§ Bairsto used a rotating commutator for making the substitution of one condenser for the other, rapidly and continuously, each condenser being in circuit for equal time intervals. He had a thermo-junction in series with each condenser, and the two were adjusted to equal sensitivity and connected differentially to a galvanometer. Thus the method became a null method. The necessity for this arose from the fact that an arc was used as generator, and thus there were fluctuations of voltage. Bairsto's resistance adjustment was made by means of a variable water resistance in parallel with the standard air condenser.

(iii) *The differential transformer method.*‖—This method has also been used for radio-frequency measurements. The principle is shown in Fig. 19. The differential transformer possesses one secondary S and two primaries P_1 and P_2 exactly the same in every respect, except that they are wound in opposite directions. The test condenser C_x is in series with one primary, and the standard variable air condenser C and resistance r are in series with the other. Current is passed through the two primaries in parallel as indicated in the diagram. It is obvious that when the condenser C and resistance r are equivalent to C_x, then the current through both primaries will be the same in magnitude and phase, and the net induced current in the secondary S will be zero. Thus the experiment consists in adjusting r and C until this condition is established. The detector used by Hund is shown in Fig. 19. It consists of two thermo-junctions T_1 and T_2 connected in a bridge network with equal resistance ratio arms: B_1, B_2, B_3, B_4 are blocking condensers. The current from the secondary of the transformer is led into two opposite corners of the bridge as shown. An auxiliary current obtained by coupling on to the main circuit is passed into the other two opposite corners of the bridge. It can be shown that the galvanometer G measures the scalar product of these two currents. Thus it not only indicates when the current in the secondary S becomes

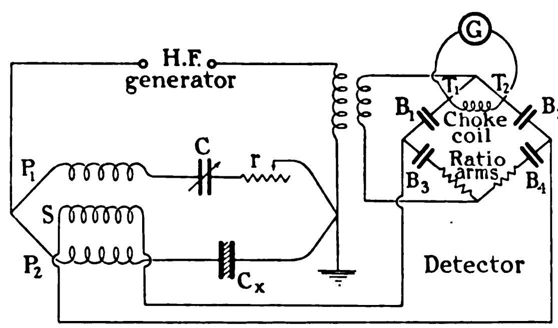

FIG. 19.—Use of differential transformer in high-frequency power loss measurements.

zero, but by changing the phase of the auxiliary current the arrangement can be made sensitive to changes of C or to changes of r, thus making the two adjustments to a certain extent independent. Trautwein * has made a detailed study of the differential transformer method, which he considers superior to all other methods at radio frequencies. He discusses the sensitivity, the means of changing the phase of the auxiliary current, and various forms of detector for measuring the scalar product of two currents. For this purpose instead of the thermo-junction arrangement he has used, (1) a string electrometer, (2) an arrangement of two diodes or two triodes with a differential galvanometer.

(*d*) *Wave-form methods.*

This method in its simplest form has been used by Thornton.† He made up large condensers, using a number of sheets of dielectric with tin-foil electrodes, the whole being under pressure. Alternating current of frequency 38 ∼ was passed through these, and the wave-form of current and voltage recorded by means of an electromagnetic oscillograph. From the records, "hysteresis" loops were obtained and power factors calculated as described in Section I.

The same method has been used at very low frequencies (of the order of 1 cycle per second) by Granier.‡

‡ GRANIER: *Rev. Gén. de l'Électricité*, 1921, vol. 10, p. 219. *Bull. de la Soc. Française des Élect.*, 1923, vol. 3, p. 355.

He used a number of different arrangements. In some cases, by means of a rotating contact device, the condenser was discharged through a ballistic galvanometer or fluxmeter, at some definite point on the cycle. Thus the cycle of quantity of charge and voltage was plotted by taking readings for a number of points round the cycle. It is, of course, necessary to short-circuit the condenser for some time between observations. In other experiments, a galvanometer was used as an oscillograph for very low frequencies. This is, of course, essentially the same as Thornton's method. A point-to-point method using an electrometer is also described,

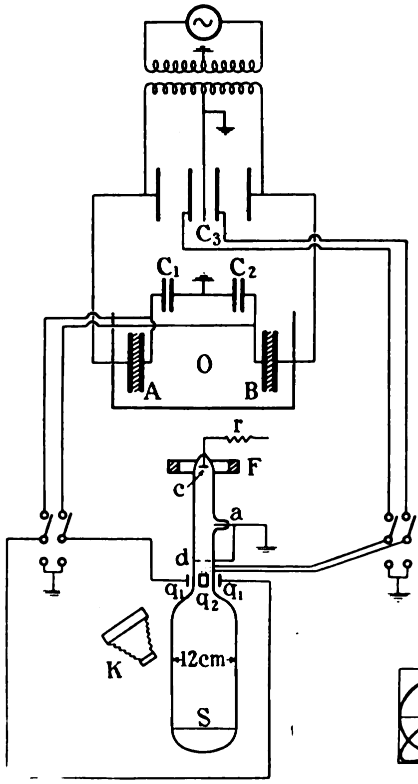

FIG. 20.—Use of cathode-ray oscillograph in power loss measurements.

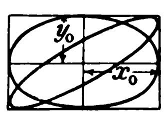

FIG. 21.—Cyclogram from cathode-ray oscillograph.

but none of these very low-frequency methods are very convenient, and the interpretation of the results is a matter of extreme difficulty. Minton * has described the application of the cathode ray oscillograph to measurements of this kind. The arrangement is shown in Fig. 20. C is the cathode, and a the anode, and when the tube is working there is a potential difference of 20 000 volts between the two. The cathode rays pass through a small hole about 0·8 mm diameter in the diaphragm d. The small pencil of rays so obtained falls on the fluorescent screen S, and produces a luminous spot at the point of impact.

There are two pairs of deflecting plates q_1q_1, and q_2q_2, between which the cathode rays pass. Plates q_1q_1 are parallel and at right angles to q_2q_2, which are also parallel. The insulating material under test was made up into two equal condensers A and B, and as the tests were made at high voltages these were placed under oil in the box O. C_1 and C_2 are two air condensers in series with A and B. The potential difference across C_1 and C_2 is proportional to the current through the specimens, and is applied to the plates q_1q_1. C_3 is also an air condenser and the potential difference across it is proportional to the applied voltage. This potential difference is applied to the other pair of plates q_2q_2. Let the voltage applied to the test system AC_1C_2B be

$$v = V_0 \sin \omega t$$

Then the current will be

$$i = I_0 \sin (\omega t + \phi)$$

where ϕ is the phase angle of the system. The deflection produced by plates q_1 is

$$x = k_1 I_0 \cos (\omega t + \phi)$$

where k_1 is a proportionality constant. That produced by plates q_2 is similarly

$$y = k_2 V_0 \sin \omega t.$$

When these operate simultaneously the image on the screen is an ellipse as in Fig. 21. The area of this ellipse is given by

$$A = \int_0^{2\pi} y dx = \pi k_1 k_2 V_0 I_0 \cos \phi$$

If the two deflections are allowed to take place separately, straight-line images are obtained of lengths

$$2x_0 = 2k_1 I_0 \quad \text{and} \quad 2y_0 = 2k_2 V_0$$

Thus the area A is given by

$$A = \pi x_0 y_0 \cos \phi$$

and $\cos \phi$ may be determined by measuring A, x_0 and y_0. For any given set-up of the apparatus, the power factor ($\cos \phi$) is evidently proportional to the area of the ellipse obtained. The images were photographed by means of the camera K. The power factor so measured is that of the test system AC_1C_2B. The power factor of the dielectric itself, i.e. A and B, was calculated from this as follows :—

The voltage e_1 across C_1 and C_2 was measured by means of an electrostatic voltmeter. The total applied voltage V was also measured (by reading the voltage on the low-tension side of the transformer and multiplying by the ratio of transformation). It is easy to show that the actual voltage across the insulator A and B is

$$E' = \sqrt{V^2 + e_1^2 - 2Ve_1 \sin \phi}$$

and that the power factor of the insulation ($\cos \phi'$) is given by

$$\cos \phi' = \cos \phi + \frac{e_1}{2E'} \sin 2\phi$$

This expression is an approximation which is accurate enough for practical purposes. The value of e_1, the potential difference across C_1 and C_2, together with the capacity value for C_1 and C_2 and the frequency, determines the current through the specimens. The voltage across them is also determined as mentioned above. Thus the total power loss can be calculated when the power factor is known.

* MINTON : *Trans. A.I.E.E.*, 1915, vol. 34 (2), p. 1627.

As regards the cathode-ray tube itself, it was found necessary to exhaust it for three or four hours at high temperature, say 350° C., in order to remove gas adsorbed on the walls. The vacuum then remained constant for two years or more. The accumulation of charges on the glass surrounding the cathode also caused trouble, and to avoid this it was sometimes preferable to exhaust at 350° C. for only half an hour. This leaves sufficient adsorbed gas to conduct away these charges, but not enough to spoil the vacuum for a long period. The deflecting plates were of brass and mounted outside the tube, using ebonite as insulator. To avoid any electrostatic shielding effect of moisture on the glass in the neighbourhood of the deflecting plates, the tube in this neighbourhood was coated with cellulose nitrate. As shown in the diagram, the record on the fluorescent screen is photographed at an angle. This does not introduce difficulties into the calculation of $\cos\phi$, since this is given as the ratio $A/x_0y_0\pi$, and both numerator and denominator are equally affected by taking the photograph in this way.

The chief feature of the cathode-ray oscillograph for measurements of this kind is that it can be used for high voltages and also for high frequencies.

(*e*) *The electrodes.*

In all methods of testing any given dielectric, it is necessary to provide it with two conducting electrodes. Liquids present no difficulty in this respect. In the case of solids, tin-foil has been widely used for making electrodes. Appleyard * first showed that when tin-foil is used, the values obtained for insulation resistance are very uncertain, due to the fact that tin-foil does not make proper contact with the dielectric. He found that mercury electrodes gave much more consistent results. Bairsto † made an investigation into tin-foil contact with dielectrics, and showed that, although tin-foil may give very inaccurate results for d.c. measurements, when a.c. measurements are made the error is only comparatively small. This is because the alternating current can pass through the large contact capacity instead of through the high contact resistance. In some cases,‡ to avoid this contact difficulty, the material has been tested in an air-gap, no attempt being made to secure metallic contact with the specimen. For certain conditions (high temperature, etc.), graphite has been used instead of mercury for electrode material. Schrader § found that he could get better contact with graphite than with mercury in certain experiments. In experiments on various kinds of glass, Schott ‖ used steel plates carefully ground flat and polished, as electrodes. The glass (in the form of flat plates) was also ground optically flat and polished, so that the glass and steel surfaces when brought together would give contact of a very high order. R. Jaeger ¶ in a series of experiments on the dielectric constants of solids, used electrodes of very thin foil (tin, silver, or platinum). Circular pieces were cut out and stuck on to the dielectric with water or oil of high dielectric constant. This, of course, increases the contact capacity, and so reduces the error due to imperfect contact. Attempts to measure the thickness of the oil film showed that it was less than 0·001 mm. Jaeger also used the air-gap method. The surfaces of such dielectrics as glass, mica, may be silvered, and this process has frequently been used for providing the material with electrodes.*

Cathodic sputtering has also occasionally been used, while H. J. McLeod † sprayed material with lead from an oxyhydrogen gun. Such methods are, of course, not very convenient when a large number of samples has to be tested. In testing flexible materials under more or less working conditions, it is convenient to wind the material tightly on to a brass rod, which forms one electrode, and then to wind tin-foil over the material to form the other. For work at high voltages, brass discs with carefully rounded corners are often used as electrodes ‡ (Fig. 13).

IV. Theories of the Anomalous Phenomena of Dielectrics.

Many theories have been proposed to account for the anomalous properties of dielectrics. The electron theory of the normal displacement can be regarded as fairly definitely established, and will not be considered here. The so-called anomalous phenomena—power loss in alternating fields and "absorption" in constant fields—alone will be dealt with. These will be considered as superposed upon the normal properties. In Section II it is shown that the laws of the power loss in alternating fields can be deduced from those of the polarization or current in constant fields, so that in considering any theory it is merely sufficient to explain one of those phenomena.

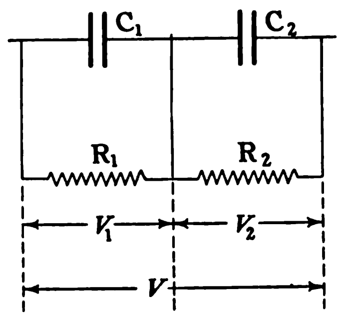

FIG. 22.—Representation of dielectric of laminated structure.

(*a*) *Maxwell's theory.*

Maxwell § showed that if the electrical behaviour of a dielectric can be represented by two constants, its specific resistance ρ and dielectric constant ϵ, then a *homogeneous* dielectric should be free from absorption. If, however, the dielectric be of heterogeneous structure and the product $\epsilon\rho$ be not the same for all the components, then absorption is a necessary consequence. It will also follow that when the condenser is subject to alternating voltage there will be a change of capacity with frequency, and a power loss greater than the

resistance of the whole structure to direct current might lead us to suppose.

Maxwell's exposition of his theory is not in the form most convenient for comparison with the results of recent measurements, and the theory has been developed in various directions by several workers. Rowland and Grover * have given its application to alternating currents. Wagner † has explained in simple terms the mechanism of absorption in such cases.

Meyer ‡ has given a restatement of the theory with special reference to dielectrics containing absorbed moisture, and in 1923 Steinmetz § gave another account of the theory with special reference to cables of laminated structure, together with a simple explanation of the mechanism of the action much the same as that of Wagner.

Following Meyer, consider the case of a dielectric of laminated structure composed of two substances. Take the simplest possible case of a parallel-plate condenser, the dielectric being formed of two layers, one of each of the components. Then the effect is the same as if we had two condensers in series, as in Fig. 22. Let C_1C_2 represent the capacities of these condensers and R_1R_2 their resistances. Let V_1V_2 be the differences of potential between their plates and V the potential difference across the whole condenser. The total current through the two component condensers is, of course, the same. Denote it by I. Then

$$I = \frac{1}{R_1}V_1 + C_1\frac{dV_1}{dt} \quad \text{and} \quad I = \frac{1}{R_2}V_2 + C_2\frac{dV_2}{dt}$$

$$\therefore\ V_1 = \frac{1}{C_1}e^{\frac{-t}{\tau_1}}\int_{-\infty}^{t} e^{\frac{-t}{\tau_1}} I dt$$

$$\therefore\ V_2 = \frac{C_1}{C_2}e^{\frac{-t}{\tau_2}}\int_{-\infty}^{t} e^{\frac{-t}{\tau_2}} I dt$$

where τ_1 and τ_2 are the relaxation times of the two components

$$\tau_1 = R_1C_1 = \frac{\epsilon_1\rho_1}{4\pi v^2}$$

These equations lead to the differential equation

$$\left(\frac{1}{C_1} + \frac{1}{C_2}\right)\frac{dI}{dt} + \left(\frac{1}{\tau_1 C_2} + \frac{1}{\tau_2 C_1}\right)I = \frac{d^2V}{dt^2} + \left(\frac{1}{\tau_1} + \frac{1}{\tau_2}\right)\frac{dV}{dt} + \frac{1}{\tau_1\tau_2}V$$

The general solution is

$$I = C\frac{dV}{dt} + \frac{V}{R} + \frac{aC}{T}e^{\frac{-t}{T}}\int_{-\infty}^{t} e^{\frac{t}{T}}\frac{dV}{dt} \times dt$$

where
$$C = \frac{C_1C_2}{C_1 + C_2}$$
$$R = R_1 + R_2$$
$$T = \frac{(C_1 + C_2)R_1R_2}{R_1 + R_2}$$
$$a = \frac{(R_1C_1 - R_2C_2)^2}{C_1C_2(R_1 + R_2)^2}$$

‡ U. MEYER: *Verh. Deutsch. Physik. Gesell.*, 1917, vol. 19, p. 139.
§ STEINMETZ: *A.I.E.E. Journal*, 1923.

The two cases of greatest interest are

Case I.—When a constant voltage E_0 is applied at the instant $t = 0$. We get

$$I = E_0\left[\frac{1}{R} + \frac{aC}{T}e^{\frac{-t}{T}}\right]$$

Thus superposed upon the constant leakage current E_0/R we have an absorption current

$$E_0 a\frac{C}{T}e^{\frac{-t}{T}}$$

The only case in which there is no absorption current is when $a = 0$, i.e. when $R_1C_1 - R_2C_2 = 0$, i.e. when $\epsilon_1\rho_1 = \epsilon_2\rho_2$.

Case II.—When alternating voltage is applied to the condenser. Putting

$$V = V_0e^{j\omega t}$$

we get

$$I = V\left[j\omega C + \frac{1}{R} + \frac{j\omega aC}{1 + j\omega T}\right]$$

Thus
$$\frac{\Delta C}{C} = \frac{a}{1 + \omega^2T^2}$$

giving the change of capacity with frequency, and

$$\frac{C + \Delta C}{C} \times \tan\delta = \frac{a\omega T}{1 + \omega^2T^2}$$

which determines the loss angle δ due to "absorption" only. There is, of course, additional power loss due to the resistance R.

It is to be noted that in this case the characteristic time function of the absorption current is

$$f(t) = e^{\frac{-t}{T}}$$

Thus according to the Superposition Principle,* the general equation of the absorption current is

$$i_2(t) = \beta C\int_{-\infty}^{t}\frac{dE(u)}{du}\cdot f(t-u)du = \beta C\int_{-\infty}^{t}\frac{dE(u)}{du}\cdot e^{\frac{-(t-u)}{T}}du$$
$$= \beta Ce^{\frac{-t}{T}}\int_{-\infty}^{t}\frac{dE(u)}{du}\cdot e^{\frac{u}{T}}du$$

This is obviously the same as the general expression given above for the absorption current if we put

$$\beta = \frac{a}{T}$$

Thus the theory can explain the Superposition Principle.

We have seen, however, that the function $f(t)$ as determined by experiment is not a simple exponential function. Thus the simple case considered is not sufficient to explain the results of experiment. The theory must obviously be extended to cases in which the dielectric is built up of several components. Meyer obtains the general solution in the case of a dielectric

* See Section II, p. 1162.

with three layers. In this case the absorption current is represented by the sum of two exponential terms, and similarly if we assume that the dielectric is built up of n component layers we obtain $n - 1$ exponential terms in the expression for the absorption current (see Steinmetz).* It is obvious that by taking a sufficient number of terms any experimentally-found curve can be represented, and thus by assuming sufficiently heterogeneous structure almost any experimental curve could be explained by this theory. Steinmetz* showed that in the case of one particular cable, two terms were sufficient to represent the curve actually obtained, and there is no doubt that the absorption current and power loss in dielectrics of laminated structure are at least in part due to the phenomena described by Maxwell's theory.

If the theory provided the complete explanation of the anomalous phenomena shown by dielectrics, we should expect that dielectrics such as quartz, iceland spar, rock salt and pure substances generally, where a homogeneous structure is to be expected, would be free from absorption, etc. However, as mentioned in Section II, Thornton † has observed the phenomena in crystalline quartz, both parallel and perpendicular to the optic axis, and also in fused quartz, whilst Richardson ‡ has found similar effects in iceland spar and rock salt as well as quartz. Both Thornton and H. A. Wilson § have observed absorption phenomena in sulphur. Thus it seems probable that Maxwell's theory does not provide a complete explanation of the anomalies, though it is certainly at least a partial explanation, in most commercial dielectrics.

(b) *Theories of dielectric hysteresis or viscosity.*

Maxwell's theory seeks an explanation of the anomalous properties of dielectrics in anomalies in structure. As this explanation seems hardly sufficient, a number of other theories have been put forward in which the anomalies were considered to be in the behaviour of the dielectric. The displacement is assumed not always to be a function of the field strength only, giving a constant dielectric coefficient, but to depend also on other conditions such as the previous state of the medium or the time rate of change of field strength. Sometimes it is assumed that there is a dielectric hysteresis effect analogous to magnetic hysteresis, i.e. a constant power loss per cycle depending only on the maximum value of the displacement, and not on the frequency. There seems to be, however, little, if any, evidence in support of this. The evidence is much more in favour of what may be termed viscous hysteresis. Theories on these lines are:—

(i) *Houllevigue's theory.*—See Grover.|| This assumes the displacement in an imperfect dielectric to consist of two parts: (1) an instantaneous displacement of the ether until the elastic forces between the ether and the molecules are in equilibrium; (2) an additional gradual yielding of the molecules under this tension, so that to the instantaneous displacement of the ether is added the displacement of the mean position of the molecules. The displacement of the molecules is assumed to be opposed by a frictional force proportional to their velocity, and this frictional force is the cause of the loss of power. Grover gives the mathematical development of the theory, but as the conclusions are not well supported by experiment and are not considered in most recent work, further detail is omitted here.

(ii) *Pellat's theory.**—Pellat's theory assumes that when a field of strength E_0 is impressed on a dielectric, the displacement instantaneously takes up the value

$$D_0 = \frac{\epsilon E_0}{4\pi v^2}$$

and then increases logarithmically towards a final value $(1 + \gamma)$ times as great,

$$\text{i.e.} \quad D_t = \frac{\epsilon E_0}{4\pi^2} + \frac{\epsilon E_0}{4\pi v^2}(1 - e^{-\alpha t})\gamma = D_0 + D_v \text{ (say)}$$

Here the first term gives the normal displacement and the second the anomalous or "viscous" displacement (D_v). The final displacement is given by

$$D_\infty = \frac{\epsilon E_0}{4\pi v^2}(1 + \gamma)$$

Now

$$\frac{dD_t}{dt} = \alpha e^{-\alpha t}\gamma\frac{\epsilon E_0}{4\pi v^2} = \alpha(D_\infty - D_t)$$

When the field strength varies with time we have

$$\frac{d}{dt}D_t = \frac{\epsilon}{4\pi v^2} \times \frac{dE}{dt} + \frac{dD_v}{dt}$$

where the second term is subject to

$$\begin{aligned} \frac{d}{dt}D_v &= \alpha(D_\infty - D_t)\dagger \\ &= \alpha\left[\frac{\epsilon}{4\pi v^2} \times E_t(1 + \gamma) - D_t\right] \\ &= \alpha\left[\gamma\frac{\epsilon}{4\pi v^2}E_t - D_v\right] \\ \therefore \frac{d}{dt}D_v + \alpha D_v &= \alpha\frac{\epsilon}{4\pi v^2}\gamma E_t \end{aligned}$$

This equation may also be obtained thus,

$$D_v = \epsilon\frac{E_t}{4\pi v^2}(1 - e^{-\alpha t})\gamma \quad . \quad . \quad . \quad \text{(A)}$$

Differentiating,

$$\frac{dD_v}{dt} = \epsilon\frac{E_t\gamma\alpha e^{-\alpha t}}{4\pi v^2}$$

Substituting from above (A) for $e^{-\alpha t}$

$$\frac{dD_v}{dt} = \frac{\alpha\epsilon E_t\gamma}{4\pi v^2} = \alpha D_v$$

$$\text{i.e.} \quad \frac{dD_v}{dt} + \alpha D_v = \frac{\alpha\epsilon E_t\gamma}{4\pi v^2}$$

|| F. W. GROVER: *Bulletin Bureau of Standards* 1911 vol. 7, p. 519.

* PELLAT: *Ann. Chimie et Phys.*, 1899, vol. 18, p. 150.
† D_∞ here being the final value corresponding to the instantaneous value E_t.

This is the general equation giving the viscous displacement in terms of the field strength. Take the special cases

1. Constant voltage E_0 applied at instant $t = 0$. Then

$$D = \frac{\epsilon}{4\pi v^2}E_0 + (1 - e^{-at})\gamma\frac{\epsilon E_0}{4\pi v^2}$$

$\therefore$ Displacement current density $= \dfrac{dD}{dt}$

$$= \frac{\epsilon E_0}{4\pi v^2}a\gamma e^{-at}$$

Thus for a condenser we have for the anomalous current

$$i_2(t) = E_0 C a\gamma e^{-at}$$

This is exactly the same as the formula given by Maxwell's theory. The only difference is that Maxwell's

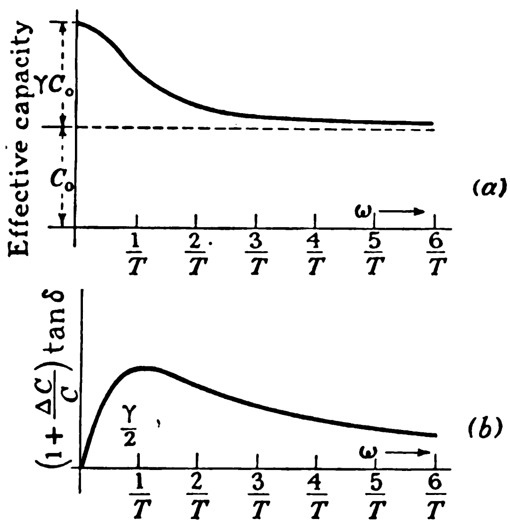

FIG. 23.—Variation of effective capacity and power loss per cycle with frequency (Pellat's theory).

theory expressed the constants in terms of the physical constants of the components of the dielectric. As in the previous case, this current obeys the Superposition Law.

2. With sine-wave voltage $E = E_0 \sin \omega t$, we find that the apparent increase of capacity due to absorption is given by

$$\frac{\Delta C}{C} = \frac{\gamma}{1 + \omega^2 T^2} \text{ putting } a = \frac{1}{T}$$

and the loss angle by

$$\frac{C + \Delta C}{C}\tan\delta = \frac{\gamma\omega T}{1 + \omega^2 T^2}$$

C is the value of the capacity when there is no absorption. It is called the geometric capacity of the condenser.

According to these formulæ the change of capacity with frequency should be as in Fig. 23 (*a*) and $\tan\delta$ should vary with frequency as indicated in Fig. 23 (*b*). Thus the power loss per cycle will be zero at zero frequency. As the frequency is increased the power loss per cycle first increases rapidly, reaching a maximum at the frequency defined by

$$\omega = \frac{1}{T}$$

It then decreases, at first rapidly and then more and more slowly, approaching the zero value again at very high frequencies. The effective capacity should increase as the frequency diminishes, reaching a maximum $C_0(1 + \gamma)$ at zero frequency.

(*c*) *Schweidler's theory.**

As was pointed out in the case of Maxwell's theory, these simple relations do not explain the observed facts. The characteristic time function $f(t)$ of the absorption current is not a simple exponential function, and the variations of capacity and $\tan\delta$ with frequency are not in general as indicated by these curves. In the case of Maxwell's theory it has been shown that the assumption of a number of components in the dielectrics leads to an expression for $f(t)$ consisting of the sum of a number of exponential terms. Schweidler similarly extended Pellat's theory by writing

$$D = \frac{\epsilon}{4\pi v^2}E_0 + \Sigma D_n'$$

where $\Sigma D_n'$ represents the sum of a number of "viscosity" terms each of which is subject to the relation

$$\frac{d}{dt}D_n' = a_n\left[\gamma_n\frac{\epsilon}{4\pi v^2}E - D_n'\right]$$

For the case of a constant voltage applied at $t = 0$ we then obtain

$$D = \frac{\epsilon}{4\pi v^2}E_0 + \frac{\epsilon}{4\pi v^2}E_0\Sigma\gamma_n(1 - e^{-a_n t})$$

and for the anomalous current

$$i_2(t) = E_0 C\Sigma a_n\gamma_n e^{-a_n t}$$

Thus again $f(t)$ is represented by a series of exponential terms.

Schweidler further supposed that there are an infinite number of such terms, the constants a_n varying continuously from 0 to ∞. The quantities γ_n will be function of a, say $\gamma(a)$, we then have

$$D_\infty = \frac{\epsilon}{4\pi v^2}E_0\left[1 + \int_0^\infty \gamma(a)da\right]$$

$$D_t = \frac{\epsilon}{4\pi v^2}E_0\left[1 + \int_0^\infty \gamma(a)\{1 - e^{-at}\}da\right]$$

$$i_2(t) = E_0 C\int_0^\infty a\cdot\gamma(a)\cdot e^{-at}da$$

and with impressed voltage $V = V_0 \sin \omega t$.

$$\frac{\Delta C}{C} = \int_0^\infty \frac{\gamma(a)a^2}{\omega^2 + a^2}da$$

$$\left\{\frac{C + \Delta C}{C}\right\}\tan\delta = \int_0^\infty \frac{\gamma(a)\omega a}{\omega^2 + a^2}da$$

* SCHWEIDLER: *Ann. der Physik*, 1907, vol. 24, p. 742.

The function $\gamma(\alpha)$ could be determined from any set of experimental results. On this theory in order to specify completely the behaviour of a dielectric we must know the dielectric constant ϵ, the specific resistance ρ and the function $\gamma(\alpha)$. Like Maxwell's theory it is obviously capable of explaining almost any set of experimental results by a suitable choice of $\gamma(\alpha)$, but as this function is the equivalent of a large number of constants it is not of great practical value.

Schweidler has given a molecular interpretation of his extension of Pellat's theory. A dielectric is regarded as possessing ions or electrons which when displaced from their position of equilibrium vibrate about that position with definite natural periods of vibration. In addition to molecules whose ions possess a definite natural period and definite damping, Schweidler supposes others to be present in which the damping is so great that their motion is aperiodic. Under the influence of a constant field suddenly applied, these ions approach a new equilibrium position in such a way that their deviation from it diminishes the exponential function $e^{-\alpha t}$. The ions with a definite natural period (very small) provide the normal displacement, while the aperiodic ions provide the " viscous " displacement.

$$T = \frac{1}{\alpha}$$

is the time-constant of these aperiodic ions and γ is the ratio of the displacement due to aperiodic ions to that due to ions whose motion is oscillatory. Pellat's theory implies only one kind of these aperiodic ions all with the same time constant. Schweidler's extension assumes a large number of different kinds of ions having different time constants, γ_n is proportional to the number per unit volume having the constant α_n. The next stage regards the damping as varying continuously, and the function $\gamma(\alpha)$ shows according to what law these ions are distributed as α varies continuously between 0 and ∞.

On Maxwell's theory, each additional exponential term means another constituent in the composition of the dielectric. If the constituents can be regarded as mixing in varying proportions in different parts of the dielectric, we shall obviously get a series of exponential terms in which α may vary continuously. Thus, whatever can be explained by Schweidler's theory can also be explained by Maxwell's.

(*d*) *Wagner's * distribution law for the time-constants.*

The general expression for the electric displacement on Pellat's theory is

$$D = \frac{\epsilon E}{4\pi v^2} + \int_{-\infty}^{t} \frac{\epsilon E}{4\pi v^2} \frac{d}{du}\left[\gamma e^{-\frac{t-u}{T}}\right] du$$

where E, the electric field, is a function of time,

u is the integration variable,

$T = 1/\alpha$ is the time-constant.

* K. W. WAGNER: *Ann. der Physik*, 1913, vol. 40 p. 817.

Schweidler's extension of the theory to the case in which there are a series of terms of different time-constants may be expressed

$$D = \frac{\epsilon E}{4\pi v^2} + \int_{-\infty}^{t} \frac{\epsilon E}{4\pi v^2} \frac{d}{du}[\psi(t-u)]du$$

where $$\psi(t) = \sum_n \gamma_n e^{-\frac{t}{T_n}}$$

In the case in which the number of terms is made infinite the variable

$$T_n\left(=\frac{1}{\alpha_n}\right)$$

varying continuously, we have

$$\psi(t) = \int_0^{\infty} \gamma(T) dT e^{-\frac{t}{T}}$$

Here $\gamma(T)\,dT$ is the amplitude sum of all the terms of

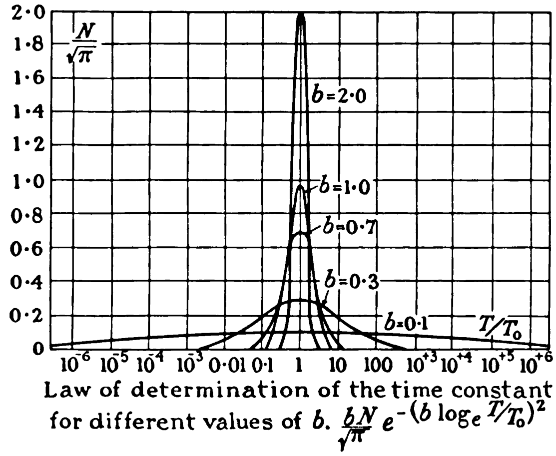

FIG. 24.—Law of distribution of the time-constants.

time-constant in the range T to $T + dT$. Thus we may regard $\psi(t)$ as the law of distribution of the time-constants. Wagner has proposed for this distribution law

$$\gamma(T)dT = \frac{\gamma b}{\sqrt{\pi}} e^{-b^2 z^2} dz, \text{ where } z = \log_e \frac{T}{T_0}$$

This law was first given by Wiechert * in explanation of the phenomena of elastic after-effect in solids. It means that there is a certain time-constant T_0 which is the most prominent, and the logs of the time-constants of the various terms are grouped about $\log T_0$, the greater the constant b the more dense is the grouping. This is illustrated by Fig. 24.

Wagner found

$$\psi(t) = \frac{\gamma b}{\sqrt{\pi}} \int_{-\infty}^{+\infty} e^{-b^2 z^2 - \frac{t}{T_0} e^{-z}} dz$$

$$\psi(o) = \gamma$$

* E. WIECHERT: *Wied. Ann.*, 1893, vol. 50, p. 335.

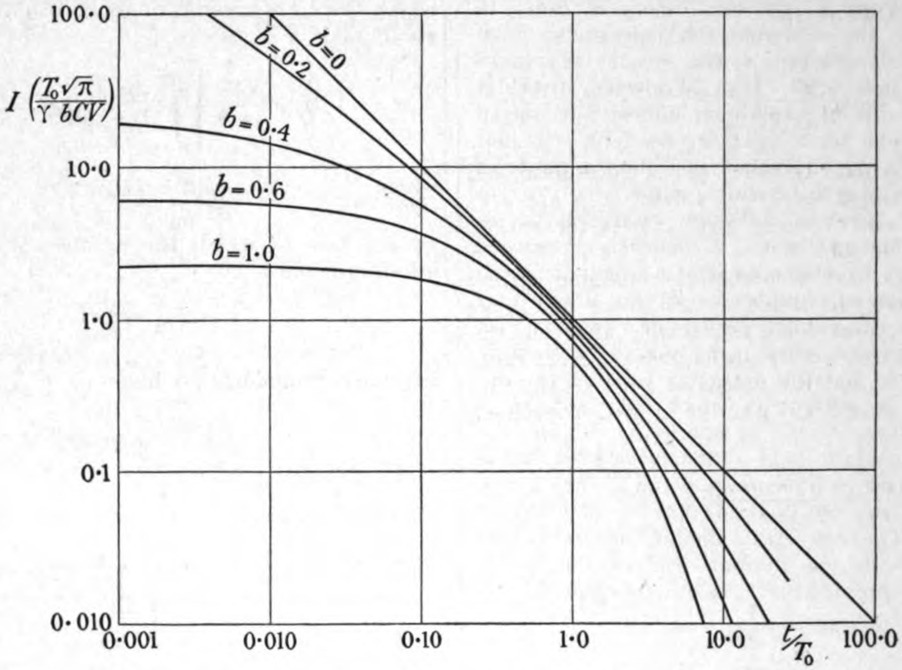

FIG. 25.—Anomalous current function in terms of time constant and b.

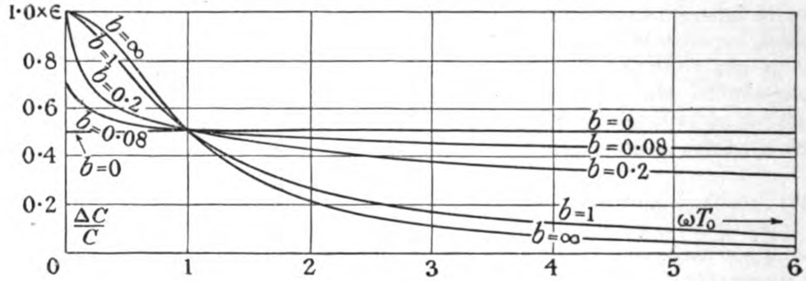

FIG. 26.—Capacity increment as a function of ωT_0 (Wagner).

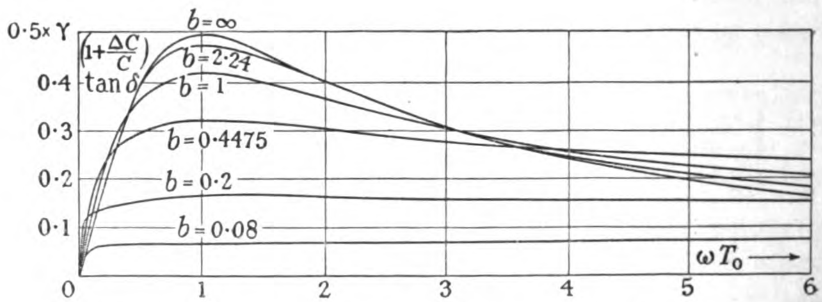

FIG. 27.—Power loss per cycle as a function of ωT_0 (Wagner).

In the case of constant voltage E_0 suddenly applied at the instant $t = 0$, we obtain

$$i_2(t) = E_0 C_0 \frac{\gamma b}{T_0\sqrt{\pi}} \int_{-\infty}^{+\infty} e^{-b^2z^2 - z - \frac{t}{T_0}e^{-z}} dz.$$

This cannot in general be evaluated in finite form, but it can be determined for given values of b and t/T_0 by Simpson's rule. Wagner gives curves for various values of b (see Fig. 25).

In practice we have seen that the charging current decreases at first very rapidly, then more and more slowly, in some cases being appreciable after months. Thus it is concluded we are dealing with a great range of time-constants, and the values of b are small. For these small values of b it is possible to make convenient approximations *:—

(1) $$-\frac{d\psi}{dt} = \frac{\gamma b}{T_0\sqrt{\pi}} \frac{T_0}{t} e^{-\left(b \log \frac{t}{T}\right)^2}$$

from which

$$\log_{10} i_2 = \text{constant} - \log_{10} \frac{t}{T_0} - \frac{b^2\left(\log_{10} \frac{t}{T}\right)^2}{\log_{10} e}$$

When log i_2 is plotted against log t this is represented by a parabola, which at the point $t = T_0$ has its tangent sloping at $-45°$ to the log t axis.

(2) Over a limited time range, we can express

$$\frac{d\psi}{dt}$$

and therefore i_2 by

$$i_2 = Bt^{-m}$$

where $$m = 1 + 2b^2 \log_e \frac{T}{T_0}$$

T being the value of t in the middle of the range of time considered. This is the experimental law given by most observers. It obviously holds over such a range that the parabola mentioned above may be considered as a straight line. In practice m is usually found to be less than unity. The above formula seems to indicate that it may also be >1. In no case does this seem to have been found. Schweidler pointed out that there are two difficulties associated with the formula

$$i_2(t) = Bt^{-m}, \text{ viz. } i_2(0) = \infty \quad \text{and} \quad \int_0^\infty i_2(t)dt = \infty$$

both of which are highly improbable. If, however, we take the full formula given by Wagner we get

$$i_2(0) = CE_0 \frac{\gamma}{T_0} e^{\frac{1}{4b^2}}$$

$$\int_0^\infty i_2(t)dt = CE_0\psi(0) = CE_0\gamma$$

both of which are finite.

* K. W. Wagner: *Ann. der Physik*, 1913, vol. 40, p. 833.

Consider now the case of sine-wave applied voltage. Wagner obtains

$$\frac{\Delta C}{C} = \frac{\gamma b}{\sqrt{\pi}} \int_0^\infty \frac{dt}{T} \cdot \frac{1}{1 + \omega^2 T^2} e^{-\left(b \log_e \frac{T}{T_0}\right)^2}$$

and putting $z = \log_e \dfrac{T}{T_0}$

$$z_0 = \log_e \omega T_0$$

$$z + z_0 = u$$

$$\frac{\Delta C}{C} = \frac{\gamma b}{\sqrt{\pi}} e^{-b^2 z_0^2} \int_0^\infty e^{-b^2u^2} \cdot \frac{\cos (2b^2 z_0 - 1)u}{\cos u} \cdot du$$

$$\left(1 + \frac{\Delta C}{C}\right) \tan \delta = \frac{\gamma b}{\sqrt{\pi}} e^{-b^2 z_0^2} \int_0^\infty e^{-b^2u^2} \cdot \frac{\cos 2b^2 z_0 u}{\cos u}$$

Tables and curves illustrating these formulæ are given in Wagner's paper.* The most important consequences of the formulæ are

1. At zero frequency $\Delta C/C = \gamma$ for all values of b.
2. At the frequency given by $\omega = 1/T_0$, $\Delta C/C = \frac{1}{2}\gamma$ for all values of b.
3. When b is vanishingly small, $\Delta C/C$ takes the constant value $\frac{1}{2}\gamma$, i.e. the capacity becomes independent of the frequency.
4. $1 + \Delta C/C \tan \delta$ (which gives the power loss per cycle when the voltage is unity) is zero when the frequency is zero: as the frequency increases it rises to a maximum at the point $\omega = 1/T_0$ and then decreases, finally approaching zero value at very high frequencies.
5. For very small values of b, $\tan \delta$ tends to become constant like ΔC.

These deductions are illustrated by Figs. 26 and 27.

(*e*) *Wagner's extension of Maxwell's theory.*

Wagner first published the above considerations by way of continuation of Schweidler's work on Pellat's theory. In a subsequent paper † he has shown how the formulæ can also be derived from Maxwell's theory. It is obvious that this must be so since the two theories lead to identical equations. Wagner describes a model dielectric structure, and develops the equations of the after-effect which it will show. The basic substance of the structure is considered to be a perfect dielectric of dielectric constant ϵ. Distributed throughout its mass are a number of small spheres of dielectric constant ϵ and conductivity σ. The dielectric is to be imagined as filling a plate condenser. In the absence of the spheres the field would be uniform. Each sphere causes a distortion of the field which is of most importance inside it, and in its immediate neighbourhood, but becomes negligible at great distances. It is now assumed that the spheres are so far apart that each disturbs

* K. W. Wagner: *Ann. der Physik*, 1913, vol. 40, p. 833.
† K. W. Wagner: *Arch. für Elektr.*, 1914, vol. 2, p. 371.

the field only just as much as if the others were absent. The behaviour of the dielectric under the uniform alternating field $E_0 e^{j\omega t}$ is then considered. The expression obtained for the electric displacement is

$$D = \frac{\epsilon E}{4\pi v^2}\left[1 + \frac{3p}{1 + \omega^2 T^2} - j\frac{3p\omega T}{1 + \omega^2 T^2}\right]$$

where $T = \dfrac{3\epsilon}{4\pi v^2 \sigma}$

$p =$ the ratio of the volume occupied by the small spheres to that of the basic substance.

This equation is seen to be of exactly the same form as given by Maxwell's theory of the simple laminated dielectric and Pellat's theory. It is pointed out that the constant, T, depends only on the material and not on the size of the spheres. Wagner then supposes that there are n different sorts of spheres all with different conductivity $\sigma_1, \sigma_2 \ldots \sigma_n$, and that their relative volume densities are $p_1 \ldots p_n$. If they are still sufficiently far apart not to affect each other we get

$$D = \frac{\epsilon E}{4\pi v^2}\left[1 + \sum_n \frac{3p_n}{1 + \omega^2 T_n^2} - j\sum_n \frac{3p_n \omega T_n}{1 + \omega^2 T_n^2}\right]$$

This equation of course leads to the various others which have been given.

A possible explanation of the distribution law of the time-constants is then given as follows: the time-constant T_n depends on the conductivity of the small particles and not on their size. Assume now that the different values of conductivity σ_n are not due to different substances, but to the same conducting substance mixed in different proportions with the basic substance. Thus p_n is a measure of the number of particles in which the mixture is of a certain definite proportion. Suppose, now, that the conducting substance tends to form small spheres of uniform composition corresponding to a time-constant T_0. A number of disturbing factors may tend to upset this uniformity both in the direction of increasing and of decreasing conductivity. Assume that any one of these disturbing causes, independently of all the others, tends to alter the composition of any sphere in the ratio $(1 + q)$. The change is as likely to be in one direction as in the other. Since the time-constant is inversely proportional to the quantity of conducting material, the disturbing factor changes the time-constant in the ratio $(1 + q)^{\pm 1}$. Denoting the effect of the different disturbing causes by successive indices, then the final value of the time-constant of any sphere may be written

$$T_r = T_0(1 + q_1)^{\pm 1}(1 + q_2)^{\pm 1}(1 + q_3)^{\pm 1} \ldots$$

$$\therefore \log T_r = \log T_0 \pm \log(1 + q_1) \pm \log(1 + q_2) \ldots$$

Put $\log T_r = z_r$, etc., and $\log(1 + q_1) = \delta_1$, etc.

$$\therefore z_r = z_0 \pm \delta_1 \pm \delta_2 \pm \delta_3 \ldots$$

If there are a great many terms δ and if they are as likely to be $+$ as $-$, then it follows from the laws of probability that the magnitudes z_r are grouped about the value z_0 according to the law: the number between z_r and $z_r + dz$ is proportional to

$$e^{-b^2(z_r - z_0)^2} dz.$$

The constant b measures the density of distribution of the magnitude z_r around z_0. Its value depends on the strength of the disturbing factors.

Thus the number of small spherical particles with time-constants between

$$T_r \text{ and } T_r\left(1 + d\log\frac{T_r}{T_0}\right)$$

is proportional to

$$e^{-\left(b\log\frac{T_r}{T_0}\right)^2} d\left(\log\frac{T_r}{T_0}\right).$$

Now the number of spheres with time-constant T_n is proportional to p_n, the volume ratio. Also $3p_n$ corresponds to γ_n. Hence

$$\sum_{T_r}^{T_r\left(1 + d\log\frac{T_r}{T_0}\right)} 3p_r = \gamma(T_r)dT_r = Be^{-\left(b\log\frac{T_r}{T_0}\right)^2} d\log\frac{T_r}{T_0}.$$

The proportionality factor B is determined by the fact that the sum of all the values $\gamma(T_r)$ is equal to γ in

$$D_\infty = \frac{\epsilon E}{4\pi v^2}(1 + \gamma) \text{ i.e.}$$

$$\int_0^\infty \gamma(T_r)dT_r = \gamma$$

which gives $B = \gamma b/\sqrt{\pi}$.

Thus the distribution law we arrive at is that previously given, viz. :—

$$\gamma(T)dT = \frac{\gamma b}{\sqrt{\pi}} e^{-b^2 z^2} dz, \text{where } z = \log\frac{T}{T_0}$$

Thus all the deductions made in Section III of this chapter apply to this dielectric model.

The theory is then extended by supposing that instead of a single conducting substance there are several, each of which tends to form spheres of a certain composition, but is influenced by disturbing factors. Thus there will be a number of characteristic time-constants

$$T_{0m} = \frac{3\epsilon}{4\pi v^2 \sigma_m}$$

There will also be a number of factors b_m governing the density of distribution of the time-constants around these values. Each of these characteristic time-constants may be expected to give rise to a maximum on the curve connecting power loss and frequency. In fact this curve may be regarded as a kind of spectrum, on which the peaks correspond to time-constants characteristic of the material.

The spherical form assumed for the conducting particles is not essential to the theory. In the formulæ it is only the disturbance of the electric field at great distances from the particles which is used, and this does not depend on the form of the particle.

(*f*) *Thornton's theory of "Inter-attraction."*

In his various papers,* Thornton has sketched a theory of the "absorption" phenomena without assuming the existence of any "abnormal" ions or inhomogeneities in the structure. The "viscous" displacement is regarded as an additional displacement of the electrons, whose initial displacement constitutes the normal charge, and this additional displacement is attributed to the forces of attraction between the displaced electrons of adjacent molecules. The theory is not mathematically developed, and it is somewhat difficult to see how it can be made to explain the observed facts. Such attraction must, of course, occur, and undoubtedly plays a part in determining the normal displacement, but there seems to be nothing to explain why this "secondary" displacement should be very slow, as it must be if it accounts for "absorption." Similarly it is not obvious why this secondary displacement should lead to power loss in alternating fields, since it is essentially of the same nature as the normal displacement, i.e. a movement of the same electrons, and the normal displacement is always regarded as being free from power loss. The theory can hardly be regarded as well established, as unlike the preceding theories it has not yet been shown to be capable of explaining the observed facts, such as the Superposition Principle.

One experiment of Thornton's, made to determine the nature of the slow polarization, is of particular interest. A flint-glass ellipsoid was suspended in a glass cell, the upper part having pole plates so that an electrostatic field could be maintained there, and the lower being filled with carbon disulphide. The ellipsoid was exposed to the action of the electrostatic field for several days, until it had reached the final stage of polarization. Its time of swing was then noted, this giving a measure of the polarization. It was then lowered into the liquid and exposed to the action of radiation from a tube of radium bromide. After five minutes' exposure the ellipsoid was raised and allowed to stand in the field for the same time that it had been removed from it; its period was found to be unchanged. The object of the liquid was to shield the ellipsoid from the effects of ions in the surrounding space. Thornton concludes:—

"If the charge on the ellipsoid had been in any sense free, whether residing on the surface or inside, it would have been rapidly removed and the period lengthened by exposure to the radium. . . . It would appear from this that the electrical movement in a dielectric when isolated in the field is entirely confined to the molecule and is therefore neither metallic nor electrolytic in type, but is the continued displacement of the atomic charges to a greater degree of separation than has been hitherto recognized." †

This point is, of course, of the greatest importance. If it is sound, it rules out the possibility of Maxwell's theory applying in the case considered, since on this theory charges do accumulate inside the dielectric at the surface of separation of the various components. It would not necessarily rule out Schweidler's theory. The general trend of Thornton's work is to make it seem very doubtful whether Maxwell's theory is capable of explaining all the anomalous phenomena shown by dielectrics.

(*g*) *Ionic theories.*

It has been mentioned in a previous section that certain phenomena shown by dielectrics, particularly the non-reversible anomalous current characteristic of liquids, suggest that in certain cases at least electricity is transported through the dielectric by means of ions as in electrolysis. Various attempts have been made to explain the different anomalies in this way. Schweidler, in Graetz's "Handbuch der Elektrizitat und des Magnetismus," gives a summary of the earlier work. In recent years comparatively little reference has been made to this theory in connection with the power losses in dielectrics, but in considering the phenomena of breakdown, Günther-Schulze * has made considerable use of it. He considers that breakdown in liquids occurs in the following manner. The heat generated by the motion of the ions against frictional forces creates bubbles of vapour, in which breakdown takes place as a consequence of ionization by collision, i.e. the breakdown of liquids is essentially a masked gas discharge. He considers that solid insulators should be divided into two classes

1. *True dielectrics.*—These are approximate non-conductors in the melted state and contain only an extremely small number of ions, if any. Examples are sulphur, paraffin wax.

2. *Pseudo dielectrics.*—These are bodies, which in the liquid state are comparatively good conductors, and are almost completely dissociated into ions. On cooling their conductivity decreases enormously, but it is considered that this is due not to a change in the number of ions so much as to a change in their mobilities, which are fairly large near the melting-point, but decrease with temperature very rapidly according to a logarithmic law. Such bodies are really conductors. They only behave as dielectrics at temperatures far removed from their melting-points on account of the great frictional resistance to the motion of the ions. Examples given of this class are glass, porcelain, marble, mica and all solid salts.

The mechanism of breakdown is thought to be different in different cases. In some cases the electric strength is determined by the field strength necessary to cause the ions already present to generate other ions by collision. In other cases the strength is determined by the field-strength necessary to increase the displacement of the atomic charges until the restoring force is overcome.

The same writer applies the idea of ionization by collision in solid dielectrics in order to explain results obtained by H. H. Poole † for the conductivity of glass at high field strengths. Poole gives the formula

$$\log \sigma = a + bD$$

or

$$\sigma = e^{a+bD}$$

† The exact effect of the radiations is so doubtful that one would require more evidence before accepting any deductions made on the assumption of a specific effect.

* GUNTHER-SCHULZE: *Zeits. für Instr.*, March 1923 p. 72.

† H. H. POOLE: *Phil. Mag.*, 1921, vol. 42, p. 488.

where σ = conductivity
D = field strength
e^a = is the electrolytic conductivity at low voltage.

Günther-Schulze * shows that this formula can be deduced by assuming that at high field strengths an ion may generate other ions by collision, the number so generated per unit length of its path being proportional to the field strength E. Further work is necessary before the theory can be regarded as established, but it is of considerable interest.

(*h*) *Debye's dipole theory.*

Debye's dipole theory is another theory of great interest in connection with the anomalies in the behaviour of dielectrics. It does not yet appear to have been considered in connection with power losses and "absorption phenomena" generally, but it seems probable that it would have considerable bearing on these matters. Debye † approaches the subject from the point of view of the physical chemist, and sets out to explain the large temperature coefficient of the dielectric constant of certain liquids such as the alcohols. He points out that the modern idea of the structure of a dielectric is that it consists of molecules in which there are electrons which cannot easily escape from the molecule, but which can be displaced a certain distance against a restoring force which binds the electron to the molecule and which is proportional to the displacement. The consequences of this theory as regards dispersion and the Zeeman effect are indisputable,‡ but it fails to explain the large temperature coefficient mentioned above. Debye therefore assumes that the molecules of a dielectric may contain, in addition to the elastically bound electrons (the displacement electrons), complete electric dipoles of constant moment. These are the electrical equivalent of molecular magnets, and the behaviour of such a body in an electric field is obviously analogous to that of a magnetic substance in a magnetic field; in fact, Langevin's theory of paramagnetism is applied. Thus when the dielectric is placed in an electric field, the displacement produced consists of two parts: (1) that due to the displacement electrons, and (2) that due to electric dipoles turning more or less into alignment with the field. The first part depends very little on temperature, but the second varies greatly with temperature changes. Debye develops a formula which accounts for many of the observed facts. It is

$$\frac{\epsilon - 1}{\epsilon - 2} = \frac{a}{T} + b$$

where ϵ is dielectric constant,
T is absolute temperature,
a and b are constants.

The inference is that certain liquids do contain such dipoles. The question then arises, Is this second term in the electric displacement elastic like the first, or does it give rise to power loss in alternating fields? Is there a true hysteresis effect? Nothing appears to have been published on this point.

Another interesting development of this theory is that the displacement no longer becomes exactly proportional to the applied field, i.e. at high intensities there is an apparent decrease in the dielectric constant.*

These questions are as yet of more interest from the point of view of molecular structure than of electrotechnics, and all the work appears to have been done by physical chemists who ignored power losses and absorption effects. Their results are, however, very suggestive.

* GÜNTHER-SCHULZE: *Phys. Zeitschrift*, 1923, vol. 24, p. 212.
† DEBYE: *Phys. Zeitschrift*, 1912, vol. 23, p. 97.
‡ This statement requires some qualification. Modern work has largely discredited the application of the classical electron theory to many dispersion phenomena and to the Zeeman effect.

V. The Experimental Laws of the Power Losses in Dielectrics.

In the present section the actual experimental results obtained for the power losses in various commercial dielectrics will be considered. The values will be examined in the light of the theories mentioned in the previous section, with a view to determining, if possible, the cause of the power loss. It is convenient to consider in turn the variation of power loss with

1. Frequency.
2. Temperature.
3. Change of state.
4. Voltage.
5. Moisture content.

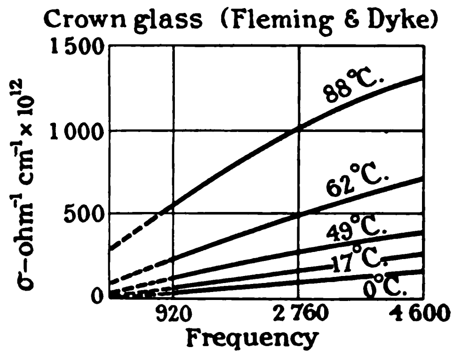

FIG. 28.—Variation of a.c. conductivity with frequency for crown glass.

(*a*) *The variation of power loss with frequency.*

(i) *Solid dielectrics.*—The earliest systematic investigation of this matter is that of Fleming and Dyke.† They investigated a number of materials including glass, ebonite, paper, gutta-percha, rubber, all in the form of thin sheets. Tin-foil electrodes were used, and each material was examined at three frequencies, all in the telephonic range, viz. 920, 2 760 and 4 600~. The power loss was expressed by giving the "alternating current conductivity" (σ) of the material. As was shown in Section I, the product of σ and the square of the effective voltage gives the power loss per cm³. Fig. 28 shows the results given by Fleming and Dyke for crown glass. These curves are typical of the results

* RATNOWSKY: *Verh. Deutsch. Phys. Gesell.*, 1913, vol. 15, p. 497.
† FLEMING and DYKE: *Journal I.E.E.*, 1912, vol. 49, p. 323.

found for practically all the dielectrics examined. The authors interpret the results as follows :—

The curves are regarded as approximating to straight lines, i.e. the effective conductivity of the material (or the power loss) is a linear function of the frequency, and we may write

$$\sigma = a + bf$$

The constant a is the conductivity at zero frequency, and is considered as representing the direct-current conductivity. b is considered to represent a constant hysteresis loss per cycle. As a possible explanation of this hysteresis loss, it is suggested that with increasing displacement, the electrons or ions are brought into an unstable position, from which they fall freely into a new position of equilibrium, and dissipate the energy expended in displacing them, in the form of electromagnetic waves, due to rapid free oscillations about the new position of equilibrium.

It is to be noted that each of these curves is derived from three points only, so that it is by no means certain that their course is that indicated by the authors. Further, the lines show distinct curvature, so that at the best this linear law can only be regarded as a rough approximation. It has been mentioned that the constant a should represent the direct-current conductivity.

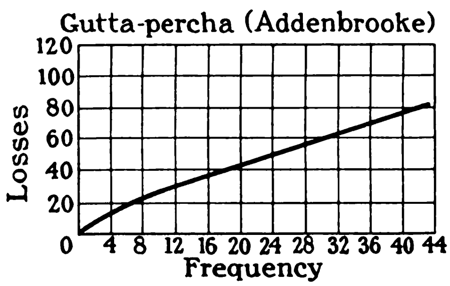

FIG. 29.—Variation of loss with frequency for gutta-percha.

Now a for crown glass at 17° C. is given as $8 \cdot 6 \times 10^{-12}$ ohm^{-1}, cm^{-1} which corresponds to a resistivity of about $1 \cdot 2 \times 10^{-1}$ ohm cm, whereas the generally accepted value is of the order 10^{-13}, i.e. a hundred times as great. Thus it is very doubtful whether the interpretation of the results given is correct. Further observations at different frequencies are necessary before any definite conclusions can be drawn, in particular observations at lower frequencies, and observations on the same specimen with direct current.

A certain number of observations at very low frequencies have been given by Addenbrooke,* together with the corresponding d.c. observations. Addenbrooke found that

1. The losses are approximately a linear function of the frequency, and this approximation becomes closer as the frequency becomes higher.
2. As the frequency gets lower the straight line bends over more towards the axis of frequency.
3. The direct-current value is considerably lower than the value at frequencies as low as $0 \cdot 2$ cycle per second.

* ADDENBROOKE : *Electrician*, 1913, vol. 70, p. 673.

Thus the general form of the curve given by Addenbrooke is as shown in Fig. 29. The observations were made chiefly on celluloid and gutta-percha in the form of thin sheets. Mercury electrodes were used, and frequencies of 1/5 to 50 cycles per second.

Proceeding now to higher frequencies an important series of observations has been made by Bairsto.* He used more or less the same materials as Fleming and Dyke, and made up condensers with tin-foil electrodes in the same way. Observations were made over a considerable range of radio frequencies. A typical set of Bairsto's results—those for crown glass—are shown in Fig. 30. The results are seen to be greatly different from those at lower frequencies. The law $\sigma = a + bf$ is no longer even roughly obeyed. As the frequency increases, the conductivity rises at first slowly, afterwards more rapidly. It then reaches a maximum, after which it decreases with an increase in frequency.

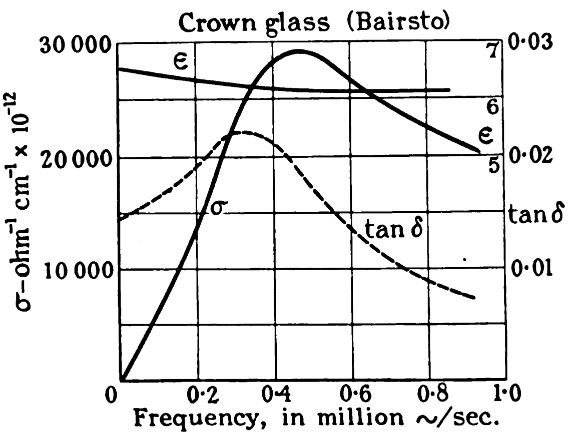

FIG. 30.—Variation of a.c. conductivity, permittivity and power factor of crown glass with frequency.

The values of the conductivity at the radio frequencies are very much greater than they are at telephonic frequency.

As regards the interpretation of the results, Bairsto follows the line of thought started by Fleming and Dyke. At telephonic frequencies he regards the losses as consisting of two parts, a the d.c. loss, $+ bf$ the true hysteresis loss. He points out that as the frequency increases, σ soon begins to increase more rapidly than the law $\sigma = a + bf$ indicates. He accordingly writes $\sigma = a + bf + cf^2$. The additional term cf^2 is considered to represent loss due to dielectric viscosity. This is considered to be negligible at telephone frequency, but to become the predominant component at radio frequencies. The power loss per cycle is very nearly represented by $\tan \delta$. Bairsto points out that at telephonic frequencies $\tan \delta$ is approximately constant, being determined mainly by the constant loss per cycle, b. As the frequency is increased into the radio range, $\tan \delta$ increases on account of the viscosity loss cf^2. Eventually $\tan \delta$, like σ, reaches a maximum value, and then begins to decrease. This decrease

* BAIRSTO : *Proc. Roy. Soc.* 1920, vol. 96, p. 363.

continues until the value becomes even less than that at telephonic frequencies. Bairsto accounts for this by supposing that the hysteresis loss per cycle b, though constant at telephonic and lower frequencies, decreases as the frequency is raised, and becomes very small at the higher radio frequencies, so that at these frequencies only the viscous loss is of any importance.

The results found by Bairsto for various other dielectrics were very similar in general character to those for crown glass. In all cases σ reached a maximum value and then decreased. In some cases there were subsidiary maxima, which were interpreted as due to some particular component of the dielectric.

The interpretation of their results by these various authors was made without any particular reference to the theories of absorption or after-effect. Now it is

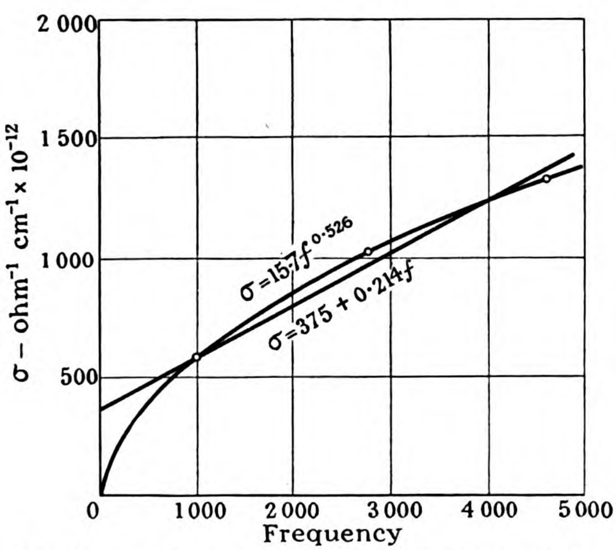

FIG. 31.—Variation of a.c. conductivity with frequency.

fairly certain that a considerable part of the loss is due to this cause, and an examination of the results in the light of the theories yield some very interesting facts.

In the first place, Bairsto's results show that when observations are made over a very great range of frequencies, no very simple law of power is to be expected.

The linear law of Fleming and Dyke can only hold over a range of frequency so small that the element of the conductivity curve contained by it can be considered a straight line. The equation $\sigma = a + bf$ probably merely represents the tangent of the conductivity curve at the point considered, and has no particular physical meaning.

We have seen that Schweidler's theory (Section II, p. 1164) indicates that the power loss due to absorption should be given by

$$W = E^2 A\omega^m$$

or $$\sigma \doteq A\omega^m \text{ where } o < m < 1$$

or $$\sigma = Gf^m \text{ where } f = \text{frequency} = \frac{\omega}{2\pi}$$

Some of Fleming and Dyke's results were examined in order to see how they fitted in with this equation. Taking the results for crown glass, they were found to obey the law probably within the experimental error, and certainly much better than they did the law $\sigma = a + bf$. The equations found were as follows :—

Crown Glass.

Temperature	Equation $\sigma = Gf^m$
0° C.	$\sigma = 0{\cdot}073f^{0\cdot91}$
17° C.	$\sigma = 0{\cdot}136f^{0\cdot889}$
49° C.	$\sigma = 0{\cdot}557f^{0\cdot78}$
62° C.	$\sigma = 2{\cdot}26f^{0\cdot68}$
88° C.	$\sigma = 15{\cdot}7f^{0\cdot526}$

A glance at Fig. 31 shows how much more accurately these equations fit the observations than do the linear equations given by the authors. It is important to notice that the curves of all these equations pass through the origin, i.e. the loss at zero frequency or the d.c. loss is negligibly small. This is what may be expected from the known value of the resistivity of glass. Further, these equations explain Addenbrooke's results. The form of the curves is exactly that indicated by Addenbrooke. Thus it seems probable that in the cases considered, the whole of the loss measured by Fleming and Dyke is due to "after-effect" and takes place in accordance with Schweidler's theory. The results of Schweidler's d.c. experiments gave values of m of $0{\cdot}74$ and $0{\cdot}70$ for two samples of glass at 20° C. He also found that m was not greatly affected by rise of temperature, although the constant β increased very strongly. Now G in the equation

$$\sigma = Gf^m = (2\pi)^m \frac{\pi\beta C}{2\Gamma(m)\cos\dfrac{(1-m)\pi}{2}} f^m$$

is approximately proportional to β, since m does not change very greatly. Thus the above equations derived from Fleming and Dyke's results are also quite consistent with the results found by Schweidler with direct current, since G is found to increase very strongly with temperature, while m decreases but comparatively little. Thus it seems probable from the results of these observers that over the range of power and telephonic frequencies the power loss obeys the law

$$W = Bf^m$$

where f is the frequency, m is an index rather less than 1, and B is a constant, depending on the voltage, size of sample and the nature and condition of the dielectric.

When the whole range of frequencies is considered, including radio frequencies, the results obtained by different observers appear to be by no means consistent. H. J. McLeod * made experiments on glass, pyrex, paraffin and mica over the range of frequencies

* *Phys. Rev.*, 1923, vol. 21, p. 53.

500 ∼ to 1 000 000 ∼ using a bridge method for frequencies up to 3 000 ∼, and the usual substitution method in a resonating circuit for the higher frequencies. He found that the law $W = Bf^m$ held over the whole range of frequencies for all the materials tested, the value of m varying from 0·85 to 0·90. This means that $\tan \delta$ continually decreased as the frequency increased, although the effective conductance always increased with increase of frequency.

A series of measurements at radio frequencies has been made by Schott.* His range of frequencies was 2×10^5 ∼ to 10^6 ∼ and he tested a number of kinds of glass, ebonite, press-spahn and compressed amber. Over this range of frequency he found that $\tan \delta$ did not change very greatly. In general it increased slightly as the frequency increased, though sometimes the change was in the opposite direction. Again, Dellinger † and Preston have given the results of a great many observations on the loss angle of insulating materials of the laminated pheno-methylene type, over the frequency range 3×10^5 ∼ to 6×10^4 ∼. They also found that variations in $\tan \delta$ were small over this range, and that it generally increased with increase of frequency, though sometimes it decreased. Although Schott made no measurements at low frequencies, he gives the results of a few observations at low frequencies made by other observers on materials similar to those he used (e.g. glass of the same grade and composition). In all these cases the value of $\tan \delta$ is higher at the lower frequencies.

Contrasting strongly with these results are those of Bairsto,‡ already mentioned. He found that $\tan \delta$ for paper, glass, gutta-percha, etc., varied greatly with frequency, reaching a maximum value somewhere in the region $0 \cdot 2 \times 10^6$ ∼ to $0 \cdot 7 \times 10^6$ ∼. This maximum value of $\tan \delta$ was usually much larger than the value at low frequencies. Lübben § has given a series of results for telephone-cable paper at telephonic frequencies, and these are found to agree fairly well with the formula $W = Bf^m$, whilst the same formula was given by Granier ‖ for observations made on poor condensers at low frequency.

Summarizing, the variation of power loss with frequency over the range of power and telephonic frequencies is usually given by the formula $W = Bf^m$, where f = frequency, and m is less than 1. If the frequency range is small, the law $W = B'f$ may be used as an approximation, in order to simplify calculation. Where these laws apply, the power loss is probably entirely due to dielectric "absorption" or "after-effect." At radio frequencies the value of $\tan \delta$ due to "after-effect" is smaller than at telephonic frequencies if the above law still holds, but the experimental results available at radio frequencies do not appear to be sufficient to decide whether or not the laws are the same as at the lower frequencies, though probably they are not. It is interesting to note, however, that all the results are possibly capable of explanation in terms of Wagner's theory, discussed in Section IV, though this explanation is far from being established.

If the dielectric losses in any particular case are due to absorption, then changes in the losses with frequency should be accompanied by corresponding changes in capacity. Bairsto * examined the results of Fleming and Dyke † and pointed out that the change in capacity ΔC, over a given range of frequency, was a definite function of the a.c. conductivity. He states that

$$\frac{\Delta C}{C}$$

is proportional to b, where b multiplied by the frequency f represents the main part of the a.c. conductivity σ, i.e.

$$\frac{\Delta C}{Cb}$$

is a constant, which is independent of the temperature of the dielectric and its state of moisture content. It is easy to show that this relation is simply an approximate form of an equation which can be derived from Schweidler's work. We have seen that this leads to the formulæ ‡

$$\frac{\Delta C}{C} = \beta \omega^{m-1} \Gamma(1-m) \cos \frac{(1-m)\pi}{2}$$

and

$$\sigma = \beta C \omega^m \frac{\pi}{\Gamma(m) \cos \frac{(1-m)\pi}{2}}$$

Schweidler found that the index m varied very little with temperature, but that the changes in β were enormous. Taking the ratio of

$$\frac{\Delta C}{C} \quad \text{and} \quad b = \frac{\sigma}{f} = \frac{2\pi\sigma}{\omega}$$

we find

$$\frac{\Delta C}{Cb} = \frac{1}{2\pi C} \times \frac{\Gamma(1-m)\Gamma(m) \cos^2 (1-m)\frac{\pi}{2}}{\pi}$$

which, since $m < 1$, reduces to

$$\frac{1}{C} \cdot \frac{\tan \frac{1}{2} m\pi}{4\pi^2}$$

For a given substance, this ratio will vary but slightly with changing conditions, although the changes in

$$\frac{\Delta C}{C}$$

and σ may be very large, since each contains the term β. Thus the relation pointed out by Bairsto merely confirms the idea that the losses measured by Fleming and Dyke were all due to absorption. When we examine

* Schott: *Jahrbuch der Drahtlosen Telegraphie*, 1921 vol. 18, p. 82.
† Dellinger and Preston: Technological Paper, *Bureau of Standards* vol. 16, No. 216, p. 502.
‡ Bairsto: *Proc. Roy. Soc.*, 1920, vol. 96, p. 363.
§ Lübben: *Archiv. für Elektrotechnik*, 1921, vol. 10, p. 283.
‖ Granier: *Rev. Gén. de l'Électricité*, 1922, vol. 12, p. 459.

* Bairsto: *Electrician*, 1915, Oct. 15.
† Fleming and Dyke: *Journal I.E.E.*, 1912, vol. 49, p. 3.
‡ Section II, p. 1164.

Bairsto's results, however, we find no maxima of capacity corresponding to the maxima of $\tan\delta$ or σ. Thus it seems probable that at radio frequencies some factor other than absorption is involved.

(ii) *Liquid dielectrics.*—The losses in liquid dielectrics such as oils are found not to vary with frequency like those in solids. Differences between the anomalous dielectric properties of liquids and solids have been discussed in Section II, page 1165. As regards power loss, the most important recent work appears to be that of Pungs.* He measured the losses in transformer oil, castor oil, and paraffin oil, at frequencies of 20 ∼ to 65 ∼ using an electrometer method. For transformer oil and castor oil he found that the power factor was of the order of ½ per cent at 50 ∼, and that the actual power loss was practically independent of frequency. He considered that this power loss was due to conduction, which was electrolytic in type. There was also a small component of power loss which varied with the frequency, but in one case this was definitely traced to impurities. In the case of paraffin oil the power losses were about 10 times smaller than those in the other oils, the power factor being of the order 0·0003. In this case the loss did vary with frequency. It was regarded as consisting of two components, one proportional to the frequency, and one independent of frequency, both being of the same order of magnitude. A. B. Bryan † has given the results of a few measurements on dielectric losses in nitrobenzene and xylene at radio frequencies. In xylene the losses were too small to measure, and in nitrobenzene the loss angle decreased strongly with increasing frequency, suggesting that the loss was mainly due to leakage and not greatly dependent on frequency. McDowell ‡ obtained similar results for castor oil, olive oil, turpentine, paraffin, benzene, toluene and xylene. On the other hand, Fleming and Dyke,§ working with a variable condenser with vaseline oil dielectric, observed a power loss at radio frequencies which increased considerably with increasing frequency. In this case the power loss could not have been mainly due to leakage.

(*b*) *Effect of temperature.*

In the case of certain commercial dielectrics, e.g. varnished cloth, all observers are agreed that the power loss increases very rapidly as the temperature rises. Measurements showing this fact have been made by Rayner,‖ Shanklin,¶ Skinner ** and Bureau †† on varnished cloth. Lübben‡‡ has obtained similar results with telephone-cable paper. This rapid increase of power loss with temperature appears to occur in all porous dielectrics, i.e. dielectrics which contain moisture, and may well be associated with conductivity which is ionic in character. Measurements made by Fleming and Dyke §§ on paper, both paraffined and untreated, show that when the paper is thoroughly dried, not only is the power loss greatly reduced, but it also increases comparatively little with rise of temperature. Fleming and Dyke also found a rapid increase in power loss with rise of temperature in the case of glass, celluloid, ebonite. For mica, pure para rubber, and dry slate, the increase was less marked, whilst for vulcanized india-rubber and gutta-percha the power-loss/temperature curve showed maxima and minima. In the case of gutta-percha the maximum power factor occurred at about − 10° C., the value falling rapidly as the temperature rose from 0° to 50°, while for V.I.R. the maximum was at − 30° C., the value then falling rapidly to a minimum at about 20° C., rising again beyond that point. An important series of observations on commercial insulating materials has been made by K. W. Wagner.* His results are in general agreement with those of Fleming and Dyke. For various grades

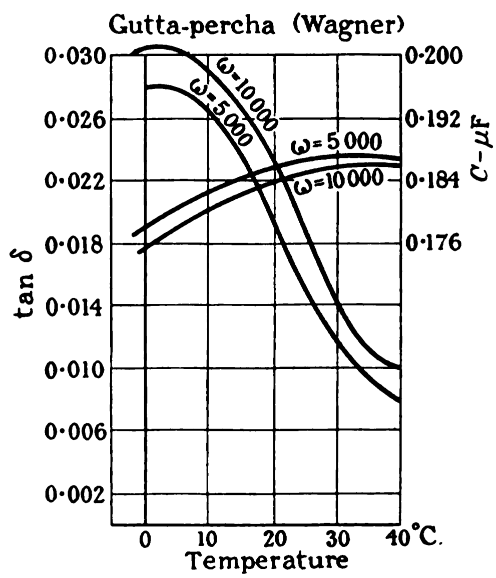

FIG. 32.—Variation of power factor with temperature.

of gutta-percha and balata, over the range of temperature 0° C. to 40° C. the power loss decreased strongly with increasing temperature (see Fig. 32). For pure para rubber there was a slow increase of power loss with rise of temperature over the range 5° to 30°, whilst for vulcanized rubber and ebonite the increase was more rapid, especially at the higher temperatures, 30° C. to 50° C., say. Wagner also gives the results of d.c. observations on the same material at various temperatures, and discusses the significance of the results in terms of his theory (Section IV, page 1179). He gives the curves representing $\tan\delta$ as a function of temperature for a number of different frequencies. For a given substance the curves are of the same general shape, and the curve for any frequency f_2 can usually be obtained from that for the frequency f, by a displacement of this curve on the chart. Wagner points out that the results mean that the probable time constant T_0 decreases strongly with temperature,

while the distribution constant b changes but little. When b does change, it appears to increase with rising temperature. For cases in which b remains constant Wagner enunciates the "Law of Corresponding States" for dielectric absorption or after-effect. "The same time law (or frequency law) holds for the 'after-effect' at all temperatures, provided that a unit of time proportional to the time constant T_0 is chosen." This will, of course, apply to both changes of capacity with frequency and to power factor, since both are aspects of "after-effect." It will not hold for power loss due to any other cause than after-effect. The various curves given by Wagner supply many illustrations of this law (Fig. 32).

Schott * has given numerous curves showing the variation of power loss with temperature at radio frequencies for several different kinds of glass. In all cases there is a rapid increase of loss with rise of temperature.

In the case of liquid dielectrics, a very rapid increase of power loss with rise of temperature appears to be general, though the dielectric constant or permittivity generally decreases as the temperature rises. Valuable data are given by Pungs.†

(*c*) *Change of state.*

Closely associated with the effect of temperature changes on dielectric losses is that of a change of state. Waxes and materials of low melting-point are widely used for insulation purposes, and the change in the character of the dielectric losses which occurs on melting is of great interest. Data on the subject are given by Pungs† (at power frequencies), Wagner ‡ (at telephonic frequencies) and Steinhaus § (at radio frequencies). Pungs worked with a mixture of resin and beeswax. He found that in the solid state the power loss was approximately proportional to the frequency (and presumably due to after-effect). It increased with rise of temperature, until the neighbourhood of the melting-point was reached. There was then a sudden drop in the power loss, but with a further rise of temperature, the losses in the liquid increased very rapidly and became independent of the frequency (and thus probably due to conduction, see Fig. 33). Wagner gives data for paraffin, ceresin, and a mixture of the two. He observed the same sudden drop in the losses near the melting-point of the material, though the loss did not appear to be independent of frequency above the melting-point. He also found a drop in the permittivity near the melting-point. Steinhaus also noticed the drop in the losses near the melting-point in the case of the poorer waxes, but for paraffin and ozokerite he did not observe this effect. His value for the power factor of paraffin wax is considerably higher than that given by Wagner, though it is impossible to say whether this is due to the difference of frequency, or differences in the quality of the material. Wagner considers the rapid fall in the power loss in gutta-percha as the temperature rises from about 20° to 40° C. to be connected with the change of state of the material, i.e. softening. Hochstädter * explains the variation of power loss with temperature for high-tension cables in the same way. Clark and Shanklin † have made measurements on a mineral hydro-carbon cable compound, as used for high-voltage cables. Their working frequency was 60 ~, and voltage gradient 16 kV per cm. They found a continuous increase of power factor with temperature over the range 50°–100° C. The permittivity decreased with rise of temperature, but there was a hump on the curve between 50° and 75° C. This was stated to correspond to the gradual change of state of the material. There was, however, no corresponding minimum in the power loss curve, so that it would seem that Hochstädter's explanation

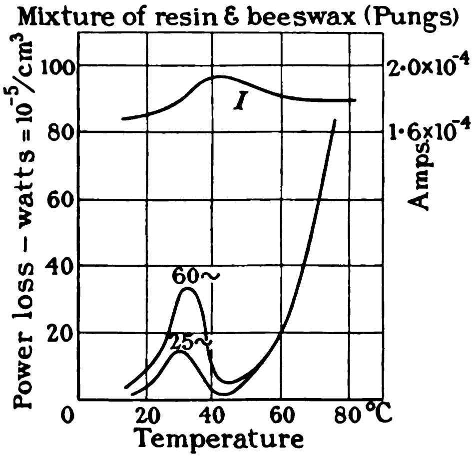

FIG. 33.—Variation of power loss with temperature.

does not apply to every case, or rather that the power loss-temperature curve does not always pass through a minimum value near the softening-point.

(*d*) *Variation of power loss with voltage.*

In Section I it was shown that the expression for power loss is

$$W = V^2 C\omega \tan\delta$$

where C is the effective capacity, and $\tan\delta$ is the tangent of the loss angle, which is in most cases practically the same as the power factor. From this it is obvious that if the capacity and $\tan\delta$ are independent of the voltage, then the power loss is proportional to the square of the voltage. For convenience this is usually referred to as the Square Law. If, on the other hand, the capacity and $\tan\delta$ increase as the voltage increases, then the power loss increases more rapidly than the square of the voltage.

The results obtained by the various investigators who have made observations on this point are very varied, and it is very difficult to form any general conclusions. Several observers have stated that when other conditions are maintained constant (in particular

the temperature), the power loss is strictly proportional to the square of the voltage, at least up to the voltages at which brush discharges begin to occur. Results supporting this are given by Monasch * for glass, ebonite, and certain cables, all tested at 80 ∼. If the high voltage is applied to the specimen for a long time, then the energy dissipated will cause a rise in temperature which may lead to increased losses. Monasch found that an apparent increase of power factor with voltage was often due to this cause, and that it was essential to eliminate any such effect. Peek † found that the square law held for varnished cloth for voltage gradients up to 12 kV per mm. His experiments were made at 60 ∼, working on an impregnated paper high-tension cable. Clark and Shanklin ‡ and Rosen § find that the power factor is independent of the voltage up to a certain critical point, beyond which the power factor increases with increase of voltage. Clark and Shanklin explain this by assuming that there are cracks or bubbles in the filling material in the cable, and that these contain gas or vapour which becomes ionized when the voltage reaches the critical point, and that it is the losses due to this ionization which cause the increase in power factor. Working with celluloid at low frequencies, Addenbrooke ‖ found that the power loss was proportional to the square of the voltage as long as there was no appreciable rise of temperature. At radio frequencies the square law was found to hold by Alexanderson ¶ and Bairsto.** Alexanderson worked at high-voltage gradients (of the order 1 000 volts per mm), and he found that the power factor increased but slightly with voltage until the breakdown point was approached. There was then a rapid rise of power factor, due no doubt to the rise of temperature. In these experiments the sample was immersed in oil to keep down corona losses.

Bairsto's experiment was made with a glass condenser. Using a balance method (see Section III) he found that the balance point was independent of voltage right up to the point at which brush discharges began to take place.

Thus the work of these investigators leads to the conclusion that for solid insulators at low voltages (in which case the losses are practically entirely due to "after-effect" or absorption), the power dissipated is proportional to the square of the applied voltage. If, however, the voltage is raised sufficiently high for ionization and brush discharges to occur, then the power loss increases more rapidly than the square of the voltage.

A case in which it is generally agreed that the losses do not obey the square law is that of porous materials which contain considerable quantities of water, such as untreated paper, cotton, etc. Important pioneer work on these materials was done by S. Evershed.†† He found that the normal conduction current through these materials varies with time, and that the conductance increases as the applied voltage increases, the law being roughly $\sigma = \sigma_0 V^{0 \cdot 3}$, where σ_0 is a constant, and V the applied voltage. Evershed explained this as follows :—

The capillaries in the structure of the material contain moisture, in the form of small drops. Under the influence of the applied field the moisture moves along the capillaries in such a manner that its conductance increases. When the field is removed the moisture returns to its old equilibrium position. Evershed's experiments were all done with constant applied voltage, but when the voltage is alternating there will be a certain part of the loss due to normal conductance, and this will obviously increase more rapidly than the square of the voltage. Wagner * found that this was the case for the cotton insulation on wires especially at low frequencies. Minton,† working with oil-treated pressboard, found that the behaviour of the material with varying voltage depended largely on the amount of moisture it contained. With high moisture content the power factor increased as the voltage increased, which is what is to be expected, but with low moisture content the power factor decreased with increase of voltage. It is interesting to note that for varnished cloth he found the power factor practically independent of voltage up to 280 volts per mil.

It seems probable that the power loss due to conduction increases more rapidly than the square of the voltage in a great many cases other than those in which it is due to moisture contained in the capillaries of fibrous materials. For example, Pungs ‡ found that it was the case for transformer oil and castor oil, though for paraffin oil the Square Law was approximately obeyed. Shanklin § obtained a similar result for transil oil at 60 ∼. In this connection, it is interesting to consider the results obtained for direct current. The experiments of Evershed have already been mentioned. Tedeschi‖ found a similar increase of conductivity with applied voltage for press-spahn and pilit, while Curtis ¶ obtained the same result for a few insulators. H. H. Poole ** working at very high voltages found a considerable increase of conductivity with applied voltage for mica, glass, shellac, and celluloid, and it seems quite possible that this may be the general rule for insulating materials at such voltages. In this case the power loss due to conduction would increase more rapidly than the square of the voltage. As an explanation of these experiments Günther-Schulze †† has advanced the theory that these dielectrics may be regarded as electrolytes in which the ionic mobility is small. At very high voltages the ions move at a sufficient speed to generate other ions by collision with the molecules of the material, and thus the number of ions and therefore the conductivity increases. It may be that this is the explanation of the increase in power factor of high-tension cables at very high voltages

noted by Clark and Shanklin,* Rosen and others, and that it is not necessary to assume the existence of bubbles of gas, though the fact that it did not occur at high temperatures goes to support Clark and Shanklin's explanation. They claim that the filling material expands and fills up the cracks or bubbles at high temperature, and thus the ionization loss no longer occurs.

A law other than the Square Law has been given by a number of other observers for various cases. Fleming and Dyke † made observations on a number of condensers at radio frequencies. They found that the power loss was given by a law of the form $W = kV^2 + \gamma$, where γ varied from $0 \cdot 15$ to $2 \cdot 24$. In the discussion on the paper, the authors state that the losses measured include ionization losses, and that the departures from the square law may be due to this. Mould ‡ has made observations at both telephonic and radio frequencies on a number of materials. He gives the same

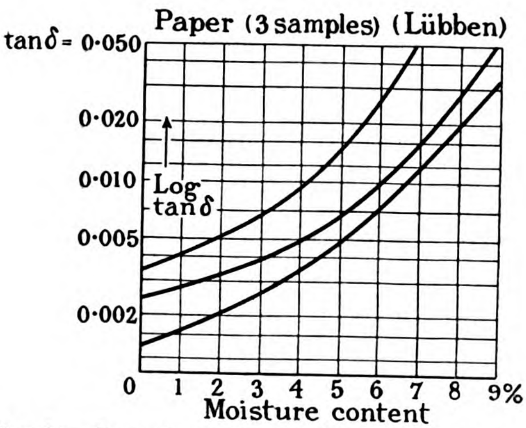

Fig. 34.—Dependence of power factor on moisture.

law as Fleming and Dyke in both cases, though the values of γ only range from $0 \cdot 03$ to $0 \cdot 33$. No explanation of the law is offered, but the author draws the conclusion that the losses must be mainly due to other causes than conductance. In view of the work of Poole and others mentioned above, it appears that the data are not sufficient to justify the conclusion. Unless ionization losses occurred in these experiments also, it does not seem possible to reconcile these results with Bairsto's.

Deviations from the Square Law at power frequencies are described by Skinner § and by Butman,|| for fuller board, micarta sheet, etc. Skinner notes that the index of V in the expression for power loss is often greater than 2, and tends to increase as breakdown approaches. This is possibly a similar phenomenon to that recorded by Poole. On the other hand, Butman found the power factor of fuller board to decrease as the voltage increased, but for micarta the change was in the opposite direction.

(*e*) *Effect of moisture.*

It is a very well-known fact that the absorption of moisture by any insulating material causes a large increase in its direct-current conductivity and in the power loss dissipated under alternating voltage. The capacity of the material also increases. Results of measurements of these effects are given by Lübben * for telephone-cable paper (see Fig. **34**). The variation of capacity, tan δ, and d.c. conductivity, with percentage moisture content is investigated in great detail. The increase of tan δ, and therefore power loss, becomes more rapid as the moisture content becomes greater than about **4** per cent. Minton † found a similar result with pressboard. Wagner ‡ has also given data for the increase of tan δ with moisture absorption for paper, and for wire insulation (silk and cotton, etc.). He shows that the use of cotton covering on a wire causes a large increase in power loss on account of its power of absorbing moisture. Fleming and Dyke § also give information as to the effect of moisture on paper, etc.

Another well-established fact is that surface leakage across an insulating material is largely dependent on moisture condensed on the surface, and is, therefore, largely influenced by atmospheric humidity. Valuable data on this point are given by Curtis.|| Addenbrooke ¶ has found that in the case of alternating voltage the surface leakage is much greater than for constant voltage, the explanation probably being that the moisture stands on the surface in small drops, and not in a continuous film, and thus Maxwell's theory of a laminated dielectric applies (see Section IV). This surface leakage will correspond to a certain power loss, which will take place even in the case of insulating materials which do not absorb water.

It is obvious that all substances which absorb water must be of heterogeneous structure, and thus they must exhibit the phenomena of absorption and power loss in accordance with Maxwell's theory. Using the known values for the dielectric constant and conductivity of water, Meyer ** has attempted to show how the observed data of power loss and absorption are consistent with Maxwell's theory, assuming water to be the most important constituent. Owing to the complexity of the problem, only a rough approximation can be expected. Certain results given by Meyer appear to correspond with the theory in the simple form taken, but in general the evidence is by no means convincing.

Compared with the average dielectric, water possesses a very high dielectric constant, and a very high conductivity. If, therefore, a particle of water contained within an insulating material is placed in an electric field, it will be acted on by mechanical forces tending to elongate it in the direction of the field. Actions of this nature were first investigated by Evershed †† in a

paper previously referred to. He showed that as a result of this, the d.c. resistance of fibrous insulators is a function of the applied voltage. Du Bois * has also called attention to this phenomenon. He points out that a drop of water, such as has been considered, would elongate into a filament which might in time bridge the electrodes. These movements of the water would cause alterations in capacity and conductivity, and this is put forward by Du Bois as an explanation of absorption and residual charge. Considering the power loss in an alternating field, he points out that in the case of filaments which bridge the electrodes the power loss will not depend on the frequency, but when they do not bridge the electrodes the loss will vary with frequency. This, of course, follows from Maxwell's theory. Further, he states that a filament carrying current may be at a higher temperature than the surrounding dielectric, and that if the temperature of the filament increases with increase of applied voltage, then deviations from the Square Law may be expected. Evaporation may lead to a breaking up of the filaments, and thus there may be a change in the power loss-voltage curve at some critical point. The conception introduces many variable factors, and it is difficult to see to what extent they will affect the behaviour of the material, but it seems probable that materials containing moisture will obey different laws from those which do not. Hayden and Steinmetz * have considered the bearing of such actions on the breakdown of insulation under high voltage.

DISCUSSION ON

"THE ECONOMICS OF LAMP CHOICE." *

Mr. W. J. Jones (*communicated*): The author deals with a matter which has been familiar to lamp manufacturers and those interested in B.E.S.A. Specifications for many years, and it is a pity that while the theoretical considerations are generally sound they have not a greater practical bearing. The illustrations which have been cited are purely theoretical, and may in some cases, as a consequence, be misleading. The author has pointed out two considerations in the algebraic solution, namely that of a lamp which is either over-run or under-run and, secondly, the point of view of a lamp designed to give a definite candle-power. This last does not meet with modern practice in which the wattage of the lamp is made the basic feature, so that both graphics and calculations require some modification. The author mentions the question of making the price of lamps proportional to the size in watts. Surely this is only to meet a purely theoretical consideration and does not in any way take into account the economics prevailing in lamp works where the cost of manufacture depends not only on the size of lamp but also on the number of that particular size manufactured. Regarding the suggestion which is made of grading lamps for dear, medium-price and cheap energy, I would suggest that this is entirely outside the province of the lamp manufacturer, but, assuming that it were advisable for the lamp manufacturers to take some action, it would involve increasing the number of types of lamps already on the market from some 2 000 to 6 000; as this would reduce the quantity manufactured of any particular type of lamp, the cost of the lamp would inevitably be increased.

Mr. D. J. Bolton (*in reply*): There is no suggestion in my paper that the lamp price could be altered and made proportional to the size. All that is suggested is that the normal rating could be made dependent upon the size (and possibly upon the price), i.e. a 60-watt lamp should be rated to have a shorter life and a higher efficiency than it now has, while a 20-watt size should have a longer life and lower efficiency than at present.

The other point raised, as to the number of types required in the event of lamp grading to suit energy price, is, of course, a perfectly valid one. It is exceedingly difficult to say what would be the all-round effects of such a step, but the saving to the consumer would be so considerable that if any large manufacturer or group found it possible to overcome the initial difficulties, such an enterprise might prove extremely popular and successful.

The paper was particularly intended to represent the point of view of the lamp user. It is true that the modern rating is in watts, but to the user that is merely a means to an end—he desires a definite quantity of illumination and when he asks for, say, a 40-watt lamp it is because he associates this with a particular candle-power.

* Paper by Mr. D. J. Bolton (see page 844).

DISCUSSION ON

"THE DESIGN OF ELECTRICAL PLANT, CONTROL GEAR AND CONNECTIONS FOR PROTECTION AGAINST SHOCK, FIRE AND FAULTS." *

SCOTTISH CENTRE, AT GLASGOW, 13 APRIL, 1926.

Mr. J. Henderson : I am in entire agreement with the principles laid down by the author, and consider that the practice of enclosing all conductors in an earthed metal sheath should be pushed to its utmost limit. The application of this principle to the power station busbars and switchgear is a much more satisfactory answer to the question of continuity of supply than the American idea of phase isolation. The duplication of busbars in the power station and at the important feeding points is to be commended, but it should not be necessary to have a special busbar as a stand-by. The sectionalizing which is now standard practice on all large systems should prevent any difference of opinion on this point, as one section of busbars may be employed as the stand-by or hospital bar for the two others, or conversely two spare bars are available for each section in emergency. This arrangement is possible with either the star or ring method of connection, but I have a strong preference for the star method with each section connected to a reactance bar through reactances which will pass the economical load of the smallest machine where the ratio of this to the largest is not less than about 0·5. On the question of the value of parallel reactances, the author might with advantage have stated whether this value should be greater than, equal to, or less than that of the inherent reactance in the generators, based on the section load. The reactances should only be installed as a means of sectionalizing the system and not as a link between sections through which a large amount of power is to be transmitted. It should be laid down as a principle that the exchange of power should be kept down to as low a limit as is compatible with efficient running of the generators. Unless in special cases, the use of series reactance external to the alternators cannot be regarded as advantageous, and may lead in the end to a great deal of difficulty and confusion. Circuit breakers capable of opening under the worst possible conditions without the use of series reactance, should be installed at the power station and main feeding points, and if this rule is adhered to the duplication of main circuit breakers can only be considered as an unnecessary refinement. I am greatly in favour of deciding the size of circuit breaker in accordance with the maximum kVA to be broken rather than risk a short-circuit which may do more than destroy the switch affected. The maximum kVA should be the criterion, and not any smaller value which is dependent on the time taken by the circuit breaker to open. I have no quarrel with making a circuit dead before changing over, but design of the change-over gear should be subordinate to speed of operation. It is obvious that screwed plugs are not conducive to quick action, and a much better arrangement is that of an auxiliary change-over switch in the cowl of the circuit breaker, mechanically interlocked to prevent operation unless the main circuit breaker is racked out. Operating engineers will all be in favour of any design which simplifies and reduces the number of operations to be carried out in effecting a change-over. The auxiliary supply should be taken off the reactance tie bar and may be suitably duplicated by a house turbine feeding continuously on to the low-tension auxiliary busbars. This would make unnecessary the elaborate change-over scheme suggested by the author, and I am not in agreement with any attempt to change over the auxiliary supply to the unit system every time a generator starts up. The house turbine has additional advantages in connection with heat balance control, but these are beyond the scope of the paper. The use of the modern reverse relay in connection with auxiliary supply should effectively prevent the complete shut-down, due to failure, of anything except the auxiliary busbars on the low-tension side, and special attention should be paid to the design of these to prevent trouble from this cause. In connection with protective gear, "stability ratio" as defined by the author is an excellent term, but I do not think it goes far enough. It is really only a relative term and is dependent on too many conditions to be of any general use. There is no reason why an absolute value should not be introduced giving an absolute comparison between different types of protective gear. The operating current in amperes stated with the "stability ratio" probably meets the case sufficiently well for all practical purposes, but the statement of the one without the other is of no value and contains no useful information. The majority of operating engineers will not agree with the tendency to cut out the earthing resistance. This tendency nowadays, and the suggestion introduced by the author to decrease the value considerably, probably arises from the inability to obtain low enough fault settings combined with high stability ratio. There are protective systems in use as applied to generators which will give stable operation and a 5 per cent setting, and I do not think that the earthing resistance should pass more than 1 000 amperes. This should enable adequate protection to be given to all except the very largest generators. I should have thought that in advocating a metal-clad supply system the author would have favoured slightly higher values of earthing resistance, but I agree that it is better to have a solid earth than to allow too small an earth fault current to flow. In the actual protective gear itself the onus of supplying gear working on sound principles, and with component parts above suspicion, lies on the manufacturer. The works tests are most important for eliminating faulty components. Balance tests for current transformers should be opposition tests and not differential tests,

* Paper by Mr. H. W. Clothier (see vol. 63, pp. 425 and 1023).

thus ensuring that a pressure test is applied between turns and layers. Serious mistakes in wiring are mostly due to a lack of co-operation between the works staff (who may understand the principles) and the erection staff (who usually do not). I am most interested in some of the causes of unbalancing detailed by the author. The causes of instability are often difficult to determine and, where local conditions are at fault, each problem will require a separate solution. Induction from overhead lines is very serious and will require well-insulated pilot cable to prevent accidental short-circuiting of the pilots due to induced voltage. This is apart from the difficulties with capacity currents or circulating currents through the earth connection.

Mr. A. P. Robertson : The author attempts to show the advantages of the solidly interconnected system in order to reduce to a minimum the amount of switching on supply systems, and says that the plant should be linked together in one common copper network. Such a system may obviate a certain amount of switching, but when a shut-down takes place at the power station the difficulty is to get all the apparatus into commission again if the system is solidly interconnected. The system ought to be capable of being sectionalized quickly. The solidly connected system is quite good in many ways, but disconnecting links should be provided and these should be operated mainly by the power station engineer. What I mean is that if a station is carrying a load demanding the operation of four machines, and an interruption occurs, in starting up again, when the first machine is switched on the bars, the whole of the load comes on and is too much for the machine, so that there should be some method of putting a machine on a section only. The duplicate busbars are certainly wanted occasionally, but I think that all busbars should be used. I agree with Mr. Henderson that there is no necessity for a set of busbars lying idle ; all the copper should be used. As regards the system of plugs, I have not had any personal experience of working these, but I think that wherever possible a solid connection ought to be used in place of screwed plugs. There is always a danger of a screwed plug not being screwed right home, in which case there is a possibility of heating just at the contacts. Trouble is then experienced with compound leaking at the joints. It is not a very common experience, but still it has been observed, and the fault has been traced to this cause. The author also spoke of a system in which the whole of the cabling between the generators and the switchboard was solidly earthed. In my experience, the trouble, in long cables earthed at each end, would be currents in the lead, and in some cases an insulator has had to be inserted at one point in the lead sheathing. In ordinary short cable it does not matter, but where the cable is of any considerable length it is necessary to prevent eddy currents. I was very interested in the size of the switchgear in the American power stations, and in the British power stations using the same size of breaker capacity. The rating of switchgear is very loosely defined by switchgear makers. Switches are rated at 50 000, 100 000 or 200 000 kVA, and after all, in many cases, these are only nominal ratings, because the makers have had no means of testing their products to destruction, or even with any great capacity behind them. Until recently, there has been nothing very definite on which to base the capacity of switches, but this state of affairs is now being rectified. The author also mentioned the use of charging resistances in switches. My experience has been that they are more dangerous than advantageous and ought to be taken off. I had never had any trouble before which could be traced to switching in, but, after the resistances were fixed, in many switches a lot of trouble resulted. The resistances heated up and a sort of deposit was formed which came out and got amongst the switch contacts. Whether it was due altogether to the material of which the resistances were composed I cannot state definitely, but since the resistances were taken off no trouble has been experienced. The oil switch-fuse has many uses but its size is a drawback. It occupies a great deal of space, and it is also very high, so that a high station is required to house it. Except for a slight difference in cost, the switch is preferable. I was interested in the one switch substation shown on the lantern slide. Where many substations are connected in busy centres it is imperative to keep the cost down, so that the switchgear should be reduced to a minimum. At the same time I do not agree with cutting it down and sacrificing any of the security. On a feeder on which there are half a dozen substations, it is only necessary to protect it by overload at each end, and to insert disconnecting links in each substation.

Mr. E. Seddon : I am one of those who have gradually been converted from the belief that the cellwork type of switchgear was the best form of construction from the operating engineer's point of view, to favouring the system of enclosing conductors in metal casings such as advocated by the author. I have spent a considerable amount of time developing designs for interlocking portions of switchgear of the cellwork construction until I found myself drifting unconsciously towards the ironclad design, which seems to point to the fact that this is the proper line of progress. There are, I think, three essential features required of any switchgear to meet the views of most engineers operating large plant. These are :—(1) That the switchgear shall be so designed as totally to enclose and seal with a suitable insulating medium all permanent conductors, and only those parts subject to wear and deterioration should be made detachable ; (2) that the design of switchgear will only permit of its operation in proper sequence to ensure that any circuit carrying e.h.t. energy cannot be interrupted except through a quick-break oil switch ; and (3) that any failure of insulation should immediately become an earth fault and the apparatus isolated as a result of such an event happening. I believe that the best layout of switchgear would result from a design involving a number of separate switch-houses, each building containing a machine panel with its complement of feeders. The busbars of the separate sections would be coupled together through cables and hand-operated oil switches of low breaking capacity.

Mr. D. Martin : The Electricity Commissioners' Report for 1924 shows that 6 681 500 000 kWh were generated in the United Kingdom during the year 1924. Of this amount I calculate that at least 1 810 000 000

kWh in 1924 and some 2 200 000 000 kWh in 1925 passed through metal-clad switchgear of the author's design. In other words, at least a third of the current generated in the United Kingdom is controlled by switchgear of the metal-clad type at some point or other in its course from the generating stations to the e.h.t. substations. What are the reasons for this phenomenal progress? To my mind the following appear to be the principal reasons:—

(1) Shocks and burns from accidental contact with live conductors are eliminated.
(2) Enormous saving in building costs and building space.
(3) Reduction of cleaning costs by about 90 per cent.
(4) Absence of fire risks in clearing short-circuit or earthing faults on the transmission system, due to metal-clad enclosure at earth potential.
(5) Impossibility of drawing an arc and its resulting destruction in the case of inadvertently opening a circuit on load, mainly due to the elimination of air-break isolating switches.
(6) Elimination of risk to human life and plant in the event of mistakes in operation, especially at times of emergency.
(7) Metal-clad construction limits injury, due to faults developing on the switchgear itself, to the unit concerned, without affecting adjacent units, provided the metal enclosure is properly earthed.
(8) The stronger mechanical construction available eliminates the explosion risks of the destructive forces developed in the oil tanks in clearing severe faults on the system.
(9) Simplicity of construction and the marked engineering features of the design.
(10) The absolute interchangeability of switches, class for class, which reduces the number of spares to be carried to a fraction of what it used to be. In Glasgow, for instance, only one switch of the 6 600-volt class "C1" type is carried, though there are over 1 000 of this class in commission.

This phenomenally small proportion of spares is sufficient proof of the adequacy of the type used in Glasgow and the perspicuity of their engineers. We have in Edinburgh an example of duplicate switches and duplicate busbars. One half of the switches only are in commission at one time. Surely this is a wasteful method. If the primary object of duplicating the switches were to speed up the time of changing over from one busbar to another without breaking circuit, the time element again becomes of importance, for it is essential that both busbars must first be running in parallel and that takes time. If the object is to have a stand-by switch, then it surely points to a lack of confidence in the switches employed, and the money spent on two switches could have been utilized in perfecting one of greater reliability, with a resultant saving of 25 or more per cent on the switchgear contract. Again, if the duplicate switch is for use in the event of the failure of its partner on load, one of the claims of the advocates for duplicate switches is weakened, for under a failure or "fault" condition the circuit is opened whether we wish it or not, and by the time it has been discovered whether the fault is in the switch or on the outer circuit more time would have been lost than in the case of the system advocated by the author in Figs. 7, 8 and 14. Further, the system advocated by the author eliminates the use of isolating links on which there is always the risk of mistakes during the hurry of an emergency. Within the past three weeks a skilled man was fatally injured by shock on a cellular-type board in a substation. He obviously must have forgotten to withdraw the isolating links on the "live" tails of cables connecting the two halves of the board in question, during the prosaic operation of routine cleaning of the gear. My experience compels me to air the view that this open-cell type of gear should be prohibited now that we have draw-out metal-clad gear. In attacking the problem of protective gear and discriminating devices we seem to have lost the original objective of our search. Whilst I do not neglect research along the lines which we have developed so far for discriminating devices, I think the question of research into fuses seems worthy of some attention. The fact that a fuse is an ideal form of overload protection is sometimes overlooked, for it can be fused to blow at full load or any percentage above full load or before the load reaches the danger point in the curve and before a cycle has had time to develop. Fig. 18 illustrates the case. Of course I fully appreciate all the physical and technical difficulties inherent in fuses, but my point is that we should not allow the subject of research into adequate fusing to be wholly dropped and forgotten. I am in favour of earthing the gear while men are working, on the lines advocated by the author, and with regard to the draw-out type now made by so many manufacturers there is no simpler method than that illustrated in Fig. 24. Personally I prefer to close the earth circuit by means of one of the circuit breakers under oil, as indicated. All the risks of loose ends and the creation of further faults are eliminated by this very simple method, and it is adopted as routine practice on at least six of the larger power supply systems in Scotland. In this connection there is still room for a suitable and reliable portable instrument to indicate whether an innocent looking piece of gear is dead or not. With regard to switchgear in mines, a subject in which I am specially interested, I think the consensus of opinion is now focused on the following ideals:—

(1) Metal enclosure of all live conductors. Manufacturers and the mines inspectors have between them seen to this fairly well. In underground workings without illumination it is a crime to have exposed live parts.

(2) There should be no enclosed air spaces. All spaces should be compound-filled except where there may be moving parts, such as switch contacts; in this event oil immersion is sufficient. Air-break gear should not be allowed. Even in non-fiery mines there is always the risk of pockets of gas being liberated at some time or other in the life of a mine.

(3) In the matter of oil-switch or circuit-breaker tanks or containers for use underground, it is advisable to use boiler plate steel in preference to cast iron. In

clearing severe faults the container is liable to be blown to pieces if it is of the more fragile cast-iron type, and the risks underground are already sufficient without adding this further unknown terror to them.

(4) The joint between the tank and the heavy switch hood should be of the flame-proof type for the same reason as in No. (2) above.

(5) Isolating switches underground should be avoided on account of the risk of earthing them in the semi-dark conditions. The only way to obviate this risk is to utilize the "draw-out" switch.

(6) In the matter of automatic trips, it is advisable to have these locked up to prevent any but the authorized electrical engineer operating them. The simplest way to obtain this is to put them inside the oil switch tank. This further ensures that they can only be adjusted while the parts are dead; this is highly desirable underground.

(7) A very important statutory requirement in regard to colliery work is an easy means of indicating earth leakage. The simplest method of satisfying this requirement is to adopt the "core balance" system of protection, which trips when an out-of-balance fault, such as an earth fault, develops in any one of the three cores of the three-phase system. The faulty circuit would thus be switched out until the authorized engineer switched on again, presumably after he had located and removed the fault. What better system of indication can there be? Here again the metal-clad gear lends itself as an ideal housing arrangement for the core-balance transformers. Recent intercourse with numerous American engineers also indicates that the advantages of the metal-clad proposition are rapidly finding favour in the United States.

Mr. F. H. Whysall: Although one can speak very highly of the type of switchgear most favoured by the author, there are other forms of switchgear which have advantages one would be wrong to ignore. To-day we have such satisfactory service from switchgear and protective apparatus generally, that to boast of immunity from breakdowns of alternators and substation plant, as I have heard manufacturers' representatives do, is giving credit for improved conditions due really to improved switchgear and protective apparatus. Present-day switchgear disconnects a fault so quickly that the plant is not subjected to the same stresses. One of the speakers in the discussion mentioned the solid system of distribution, and the systems of protection by interconnecting apparatus. We are all in favour of simplification if we can justify it by experience and by the apparatus which we have at our command. I can remember operating switchgear similar to that described by Mr. Martin. Some early types of switchgear were very crude, and some were very elaborate in design. I have often wondered whether a study of some of the old designs, such as the Geipel switch pillar, would not be of assistance when considering new problems.

Mr. H. W. Clothier (*in reply*): The acceptance and support of the general principles of the paper is the tenor of the discussion. These principles have in a very large measure been initiated in demand and developed under the service conditions of this city (Glasgow). By the adoption of metal-clad switchgear for substation equipment and of the 20 000-volt installation at Dalmarnock power station, this municipality has done much for the progress of switchgear design.

The previous discussions and replies in the *Journal* (1925, vol. 63, pp. 446 and 1023) deal with some of the points of detail. For example, in line with Mr. Henderson's plea for a further definition of stability for protective gear, I have made a recast of the proposals (see vol. 63, p. 1033) and have applied this to four types of protective gear (vol. 63, p. 1036). Mr. Henderson prefers to take the supply to the generator auxiliaries off the reactance tie-bar, as this avoids the change-over after the generator has started up. The auxiliary transformers would, however, have to be coupled to these busbars by circuit breakers. The advantage of the unit system is that one main panel suffices to control both the generator and its unit auxiliary transformer; and, furthermore, one system of protection covers the two.

Mr. Henderson and Mr. Robertson both deal with the problem of linking up the sections of a system. The subject requires more time than is now available, but it seems to me that the whole system should be solid, in so far that all copper is in service at the same time and that faults are cut out as they occur by means of automatic protective gear. The size of reactances (where necessary) on the larger system is controlled by the breaking capacity of the circuit breakers installed in the power stations and on the system. When the circuit breakers are large enough to dispense with the aid of reactances a minimum amount of operation is required with changing conditions of load. On the other hand, when it is inconvenient to have the circuit breakers large enough to deal with the load in its entirety, reactances become most useful for interconnecting the plant and network arranged in sections.

I realize that there must be section switches, as Mr. Robertson points out. The question as to whether these should be hand-operated or automatic is important, and is one for the operating engineer to determine in conjunction with the lay-out and operation of the plant as a whole. I should prefer automatic operation on the occurrence of faults.

Mr. Martin mentions the need for further consideration of fuses as discriminating devices. Fuses certainly have some most desirable characteristics. When used to protect a small supply taken from a large network, the switch-fuse illustrated in Fig. 27 will, owing to the fuse's great rapidity of action, clear a short-circuit before the latter has had time to rise to its maximum severity. Unfortunately, when fuses are used as a substitute for reactance the current-limiting effect under short-circuit just referred to is often lost, since the ratio of the short-circuit current available to the normal current transferred through the fuse is insufficient to produce the necessary rapidity of operation. Their use for this purpose is therefore restricted to cases where the transference of power is small in proportion to the power available.

Mr. Sedden's comments are most opportune. I think that his views on switchgear development are typical of those of many experienced observers and users,

particularly in regard to the course indicated by the study of the sequence of interlocked operations to avoid errors in manipulation.

Mr. Whysall has hit upon a curious fact. One of the earliest forms of high-tension switchgear was of a metal-clad pillar type. About 1894 this began to be replaced by slate cell-type gear. Had an endeavour been made at that time to improve upon the pillar construction, we might have come much earlier to metal-clad construction.

PROCEEDINGS OF THE INSTITUTION.

744TH ORDINARY MEETING, 22 APRIL, 1926.

Mr. R. A. Chattock, President, took the chair at 6 p.m. He reported the death of Sir Henry Mance, LL.D., C.I.E., Past-President, and a vote of condolence with the family of the deceased was carried, the members standing in silence.

The minutes of the Ordinary Meeting held on the 8th April, 1926, were taken as read and were confirmed and signed. Messrs. I. H. Jenkins and E. W. Moss were appointed scrutineers for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows :—

Elections.

Members.

Cusworth, James.
Innes, William.

Associate Members.

Mackay, James Arthur, B.Sc.
Seth, Shankar Dayal, B.Sc.

Graduates.

Banerji, Srish Kumar, B.A., B.Sc.
Barrar, Sydney John.
Bourn, Leslie Edwin A.
Chauhdri, Ghulam Kadir.
Cook, Ernest Henry.
Cooper, John Ashton J.
Creswick, Philip.
Hartland, Sydney.
Jacob, John.
Kerr, Albert Edward.
Kilpatrick, James Stevenson.
Kitching, Donald Albert.
Lyne, Robert Habby.
Mill, Eric Sidney.
Milward, Frederic Andrew.
Mirchandani, Toloram J., M.Sc.
Prabhu, Manjeshwar Govinda, B.E.
Prosad, Bhagwat, M.Sc., B.L.
Roberts, Albert.
Robey, Leslie John.
Ryan, Louis.
Suri, Kishen Das.
Tennison, Alfred John.
Tree, William George.
Williams, Daniel John.

Students.

Allen, Charles Vivian.
Barkwith, Sidney.
Bennett, William Clifford.
Broderick, John.
Buxton, George Edward.
Clarke, James Blasdale.
Collett, William Alfred.
Cooper, Walter Dunbar.
Dixon, Irving Blaiklock.
Dixon, William Garnet E.

Students—continued.

Evans, William Arthur.
Flint, Ernest Frederick.
Francis, Arthur.
Gill, Frederick William.
Goodchild, Ronald Frank.
Gould, Robert Howe (Jun.).
Griffiths, Norman Weddell.
Gulati, K. Badri Nath.
Hinton, Cyril Herbert.
Kember, Stanley.
Little, Eric Charles.
McClelland, William Andrew.
Mhatre, Govind Keshavrao.
Montgomery, William John.
Mundie, Colin Macpherson.
Nicol, Colin Traquair.
Orr, James.
Palmer, Frank Henry G.
Richardson, Henry.
Saunders, Hector Douglas E.
Serby, John Edward, B.A.
Sharma, Ilam Chand, B.Sc.
Skelcher, Frank William.
Smith, Leslie.
Sumner, Walter.
Thomson, Murray Forbes.
Wardle, Granville Ebhorn.
Whelan, Alfred John.
Widdup, Francis Alan.
Widger, Leslie.

Transfers.

Associate Member to Member.

Cohen, Bertram Sydney.
Dixon, Edwin Henry, B.Sc.
Gow, Alexander George.
McLachlan, Dugald Henderson.
Nicholson, John Hedley.
Odam, John Harold.
Pontet, Bernard.
Sillar, Harold MacKnight.
Taylor, John Lyon.
Williams, Frederick Herbert, B.Sc.Tech.

Graduate to Associate Member.

Charles, Norman Henry, B.Sc.(Eng.).
dos Ramos, Herculano Lourenco.
Gibbs, William Reginald.
Hall, Harry, B.Sc.Tech.
Jones, Reginald Hugh, M.Sc.

Student to Associate Member.

Broughall, John Alan, B.Sc.(Eng.).
Cash, Harry Hutchinson.
Fowler, John, B.Eng.
Gallon, William Anthony.
Gooch, Leslie John.
Hewitt, John Leslie.
Johnson, Francis Hannam.
Lywood, Wallace Drake M.
Shephard, Alger George.
Trutch, Charles Joseph H., B.Sc.(Eng.).
Wadlow, Donald Leslie.
Warren, Wilfred Ernest, B.Sc.(Eng.).

Student to Graduate.

Battersby, George Herbert, B.Sc.(Eng.).
Bayley, Godfrey George.
Birt, Ronald, B.Sc.(Eng.).
Bourne, Percival Edwardes.
Colebrook, Hector Frank, B.Sc.
Collier, Harold.
Davies, Bertram Jones.
Duthie, George Ferguson, B.Sc.
Elliott, Harold John.
Hall, Maitland Heseltine.
Kingdon, Thomas Karl.
Manning, Clifford Breillat.
Moseley, Ernest Gower.
Sharma, Banwarilal, B.Sc.
Shilson, Leslie James.
Simpson, Alexander Victor.
Stainsby, James William.
Standring, Ian William, B.A.
Stewart, Ian Dunlop.
Taylor, Louis Norwell.
Tyler, Leonard Benjamin.

Messrs. P. M. Baker, A. M. Coombs and A. F. Harmer were appointed scrutineers of the ballot for the election of new members of Council.

The President announced that, in view of Col. Crompton's absence in America in connection with the International Electrotechnical Commission, the presentation to Col. Crompton of the Faraday Medal had been postponed until the 24th June.

Sir J. J. Thomson, O.M., M.A., F.R.S., then delivered the Seventeenth Kelvin Lecture entitled " The Mechanics of the Electrical Field " (see page 721).

The President : It is my very great pleasure to move a hearty vote of thanks to Sir Joseph Thomson for the exceedingly interesting Kelvin Lecture that he has delivered. Though many of us perhaps could not follow all the intricacies of the atom that he has explained to us, I think that we shall be able to gather a very good idea of the wonderful line of thought which physicists are now following.

Dr. A. Russell : I have very great pleasure in seconding the vote of thanks. I have heard many Kelvin Lectures, but I have never heard one so interesting and wonderful. I had the privilege of being a pupil both of Lord Kelvin and also of Sir Joseph Thomson. There are one or two points of resemblance between them. They were both Second Wranglers, and they both impressed their fellow students very much with their ability. In my freshman's year at Cambridge in 1882 the mathematical lecturer told me of the great physicists and mathematicians that were there. He mentioned Lord Rayleigh, Stokes, Cayley and others. He also said that there was a young man, Thomson, working at the Cavendish Laboratory who was a second Newton. That was prophecy better than he knew, because in 15 years' time Sir Joseph had discovered the electron. Sir Joseph has followed Newton and has given us a corpuscular theory of light which is very much more wonderful than Newton's theory and which will give us food for reflection for many years to come.

Sir Oliver Lodge : We have heard a great discourse from the Master of Trinity and a master of physics. I unfortunately missed the beginning of the lecture, but I understand that Sir Joseph Thomson has been saying someting on the lines of his paper on the " Intermittence of Electric Force " which I have recently partly read in the *Proceedings of the Royal Society of Edinburgh*. All Sir Joseph's contributions earn our admiration, and I feel that a great deal will come of this curious admixture of the corpuscular and undulatory theories, and the chances of stray encounters. I myself do not feel that we have got to the bottom of it ; I do not know whether the lecturer does. I am not prepared to give in to the corpuscular theory yet, but certainly the quantum is a reality and introduces something odd which we must face. It is strange that we do not get radiation from a hydrogen atom, that the atom is stable ; but Sir Joseph seems to think that we might get radiation from a proton. Could it be from a pulsating proton ? I have been wanting the electron to pulsate like a hollow sphere under pressure. If it were to do so it might give these Millikan extra-high-frequency rays. The way in which an electron can be extruded by successive impacts of intermittency which operate during one part of its orbit—the elliptical orbit, not the spherical orbit—so that it accumulates energy until ultimately it expels it or is expelled, seems to me much in accord with what my brother and I worked out as the compound interest accumulation method, with occasional payment of a dividend, for expending radiation by quanta. Something is wanted to accumulate energy until it reaches a critical point, when the excess is paid off, and then it goes on to accumulate again at compound interest. The law of radiation says that there is that compound interest involved ; and I think that this intermittent probability impact theory is likely to give us a mechanism for it. It is noteworthy that Sir Joseph's work, combined with that of Prof. Whittaker of Edinburgh, is specially appropriate to a Kelvin Lecture, because it is trying to introduce more concrete ideas, and is a return to dynamics, so that the problems can be worked out on orthodox principles, with attempted explanation in terms of dynamics of those strange things which have crept into science during the 20th century and which none of us fully understand. Some have been inclined to say that the Newtonian dynamics was exploded by the new ideas and facts recently discovered. I think that Lord Kelvin would be horrified at that, and at the speculative character of modern physics, but admittedly their incorporation into dynamics is a matter of great difficulty. I think we have heard one of the steps towards the solution of that difficulty to-night. There are many interesting points in what Sir Joseph said about the avoidance of loss of energy and the formation of stationary waves by reflection. I am surprised that there can be reflection under free ether conditions, so that the waves do not go out beyond a certain distance and return without loss of energy, simply on dynamical principles, by reason of the period of the wave agreeing with the natural period of the ether oscillation at that place. If the ether has a natural period of oscillation it must have a fine-grained structure. Many things suggest that ; and I understand that that was one of Sir Joseph's contentions near the beginning of his lecture. I am not presuming to discuss a Kelvin Lecture, but am merely voicing our joint admiration for the brilliant pioneering work the lecturer has done and is still doing.

The vote of thanks was put to the meeting by the President, and was carried unanimously.

Sir Joseph Thomson briefly replied, and the meeting terminated at 7.15 p.m.

745TH ORDINARY MEETING, 29 APRIL, 1926.

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 22nd April, 1926, were taken as read and were confirmed and signed.

A list of donations to the Benevolent Fund (see page 623) was taken as read, and the thanks of the meeting were accorded to the donors.

A paper by Messrs. B. S. Cohen, Member, A. J. Aldridge, Associate Member, and W. West, B.A., Student, entitled "The Frequency Characteristics of Telephone Systems and Audio-Frequency Apparatus, and their Measurement" (see page 1023), was read and discussed.

On the motion of the President a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 8.25 p.m.

54TH MEETING OF THE WIRELESS SECTION, 5 MAY, 1926.

Major B. Binyon, O.B.E., M.A., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 14th April, 1926, were taken as read and were confirmed and signed.

A paper by Dr. R. L. Smith-Rose and Mr. R. H. Barfield, M.Sc., Associate Members, entitled "The Cause and Elimination of Night Errors in Radio Direction-finding" (see page 831), was read and discussed.

On the motion of the Chairman a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 7.50 p.m.

54TH ANNUAL GENERAL MEETING, 27 MAY, 1926.

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The notice convening the meeting was taken as read. The minutes of the Ordinary Meeting held on the 29th April, 1926, were also taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

Messrs. J. O. Girdlestone and I. W. Chubb were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows :—

ELECTIONS.

Member.

Lancaster, John Gill, M.Sc.

Associate Members.

Bass, Walter Alfred G., B.Sc.
Cargill, James Jamieson, B.Sc.
Fraser, John Charles W.
Greer, Henry James.
Hornbuckle, Thomas, B.Sc.(Eng.).
Howard, Atholl Charles.
Kemp, Leslie Charles, B.Sc.(Eng.).
Kerridge, Fred Bernard.
McLean, Neil.
Shklovsky, George Edward.
Thompson, Charles Barnard.
West, Robert Allen.
Williams, Harold Montague.
Winson, Victor Hautot, B.Sc.
Woodforde, Reginald Fielding M.
Woodward, Ernest Edward, B.Sc.

Graduates.

Rentell & Co., Ltd.; Royal Technical College, Glasgow; Chief Experimental Officer, Signals Experimental Establishment, Woolwich; W. Hanneford Smith; Messrs. E. & F. N. Spon, Ltd.; Superheater Co., Ltd.; Syndics of the Cambridge University Press; Vereeniging van Directeuren van Electriciteitsbedrijven in Nederland; Weston Electrical Instrument Corporation.

The President, after summarizing the Annual Report of the Council (see page 655), moved "That the Annual Report of the Council for the year 1925–26 as presented be received and adopted."

Mr. E. W. Moss, in seconding the resolution, inquired whether the Council had considered the proposed Bill for the Registration of Engineers.

Mr. L. W. Phillips suggested that steps be taken with a view to members of the various electrical institutions in this country, America and the Continent, having the opportunity of purchasing at reduced rates the technical journals published by these institutions. He thought that the Faraday Medal should be made of gold or platinum instead of bronze, and also suggested that steps be taken with a view to membership of the Graduate class becoming a regular step in the ladder of Institution membership. He urged that steps be taken to delete the Bye-Law of the Institution regarding "enemy" membership.

Mr. F. W. Purse, after referring to the relatively small increase in Corporate Membership during the last two years, called attention to the fact that the average expenditure per member came out at £2 10s. per annum, so that Students paying £1 1s. subscription were far from bearing their share of the expenditure. He also urged some re-adjustment of the relative subscriptions of Members and Associate Members with a view to a larger number of the latter transferring to the former class.

Mr. A. H. Allen inquired whether the Council proposed to take any further steps in regard to the Electricity Bill before Parliament, beyond the letter which had been addressed to the Government.

The President, in reply, stated that, in view of the difference of opinion within the Institution in regard to the Bill, the Council had decided to take no further steps in regard to it. The Engineers' Registration Bill had been before the Council and the Council would take such action as appeared appropriate. Mr. Phillips's suggestions would receive consideration. As regards the Faraday Medal, bronze had been deliberately chosen by the Council after very careful consideration of all the circumstances. The Council had decided to alter the Bye-Law relating to enemy members, and this decision would be given effect to at the next revision of the Bye-Laws. In regard to Mr. Purse's criticism of the small increase in the number of Corporate Members, he thought that this was solely due to the stiffening up of the requirements. He was not, however, in favour of the Students' subscription being increased, as he thought they should receive every encouragement to become members of the Institution.

Mr. P. D. Tuckett (Hon. Treasurer) said: "I beg to move 'That the Statement of Accounts and the Balance Sheet for the year ended 31st December, 1925, as presented, be received and adopted.' I think I may say that the Accounts again disclose a healthy and prosperous position. The income has increased by a total of £1 459, and although it is true that the ex-

penditure has increased by nearly £5 000, we find, when we come to analyse it, that the increase is mainly attributable to one or two special items which were foreseen a year ago and are not likely to recur. The management expenses have increased by £981, the Institution building expenses by £2 055, and the *Journal* expenses by £1 087. Of the increased management expenses salaries and wages represent an increase of £569—an increase which reflects the increasing activities of the Institution and the growing seniority of the members of the staff. The £453 increase in the cost of printing is the other item of management expense showing a substantial increase, and it is accounted for by the biennial publication of the List of Members, so that a year hence there should be a corresponding reduction. Far the largest item in this year's expenditure as compared with previous years is the £3 786 for re-wiring the Institution building. It has proved a very costly expense, but it had to be incurred. Fortunately it is quite exceptional and I know of no liability of similar magnitude which we are likely to be called upon to face. Whilst dealing with the Institution Building expenses it may be of interest to note that the cost of heating shows a reduction of £184 as a result of the considerable sum which we spent the previous year in renewing the boilers. The increased cost of the *Journal* is largely due to some exceptionally long papers. There are various other small increases to which I need not particularly refer, but which I shall be glad to explain if any member desires further information about them. The net result for the year is that we are able to carry £2 000 to the Reserve Fund, as against £3 500 the previous year, and £1 196 to the General Fund as against £2 925 the previous year and £3 957 two years ago. The surplus for the year is thus substantially smaller than that shown during the two previous years, but I am glad to say that the subscriptions again show an increase of £471, and as long as this continues to be the case there can be little cause for anxiety as to our financial position. There is an increase in the income from investments of £372, and the Tothill-street property has brought us in £360 more than last year, thanks to a reduction of £375 in the cost of repairs and alterations. Turning to the Balance Sheet it will be seen that the mortgage on this building is reduced by £1 127, whilst the repair fund has been increased by £587 in consequence of our having incurred an expenditure of only £913 as against the annual contribution of £1 500 carried to the fund. The investments show an increase of £2 616 on the year, representing the invested surplus, and I am glad to say that their market value is practically the figure at which they stand in the Accounts, the depreciation being a negligible amount of less than 1 per cent. As set out in the Report, the assets amount to £145 336 against liabilities of £8 008, leaving a surplus of £137 328, an improvement of £4 312 on last year, so that the position is substantially strengthened, although the increase in the surplus is not as great as in the two previous years. So far as we can foresee, the expenditure of the current year should be less than that of the year under review, so that as long as the subscriptions continue to grow I think the members have every reason to feel satisfied with the financial position in which the Institution stands."

The resolution was seconded by **Mr. R. W. Paul.**

In reply to a question by **Mr. L. W. Phillips,** the Hon. Treasurer pointed out that the item of £235 11s. 6d. on the income side in respect of examinations was in no sense a profit; it was merely the difference between the fees and the expenses of printing and took no account of the incidental establishment charges, all of which were merged in the general expenditure of the Institution.

Mr. H. P. Girdlestone urged that the notices of meetings should be printed on one side only of the Meetings Card.

Mr. F. W. Purse inquired whether the Hon. Treasurer was entirely satisfied as to the financial position of the Institution in view of the fact that the total expenses, which in 1923 were £24 573, had amounted to £30 607 in 1925. He also urged the sale of the Tothill-street property.

The Hon. Treasurer, in reply, said that it was the intention of the Council to take advantage of the first opportunity of selling the Tothill-street property. In regard to the increase in expenditure, he pointed out that there had been in 1925 a non-recurring item of nearly £3 800 for the re-wiring of the Building. The Council had also been more liberal in grants made to such bodies as the British Engineering Standards Association and the Electrical Research Association and in the expenditure on lectures and papers, all of which had met with no disapproval whatever.

The resolution to receive and adopt the Accounts and Balance Sheet was then unanimously adopted.

The following resolution, moved by **Mr. F. W. Purse** and seconded by **Mr. Roger T. Smith,** was carried with acclamation: "That the best thanks of the Institution be accorded to the following officers for their valuable services during the past year: (*a*) The Hon. Secretaries of the Local Centres and the Local Hon. Secretaries abroad, and (*b*) The Hon. Treasurer (Mr. P. D. Tuckett)."

Mr. P. Rosling then moved: "That Messrs. Allen, Attfield & Co. be appointed Auditors for the year 1926–27." The resolution was seconded by **Mr. A. H. Allen** and carried unanimously.

The meeting terminated at 7.10 p.m.

55TH MEETING OF THE WIRELESS SECTION, 2 JUNE, 1926.

Major B. Binyon, O.B E., M.A., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 5th May, 1926, were taken as read and were confirmed and signed.

A paper by Mr. P. W. Willans, M.A., entitled "Low-Frequency Intervalve Transformers" (see page 1065), was read and discussed.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 8.5 p.m.

INSTITUTION NOTES.

Scholarships.

The following Scholarships for 1926–1927 have been awarded by the Council :—

David Hughes Scholarships (value £50 each).

R. C. Mildner (University College, London).
W. S. Milner (Sheffield University).

Salomons Scholarships (value £50 each).

H. H. Fairhurst (Manchester College of Technology).
G. W. Lanyon (King's College, London).

Paul Scholarship (value £100).

R. G. Fuller.

Regulations for the Electrical Equipment of Buildings.

The Council have approved further alterations to the Eighth Edition of the above Regulations. Copies of the pamphlet containing the new alterations and those issued in July 1925 can be obtained from the Secretary for insertion in existing copies of the Regulations.

It is proposed to issue a revised (Ninth) Edition of the Regulations as early as possible next year.

Faraday Memorial Book Fund.

The Council have been asked by the Mayor of Southwark to draw the attention of members of the Institution to a project to commemorate Michael Faraday by forming a collection of standard current literature on electrical and allied sciences in the Central Reference Library of the Borough of Southwark, in which district Faraday was born.

It is proposed to form a Fund the income from which will be expended yearly in the acquisition of new books. Donations should be sent to The Mayor, Southwark Town Hall, Walworth Road, S.E. 17, from whom further particulars can be obtained.

Electric Storage Battery Locomotive Competition.

The Mines Department has recently issued the Report of the judges who were nominated, in connection with a prize of £1 000 offered by the late Mr. Charles Markham, to prepare a specification for, and to adjudicate upon, electric storage battery locomotives for use in British coal mines. One of the judges was Mr. Roger T. Smith, who was nominated by the Institution at the invitation of the Mines Department.

Ten British manufacturers submitted proposals for competition and the designs of five of these were selected as suitable for manufacture. Extensive trials were carried out, of which particulars are contained in the Report, and a general description is given of the successful type of locomotive. Copies of the Report can be obtained from H.M. Stationery Office, price 1s. 3d. net.

National Certificates and Diplomas in Electrical Engineering.

The following have been approved under the scheme drawn up by the Board of Education and the Institution :—

Approved for Ordinary Grade Certificates (Senior Part-time Course) :—

Goldsmiths' College.

Approved for Higher Grade Certificates (Advanced Part-time Course) :—

Widnes Municipal Technical School.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 August–25 October, 1926 :—

OBITUARY NOTICES.

HENRY FLEETWOOD ALBRIGHT was born at Lancaster, Pa., on the 5th October, 1868, and died on the 11th May, 1926. He was vice-president of the Western Electric Company, in charge of all its manufacturing plants in the United States, and also played a prominent part in the planning and organization not only of the plants of the Western Electric Co., Ltd., in England, but also of many of the telephone manufacturing plants in continental Europe. The biggest testimonial to his business genius is the well-designed Hawthorne Works of the Western Electric Co. He was educated at Philadelphia, Pa., and after a short time with the Thomson-Houston Co., as a sales engineer, he joined the Western Electric Co. in 1892. In 1894 he was transferred to the construction department at New York, his first work being the reconstruction of the power plant. The marked increase in efficiency of the plant won for him the position of factory engineer. One year later he was made assistant superintendent, and four years later, in 1899, he became superintendent of the New York factory. It was about this time that he began to group together under responsible heads departments which performed the same general functions. In 1905 the first buildings of the Hawthorne Works were erected and he personally supervised the drawing up of an ultimate factory lay-out, which has been consistently followed ever since. He also planned the lay-out for the factory now under construction at Kearny, N.J. In 1908 he became general superintendent of the company's manufacturing plant, when he moved to Chicago, and in 1917 he was elected a vice-president of the company. Throughout his career he was keenly appreciative of the human side of industry, realizing earlier than many the importance of sound employee relations. He joined the Institution in 1895 as a Foreign Member and was elected a Member in 1902.

DAIZABURO AWOKI, a member of the fifth class of the Imperial Japanese Order of the Sacred Treasure, died suddenly on the 13th September, 1924, at Tokio. He was born in 1859 in Chiba Province, and graduated in 1884 after taking the electrical engineering course of the Imperial Japanese College of Engineering. He at once obtained an appointment as an engineer in the Japanese Telegraph and Telephone Department, and subsequently served as postmaster at Kagoshima, Kobe, Kyoto and Yokohama. He retired in 1905 and later became a director of various companies. He was elected a Foreign Member of the Institution in 1888 and a Member in 1911. I. N.

COLONEL CHARLES FREDERICK COBBE BERESFORD, R.E., whose last appointment was Colonel on the Staff Chief Engineer in Ireland (1898–1902), was born in 1844, being the elder son of the late Rev. Charles Claudius Beresford, and great-grandson of the Rt. Hon. John Beresford, M.P., brother of the 1st Marquess of Waterford, and second son of the 1st Earl of Tyrone. He obtained his first commission in the Royal Engineers in 1865, and as a subaltern he was employed with the G.P.O. Telegraphs, and for 4 years with the Telegraph Troop of the Royal Engineers. He married in 1877 Edith Gertrude, daughter of Salisbury Baxendale, Esq., of Bonningtons, Ware. He was promoted Captain in 1878, and in 1879 passed for the Staff College, passing out in 1880. In 1881, Captain Beresford served with the Expeditionary Force in the Transvaal, being present at several of the actions, and rendering excellent service with the field telegraphs and signalling. On his return to England, he was posted to the Intelligence Branch in the War Office, but in 1883 he returned again to the Postal Telegraphs. In 1885 he was sent as Director of Telegraphs with the Sudan Expeditionary Force, to Suakin, for which service he received the medal and clasp and bronze star. After the campaign was over, being promoted to Major's rank, he was given command of the 2nd Division of the Telegraph Battalion, employed with the Postal Telegraphs, holding that appointment for four years. In 1889 he was selected for the command of the 1st Division of the Telegraph Battalion at Aldershot, commanding it until he was promoted Lieut.-Colonel in 1892. His later services were with the general duties of his corps. He was promoted Colonel in 1898. He was an ardent advocate of telegraph services in the Army, and was largely responsible for the progress made, furthering with all his power the alliance between Civil and Military Telegraphs. He contributed many papers to the *Journal* of the R.E. Institution, on the use of telegraphs and telephones in the field, as well as on the collection and transmission of intelligence in war. He was placed on retired pay on account of age in 1902, and died at Camberley, where he resided, on the 13th December, 1925. He joined the Institution as a Member in 1877 and served on the Council in 1887–88. He also served as Vice-Chairman of the Dublin Local Section Committee in 1900. F. G. B.

JAMES THOMSON BOTTOMLEY, M.A., D.Sc., LL.D., F.R.S., who died in Glasgow on the 18th May, 1926, was born in Belfast on the 10th January, 1845. His father was William Bottomley, a J.P. of Belfast,

and his mother a sister of the late Lord Kelvin. He was educated at Queen's College, Belfast, and Trinity College, Dublin, where he had a distinguished career and was gold medallist when he took the degrees of B.A. and M.A. He started his scientific career by becoming assistant to Prof. Andrews at Belfast, afterwards becoming a demonstrator of chemistry and physics in King's College, London, and in 1870 he came to Glasgow University to act as Arnott and Thomson demonstrator in the Department of Natural Philosophy, at the head of which was his uncle, Sir William Thomson. He held this position until 1899 when Lord Kelvin resigned from his professorship. During these 29 years Dr. Bottomley was continuously engaged in research work and his researches covered a very extensive field, including liquefaction of gases, the use of liquid air for experiments on radiation at very low temperatures, the air thermometer, the bolometer, emissivity and conductivity of wires in vacuum, radiation from bright and black bodies, vacuum pumps, thermocouples, modulus of elasticity, and the electrical properties of platinoid, etc. These papers were contributed mostly to the *Proceedings of the Royal Society* and the British Association Reports. He published a book on Theoretical Mechanics, in two parts: Vol. I, Dynamics; Vol II, Hydrostatics. But as an author he is best known for his "Four-Figure Mathematical Tables: comprising logarithmic and trigonometrical tables, and tables of squares, square roots, and reciprocals." As time went on Sir William Thomson delegated to Mr. Bottomley a good deal of the lecturing to students. He belonged to a type not uncommon in our universities, of distinguished scholars and amiable gentlemen, enthusiastic in their own department of study, and with every good desire in the world to help their students, but largely unable to impart their knowledge in the class room. Uncle and nephew were both deficient in this respect, the one in being too advanced and abstruse for the average student, the other in being too ridiculously simple. He elaborated the obvious, sometimes painfully, though unconsciously, wasting time striving to elucidate minor points which all understood. He did not seem able to state the salient points and pass on. As consulting engineer Dr. Bottomley acted for the Scottish Asylums Board and for Nobels, Ltd. He had a regular electrical engineering consulting practice, mostly concerned with lighting installations, such as Skibo Castle, Roxburgh Castle, etc. Dr. Bottomley became associated with the business of Kelvin, Bottomley and Baird, when the firm was floated as a private limited company in 1900, and on the death of Lord Kelvin in 1907 he was appointed chairman, a position which he continued to fill until his death. In recognition of his distinction as a scientist and of his long and honourable connection with the Glasgow University the degree of Doctor of Laws was conferred upon him in November 1904. He was elected an Associate of the Institution in 1872 and a Member in 1889. He was a Member of Council in 1873 and in 1910 served on the Committee of the Glasgow Local Section, now the Scottish Centre. M. M.

HENRY WHITE BOWDEN commenced his electrical career at Wolverhampton, where he was articled as a pupil with Messrs. Elwell Parker and Co. For two years he was electrical engineer to the Eastbourne Electric Light Co. In 1891 he took up the position of general manager to the House-to-House Electric Light Co. at Kensington (now the Brompton and Kensington Electricity Supply Co.). He was prominently connected with that company's affairs for many years, and during this period of continuous extension also became a director of the old Blackheath and Greenwich Electric Light Co. (now the South Metropolitan Electric Light and Power Co., Ltd.) in 1898 and supervised the erection of much of the plant of the South Metropolitan Co., of which he was managing director and engineer-in-chief. In 1906 he also joined the Board of the Woking Electric Supply Co. He was one of the pioneers of electricity supply in London, and in these days, when so much is being done to bring electrical service within the compass of the general populace, it is interesting to recall that he was very early in the field with free-wiring installation arrangements which gave the consumer up to six points free of charge. He resigned his position as engineer-in-chief of the South Metropolitan Co. in 1919, also his seat on the board, but he continued as consulting engineer to the company. He died in May, 1926, at the age of 58. He was elected an Associate of the Institution in 1889 and a Member in 1904.

J. H. B.

EDWARD EUGENE BROWN, born in the early sixties, died peacefully in his sleep at his home in Brighton on the 19th March, 1926, after much suffering from heart trouble. He was educated at Denmark Hill Grammar School and at the Birkbeck Institution, and, later, at Finsbury Technical College and at the Durham College of Science. He was originally intended for the medical profession, and spent a year in his uncle's surgery at Haverfordwest, Pembrokeshire; but his own desire was always for engineering, and he eventually turned to that as a career. After being in several workshops in London and in Cardiff, and after some further experience in Sunderland, he went in 1885 to the works of Messrs J. H. Holmes and Co. in Newcastle-on-Tyne, where he remained for 21 years, beginning as a draughtsman, and afterwards becoming chief designer. He was associated with Mr. J. H. Holmes in the design of the dynamos used to supply current to the electric lamps at the 1887 Newcastle Exhibition, and of some early train-lighting sets made for the late Mr. Langdon of the (then) Midland Railway Co. in 1889. After he left Newcastle in 1906, he spent some years in Bath with the Griffin Engineering Co., Ltd., makers of internal-combustion engines and gas producers; and he was subsequently with the Braulik Engineering Co. in London. About the beginning of the 1914–18 war he joined the Sperry Gyroscope Co., Ltd., and worked in their drafting and design department until 1916, when he went to the Steel Wing Co., Ltd., of Hither Green, manufacturers of all-metal aeroplanes of the corrugated strip type. The first metal B.E.2.D. wings were built to his designs in 1917, and the tests of these gave the necessary data for the development of the company's special method of construction, with the early stages of which he was thus associated.

Although he was compelled by ill-health to give up much of his work, he continued to be in touch with the Steel Wing Co. about their patents until his death. He appears to have had other minor engineering interests, but what has been written indicates the main course of his life's work. Of Welsh origin, he was intensely musical and artistic in his temperament, and had some skill both as a painter and as a violinist. He was, in addition, a man of wide reading, and one who travelled much in Europe. To his associates his generous sympathies made him always kind, and he was most willing to help young people during their training time in every way within his power. As one who knew him perhaps better than most people says of him, "on the human side he was genial, modest, good-humoured and a loyal friend." So he obtained the worthy regard of his colleagues by his personal character as well as by his knowledge and his ability; and he has the reward of a full and active life. He joined the Institution as an Associate in 1890, and became a Member in 1891. He was amongst those who went to Switzerland with the Institution in 1901, and he was Chairman of the Newcastle Local Section (now the North-Eastern Centre) of the Institution during the Session 1904–5. T. C.

CECIL LEONARD CARTWRIGHT was born at Braintree, Essex, in 1877. He completed his education at King's College, London, and then went for some years to the Westinghouse Co. in Pittsburgh, U.S.A. In 1907 he was appointed Professor of Mechanical Engineering at the College of Engineering, Guindy, Madras. In 1920–21 he served as Acting Principal of the College, and was appointed Principal in 1922. He died at Great Bardfield, Essex, on the 18th April, 1926. He joined the Institution as an Associate Member in 1912 and became a Member in 1914.

CONRAD WILLIAM COOKE died at Hampstead on the 9th January, 1926, in his 83rd year. By his death the Institution loses one of its oldest members. He was well known to all who were connected in any way with the early days of electrical work. Born in 1843, the son of an eminent artist, he was trained in the establishment of Messrs. J. Penn and Son, the well-known engineers of Greenwich. He began professional work as a civil engineer by surveying and laying out the first Isle of Wight railway under Sir Charles Fox. Afterwards he became assistant to Sir Joseph Whitworth. His connection with electrical work seems to have begun at the time of the invention of the Gramme dynamo in 1870. This greatly attracted him. He recognized that it made direct-current dynamo-electric generation practicable, for it gave a current not merely continuous in direction but also sensibly uniform in strength. It is said that the patent specification of this invention was brought out of Paris by balloon during the siege by the Germans in 1870. Cooke recognized its importance and introduced and made the machine here. He used it to supply a searchlight on the clock-tower of the Houses of Parliament, all the work being designed and carried out by him. He joined the Institution's predecessor, the Society of Telegraph Engineers, as an Associate, in 1875, and became a Member in 1878. He remained a Member and maintained his interest in electricity all his life, but his activities were not confined to that branch of engineering. He experimented on improvements in gas lighting, took part in the introduction of the incandescent gas lamp here, and became consulting engineer to the Welsbach Co. He was led to take a great interest in the telephone by being present when Kelvin first described Bell's invention—at the British Association meeting in 1876. He then wrote the oft-quoted article on this invention which appeared in *Engineering*. In 1879, in a lecture at the Society of Arts, he first showed the loud-speaking receiver of Edison. He was the author of the two portly volumes on "Electric Illumination," which were published in 1882 and 1885 by *Engineering*. They are still useful as books of reference as to early applications. He wrote a memoir of Gilbert, of Colchester, and with Prof. Silvanus Thompson founded the Gilbert Club to produce the handsome translation, by P. F. Mottelay, of Gilbert's "De Magnete" (1893). He was interested in astronomy and was chosen to take part in the Solar Eclipse Expeditions of 1896, 1900 and 1905. His general engineering knowledge made him a valued member of the juries of many exhibitions, including the Chicago Exhibition of 1893. He was of a very happy disposition—this, and his broad views, great experience and erudition, made him a general favourite in the engineering world, and he was able to enjoy life to a mature age. He had five sons and a daughter by his first wife. These all survive him, as does his second wife, Miss Sophie Augusta Bonnavie, daughter of a Christiania advocate. He presented to the Institution library a very interesting and admirable collection of drawings made by his father, E. W. Cooke, R.A., F.R.S., the marine painter, of scenes on H.M.S. "Agamemnon" during the laying of the first Atlantic cable in 1857 and 1858. In an accompanying letter he mentioned that his father was the only Royal Academician who was also a Fellow of the Royal Society. This collection, which also contains some excellent photographs taken on this cable ship, cannot fail to be of interest to old telegraph men. W. M. M.

WILLIAM RANSON COOPER, M.A., B.Sc., was born in 1868, at Hampstead, and died on the 15th March, 1926. He graduated in the Royal University of Ireland as Master of Arts in Mathematical Science in 1890, afterwards going to the Central Technical College, where he studied for three years. Gaining a works premium there, he went to the Richmond Electricity Supply station, and to Messrs. Latimer, Clark, Muirhead and Co., who were then manufacturing dynamos and other electrical plant. He next went to King's College and took his B.Sc., London, in physics and chemistry. In 1895, Mr. G. H. Baillie and he joined Mr. J. Swinburne as assistants, becoming partners soon after. Mr. Swinburne had started *Science Abstracts*, and was editor at first. Mr. Cooper took over the editorship with its rapidly growing responsibilities; and its subsequent success is largely due to the good work he did in those days. During his partnership he did a great deal of difficult work. At one time he would be

analysing the rare earths used in gas mantles; at another, he was putting in sewage plant and refuse destructors. Not only had he a good knowledge of general engineering, but he was also a good chemist and an able electrician, with a good mathematical foundation. His chief characteristic from a technical point of view was accuracy and thoroughness. All his work could be relied upon absolutely. It was always done, and always done correctly. While in partnership with Mr. Swinburne he became editor of the *Electrician*. As this gradually absorbed his whole time his partnership was dissolved, but not the friendship which went with it. He was secretary and director of the Damard Lacquer Co., makers of phenol formaldehyde resin products; and the success of that company is largely due to his strenuous work in its development. He wrote a valuable work on "Primary Batteries," and edited the present edition of the *Electrician* primers. He also revised W. G. McMillan's "Electro-Metallurgy." He contributed various papers to scientific societies and the technical Press. In 1902 he was awarded a Telford Premium by the Institution of Civil Engineers for a paper on "Electric Traction." He was also interested in automobile matters, and carried out investigations on the problem of dust prevention. He served on the Council of the Institution of Electrical Engineers (1900–3), and of the Faraday Society. He was also vice-president of the Physical Society, and was honorary secretary for many years. He was always a modest man, in spite of his ability; and he was always fair and pleasant to deal with. If he had a temper, there was no evidence of its existence. He had a cultivated mind, was well-informed outside his profession, and was musical. He was elected an Associate of the Institution in 1895, an Associate Member in 1899, and a Member in 1903. J. S.

GEORGE STEPHEN CORLETT, who died at Wigan on the 28th March, 1926, at the age of 59, after residing in that town for nearly 40 years, was born at Andreas, Isle of Man, where for many years his father was a member of the Manx House of Keys. He received his education at King William College, Casteltown, Isle of Man, and served his apprenticeship with an electrical engineering firm in Cardiff. After a short time in Newcastle-on-Tyne he went to Wigan and founded the Corlett Electrical Engineering Co. In 1914 he severed his connection with the company and set up as a consulting engineer, specializing in the applications of electricity to mining, and in that connection his advice was widely sought. He was elected a Member of the Institution in 1911.

GEORGE HENRY COTTAM was born in 1850 and died on the 1st April, 1926, at his home in Coulsdon, Surrey. He was a son of the late Beaumont Cottam of Walsall and was educated at the Grammar School there and afterwards at Neuwied, Germany. He was apprenticed to Messrs. Wm. Foster and Co. of Lincoln for 5 years, and after some 16 years' experience in general engineering he took up the electrical side in 1882. Subsequently he worked for the Faure Electric Accumulator Co. and the Anglo-Austrian Brush Co. and superintended the erection of electrical undertakings in Hungary. Electric light and traction work in Spain was followed by an appointment at the Bankside generating station of the City of London Electric Lighting Co., Ltd., on behalf of the Brush Co., the contractors. In 1893 he superintended the erection of the electricity works at Hanley and afterwards took up the position of electrical engineer to that municipality. In 1895, following the resignation of Mr. Chattock, he was appointed chief electrical engineer to the Hampstead Vestry, afterwards the Hampstead Borough Council, which appointment he resigned in 1912, afterwards being retained as consulting engineer up to the time of his death. He was hon. treasurer of the Incorporated Municipal Electrical Association from 1896 to 1900. He was elected an Associate of the Institution in 1892 and a Member in 1895. L. M. C.

WALTER DIXON, who died on the 12th July, 1926, was born in Hull in 1861, and was educated in that city. He commenced his engineering career with Messrs. Amos and Smith, Ltd., engineers, Hull, with whom he remained for about 10 years. On leaving he joined the firm of Messrs. Richard Hornby and Sons, Ltd., Grantham, for whom he supervised some important contracts in London, Ireland and other places. In 1891 he went to Glasgow to join Mr. M. B. Mountain, who represented the firm of Messrs. Ernest Scott and Mountain, Ltd., Newcastle, the Priestman oil engines and other interests. He afterwards founded the firm of Walter Dixon and Co. electrical contractors, Glasgow, and carried out many important iron and steel works electrification schemes. At this stage also he was connected with the late Mr. James Riley in the early development of the gas engine for iron and steel works, and he was also among the pioneers in the introduction of three-phase alternating current to iron and steel and allied works. About 1903 Mr. Dixon gave up his contracting practice, and the firm's energies were devoted to consulting work. Among some of his achievements in this connection may be mentioned the complete electrification of the properties of the Ebbw Vale Steel, Iron and Coal Co., Ltd., with which he was connected for over 20 years, during which period the scheme grew from quite small dimensions to an installation consisting of three or four large power stations, with a total equipment of over 30 000 kW. He was also responsible for the electrical equipment of the Rothesay Dock, belonging to the trustees of the Clyde Navigation, which was the first dock in this country to be electrified completely, and embodied many features which had not previously been undertaken in any part of the world. Mr. Dixon's interests were varied, and, apart from his business, he was actively interested in numerous learned societies to which he contributed many papers. He was a Past-President of the West of Scotland Iron and Steel Institute, and at the time of his death was President of the Glasgow and West of Scotland Branch of the Institution of Mechanical Engineers. He was elected a Member of the Institution of Electrical Engineers in 1898. F. A.

GEORGE RICHARD DRUMMOND was born in 1876. His general education was obtained at the Roan

School (Greenwich), Margate College, and King's College. He received his technical training from 1895 to 1900 with Messrs. Siemens Brothers, of Woolwich, and during the same period attended night classes at Finsbury Technical College. While with Messrs. Siemens he passed through the instrument shops, cable-testing room, dynamo department and calibrating and testing room. For a short time before he left Messrs. Siemens he was in charge of their lighting and power station. In 1900 he went as senior charge engineer to the Leyton and Leytonstone electricity works, where he remained for two years. In 1903 he went to India as the electrical engineer to the Bombay, Baroda and Central India Railway, for whom he put down and ran two d.c. central stations. From 1904 to 1913 he occupied the position of electrical and mechanical engineer to Bikaner State. During this period he prepared and installed a three-phase h.t. lighting and power transmission scheme, including five substations. He also installed a complete telephone scheme for Bikaner capital. He had complete charge of the Bikaner waterworks, including four complete pumping stations, two being electric and two steam. In 1908 he was appointed by the Maharajah of Gwalior consulting engineer to Gwalior State, for whom he prepared a three-phase h.t. transmission scheme with substations. He later went to the State of Jodhpur, where he designed and installed a new power house and equipment on modern lines. In 1916 he was appointed chief electrical engineer to the Lahore Electric Supply Co., where he remained for some years. During that time he drew up designs for the complete reorganization of the Lahore Company's system, and although the war and financial difficulties prevented Mr. Drummond himself from carrying out the work he had designed, it has been done since by others. During the period 1916–1921 he also acted as consulting engineer to the Jullundur Electrical Syndicate and the Sialkote Electrical Syndicate. He left Lahore in 1921 and, after some years' absence from the North of India, returned in 1925 to take up the position of electrical engineer to the Amritsar municipality, for whom he was engaged at the time of his death in drawing up designs for the extension of their plant and system. He was never a purely station engineer, and found himself unable to remain in any position which merely required administrative duties from day to day. He was full of energy and was always looking for an outlet for this in positions where new works or reorganization were required. During his life in Northern India he acted as consultant on many occasions for Indian States and others requiring technical help and advice. After so many years of energetic life on the plains of India, in climates and under conditions trying to even the strongest, he found another hot season on the Punjab plains too trying for him. He died at Rawal Pindi from heat stroke on the 12th July, 1926, while on his way to the hills to recuperate. C. C. T. E.

ANDREW GRAY, M.A., LL.D., F.R.S., was born at Lochgelly, Fifeshire, on the 2nd July, 1847, and died in Glasgow on the 10th October, 1925, in his seventy-ninth year. In his native village school he was well grounded in arithmetic and practical mathematics, including surveying, and shortly after leaving school he came, in Edinburgh, under the influence of James Pryde, the editor of "Chambers's Mathematical Tables" in the old Watt Institution. He matriculated in the University of Glasgow in 1872 and graduated M.A. with honours in Mathematics and Natural Philosophy in 1876, became private secretary to Sir William Thomson (afterwards Lord Kelvin), and in 1880 was promoted to be chief official assistant. On the foundation of the University College of Wales at Bangor in 1884 he became its first Professor of Physics. In 1899 he was appointed Professor of Natural Philosophy in the University of Glasgow, to succeed Lord Kelvin, a post which he held until 1923, when through ill health he was forced to resign. In 1884 he published "The Measurement of Electric Currents and Potentials in Absolute Measure." Then between 1888 and 1893 he issued "The Theory and Practice of Absolute Measurements in Electricity and Magnetism," in three volumes. In 1921 appeared a revised edition in one volume of 837 pages. It is an enduring testimonial to the industry, as well as to the powerful and wide grip of electrical and magnetic measurement possessed by him. In 1898 appeared a "Treatise on Magnetism and Electricity." In 1896 he received from his Alma Mater, the University of Glasgow, the degree of LL.D. and was made a Fellow of the Royal Society of London. Prof. Gray first joined the Institution as a Member in 1900. He resigned his membership in 1905 and rejoined the Institution in 1912. In 1914 he delivered the Kelvin Lecture, taking as his subject Lord Kelvin's work on gyrostatics. The lecture was illustrated by means of the original Kelvin tops, which were taken from Glasgow to London and shown in action. In 1919 appeared the monumental "Gyrostatics and Rotational Motion," the fullest treatment of the subject in any language: it stands alone among books treating of the properties of rotating bodies. Prof. Gray's knowledge of the equations involved, it is stated, latterly became almost intuitive. M. M.

ANDRÉ HILLAIRET, head of the Hillairet works at Paris, was born on the 6th September, 1857, and died on the 23rd February, 1926. He completed his education at the Lycée d'Angoulême and subsequently at the Lycée St. Louis, Paris. From 1877 to 1880 he studied at the Ecole Centrale des Arts et Manufactures and obtained its engineering diploma. He at once turned his attention to the electrical industry, the future importance of which was evident from the Paris Exhibition of 1881. In 1880 he became manager of the Breguet works, and in 1885 founded the Hillairet-Huguet works, which soon became well known for their dynamos and motors, particularly in connection with electric capstans for hauling wagons on rails. In 1884 he published an important book on the subject of electric transmission. In 1890 he carried out at Domenes the first high-tension traction installation in France, and in 1894 improvised in a few days an electric traction installation at the Béraudière mines. He was on the governing body of the Ecole Centrale, a member of the Electricity Committee of the Ministry of Public Works, a member of the French Electrotechnical Committee, president of the Societé Française

des Electriciens in 1901, and president of the Societé des Ingenieurs Civils de France in 1906. In these societies he held a prominent position owing to his ability and his unfailing memory which enabled him to recall on any occasion stories and incidents forgotten by most of his colleagues. By his death electrical engineers in France have suffered a great loss. He joined the Institution in 1897 as a Foreign Member, and became a Member in 1911. J. G.

FRANCIS HIRD, B.A., managing director of Siemens Brothers and Co. died on the 25th March, 1926, in his 59th year. He was born in 1867, the second son of William Hird of Darlington, and was educated at the Bradford Grammar School and at Trinity College, Cambridge, where he obtained a Natural Sciences Exhibition. At Cambridge he devoted his attention to natural science, specializing in physics, and took a First Class in the Natural Science Tripos in 1887 at the unusually early age of 19. Two years later he joined the staff of Messrs. Siemens Brothers and Co., with which firm the whole of his professional and business life was destined to be spent. In the earlier years of his connection with Siemens Brothers, Mr. Hird's attention was given chiefly to the technical side, and after three or four years' service he became chief dynamo designer to that company. In September 1902 he was appointed chief engineer of the electric light and power department, and took a prominent part in forwarding the many important developments in electric lighting and power transmission which were taking place at that time. Amongst these may be mentioned the original equipment of the Waterloo and City Railway; a considerable portion of this was designed and constructed by Messrs. Siemens Brothers, and Mr. Hird took a keen personal interest in this contract and was responsible for many of the special features introduced in this, one of the earliest of the London "tube" railways. When the dynamo works of Messrs. Siemens were removed from Woolwich to Stafford, Mr. Hird was acting as consulting engineer to the electric light and power department, and in that capacity was a frequent visitor to Stafford, although his headquarters were in London at York Mansions, and until 1904 when he was appointed manager of the Stafford Dynamo Works and took up a permanent residence at Stafford. This may be said to have been the turning point in his career, when it became necessary for him to devote more and more of his time to the administrative rather than the technical side of the business, and although the position he attained shows his great abilities in both administrative and commercial lines, he often used to deplore the fact that he could not devote more time to keeping up with the newer developments of science in its technical applications. In spite of these limitations his scientific and technical knowledge was of no mean quality, and his knack of getting as it were intuitively at the gist of the argument enabled him to advise his staff on any difficult technical problems, especially on new development work, and he was always ready to assist his departmental chiefs in any technical difficulty. When Siemens Brothers decided on the policy of reorganizing the apparatus department at Woolwich on the lines of modern mass production, Mr. Hird was asked to return to Woolwich and take charge of the new organization. In 1908 he was given charge of both the manufacturing and commercial sides of the apparatus department. In this capacity he had the opportunity of putting to work some of the first automatic telephone exchanges opened in this country. In June 1922 he was appointed general manager of Siemens Brothers and Co., and in April 1925 managing director of the company. On the 1st February, 1926, less than a year after this last appointment which crowned his career, he was taken ill whilst in the chair at a conference with his chief officials, and although his illness was not at first considered serious he never rallied, but gradually grew weaker. During his 37 years' service with Siemens Brothers he saw and took part in nearly all the immense developments of the electrical industry which have taken place during the period; first in heavier engineering works, dynamo and central station design, and latterly in telephone and wireless work. Highly respected by his colleagues, he will be remembered by them and by the many leaders of the electrical industry with whom he came in personal contact, as a man of great technical and commercial abilities with a very quick grasp of any new problem, possessed of a strict sense of duty and devotion to the interests of the firm with which he was identified, and of invariable kindliness to all with whom he came in contact. All who knew him personally will feel that not only his firm but the whole electrical industry is the poorer from his untimely death. He was elected a Member of the Institution in 1903, and although the calls on his time did not allow of his taking a prominent part in its affairs, he always had its interests at heart. In 1906, while at Stafford, he served on the Committee of the Birmingham Local Section, now the South Midland Centre. W. B. H.

HARRY HOLLIDAY was born in Melbourne in 1887, elder son of the late Mr. T. Bradley Holliday, a well-known engineer in that country. After spending a short time with Messrs. Dick Kerr and Co. on tramway construction, he was appointed in 1906 assistant to the general manager of the Hastings Tramways Co., Ltd. A year later he became engineer and manager to the Torquay Tramways Co., Ltd., a position which he filled until 1914, when he was appointed engineer and manager to the Rhondda Tramways Co., Ltd. This position he held until his death, which took place on the 12th June, 1926, as the result of a chill contracted on returning from Switzerland, where he had been for the previous six months owing to a breakdown in health. He was elected an Associate Member of the Institution in 1912 and a Member in 1918.

I. L. W. V. JENSEN was born on the 8th May, 1859, and died on the 5th March, 1925. He was for many years the chief engineer of the Copenhagen Telephone Co., which he joined in 1882. A man of brilliant parts and exceptional learning acquired by unremitting energy, he quickly rose to a leading position in technical matters. His insight into mathematical physics and his extensive knowledge of materials and their properties, rendered him an undisputed authority

on everything appertaining to the construction of apparatus. In respect of electrotechnics and mechanics he was most exacting, his maxim being that the best is not too good. Dr. Jensen's mathematical gifts won him the highest esteem of mathematicians both at home and abroad, and if he had not devoted himself by preference to telephony he might have made a great name in mathematical history. He was the recipient of many scientific honours. President of the Mathematical Association, member of the Scientific Society and of various Danish and foreign learned bodies, vice-president of the Danish Electrotechnical Committee, he was Dr. Phil. *honoris causa* of Lund University. For many years a sufferer from ill-health, he was compelled in 1924 to retire from active work. His name will be associated for all time with the development of technical science in connection with the Copenhagen Telephone Co. He was elected a Foreign Member of the Institution in 1887 and a Member in 1911. From 1899 until his death he acted as Local Honorary Secretary and Treasurer for Denmark.

ANDREAS PETER LUNDBERG, who died on the 22nd February, 1926, was born on the 7th March, 1831, at Bjorneborg's Bruk, Wermland, Sweden. He was apprenticed to a mathematical instrument maker in Stockholm. At the end of his apprenticeship, King Oscar I of Sweden personally secured for him a premium from the Government to enable him to visit foreign countries and so extend his experience. This followed the making of some special nautical instruments which were presented to the Crown Prince (afterwards Oscar II of Sweden) by some of his brother officers in the Navy. The Society of Arts and Trades in Stockholm, as a tribute to the excellent workmanship then displayed, presented Mr. Lundberg with its diploma and silver medal. He was the maker of the intricate Scheutz calculating machine, which was put into use in Somerset House and in the United States, after being shown at the Paris Exhibition of 1855. Subsequently he was employed by various mechanical firms in France, Germany, Denmark, Sweden, Russia, etc., and also as an engineer in the Russian Navy. In 1862 he visited England, where he became a naturalized British subject and remained until his death. He was employed, either as workman or foreman, by Messrs. Thomas Cooke and Sons of York, by Mr. John Browning, and by Messrs. Troughton and Simms. Later, he joined Messrs. Siemens Brothers, and while with that firm acted as foreman of the cable shop and also as assistant engineer on board the original C.S. "Faraday," when the first section of the direct United States cable was laid in 1874. After a venture in business on his own account in Bayswater, he was engaged in 1879 by Colonel R. E. Crompton, C.B., who was just then entering the profession. Mr. Lundberg was always proud of the fact that he was Col. Crompton's first man at Chelmsford, where he assisted in the development of the early types of Crompton arc lamps, etc. He also acted as this firm's representative at the first great Electrical Exhibition, which was held in Paris in 1880 and 1881. In 1882 he founded the firm of A. P. Lundberg and Sons and invented and manufactured the numerous requirements which became necessary as lighting by electric glow lamps developed, such as switches, plug connectors, lampholders and kindred apparatus. His firm also developed an examination scheme in electric switching, installation work, etc. This scheme brought home to many, who had previously given no thought to it, the possibilities of the subject. He joined the Institution in 1894 as an Associate, and became a Member in 1898.

SIR HENRY CHRISTOPHER MANCE, C.I.E., LL.D., who died at Oxford on the 21st April, 1926, was born in 1840. Educated privately, he joined the Persian Gulf Telegraph Department in 1863, and was employed on the laying of the first Persian Gulf submarine cable. Although one of the youngest of the expedition, he was selected for early promotion, and in 1879 was appointed electrician to the Department, which position he held until his retirement in 1885. He was the author of "Mance's method" for testing the internal resistances of batteries, communicated to the Royal Society in 1871 by Lord Kelvin, then Sir William Thomson; also the author of "Mance's method" for eliminating the effects of polarization and earth currents when testing cables having partial earth faults; this led to important economies in cable repairs. He further communicated various papers published in the *Proceedings* of the Society of Telegraph Engineers, on "A Method of Duplex Working," "The Respective Merits and Durability of Gutta Percha and India-rubber Joints," and "The Relative Susceptibility of Gutta Percha and India-rubber to Attacks from the Teredo." He also designed a "system of automatic translation suitable for unstable relays," which system was adopted in connection with the Persian Gulf cables. He was the first to publish a description of the remarkable light-circles phenomenon seen at rare intervals in the vicinity of the Persian Gulf, the light circles passing over the surface of the sea at the rate of 100 miles an hour. Mance's most noteworthy contribution to scientific development was the invention of the heliograph in 1869 at the age of 29. By a curious coincidence the idea first occurred to him on the coast of Baluchistan, where, over 2 000 years before, Alexander the Great had signalled to his armies from the neighbouring hills by means of the sun's rays reflected from his shield. As has occurred before, the Government were slow to realize the value of the new invention, and it was thanks to the initiative of Mance, who sent a number of his instruments to Lord Roberts for use during the second Afghan War, that the practical value of the invention was strikingly demonstrated, with the result that it has since been adopted in every military service, and has incidentally been made famous by Kipling in one of his "Departmental Ditties." Sir Henry Mance joined the Society of Telegraph Engineers as an Associate in 1873, and became a Member in 1877. He was a Member of Council in 1890, a Vice-President from 1892 to 1896, and President of the Institution of Electrical Engineers in 1897. He was also a member of the Institution of Civil Engineers and the Physical Society. After his retirement from the service of the Indian Government, Sir Henry continued to interest himself in electrical subjects. He was chairman of the Oxford Electric Co. from its foundation. He was

on the Boards of the Electric Construction Co., Davis and Timmins, Ltd., and the West African Telegraph Co., and a member of the Provincial Electric Supply Committee of the United Kingdom. Sir Henry was fond of sport of all kinds, a good shot, a lover of music, with a good voice, and a reciter of no mean order, and possessed a fund of personal experiences which made him a never-failing source of interest to his friends. Endowed with an essentially human and sympathetic disposition, he never spared himself to help a friend in need. He was practically blind for the last 10 years of his life. Undaunted, he stuck to his work and kept himself in touch with developments in spite of the effort of memory needed. He learned to read Braille after the age of 70. He was created C.I.E. in 1883 and Knight Bachelor in 1885, and was awarded the degree of Hon. LL.D., Aberdeen, in 1903. He married in 1874, and leaves a widow, three sons and two daughters.

H. O. M.

JOHN MACINTOSH MACKAY MUNRO died at the age of 72 on the 29th December, 1925, at Edinburgh. He was educated at the Glasgow Academy and the Andersonian College. After early experience in telegraph work he made the instruments and erected the first practical telephone line in Glasgow in 1877. In the following year he invented and put on the market several forms of incandescent metal-filament lamps. Some of these were described in *Le Monde de la Science* of that year and in the *English Mechanic*. On the 1st May, 1880, he issued circulars relative to the formation of a telephone exchange in Glasgow, the proposed annual rental for subscribers being £5. By 1880 the Kelvin-street works of Messrs. Anderson and Munro were lit by Serrin lamps, and in that year also the firm installed arc lamps in, and in front of, the offices of the *Glasgow Herald*. This was described in that paper as the first application of electricity to street lighting in Glasgow. Early in 1881 Mr. Joseph Swan utilized Mr. Munro's dynamos to show Sir William Thomson and others his new carbon glow lamps, and in that year installations were fitted by the firm in factories at Selkirk and Hawick. Sir William's own house at the University was wired about this date and was later referred to by Lord Kelvin as "the first private residence on this planet to have electric light as the normal and sole illuminant." Among his patents in 1882 were lever switches, an integrating wattmeter and a gravity voltmeter and ammeter. These were followed by numerous others relating to dynamo windings, etc. In 1883 he invented and patented concentric wiring and applied this system to the wiring of the S.S. "Cavalier." He was soon busily engaged with water-power and gas-engine electrical installations all over the country. The Glasgow fire-alarm system was designed and fitted by his firm in 1885. In 1888 he designed and equipped the electric railway at Carstairs; this was for many years the only example of electric traction in Scotland. In 1892 Mr. Munro, who was then a recognized authority on hydro-electric work, was called to Norway to survey the Glommen and the Drammen rivers for the Christiania power scheme. He was responsible for much of the pioneer town-lighting in Scotland and was consulting engineer to the Kelvinside Electricity Co., the towns of Irvine, Lanark, Skelmorlie, Cambuslang, Galashiels, Bo'ness, etc., and designed and erected supply stations for the Glasgow and South-Western Railway Co., and the Clyde Trust and other public bodies. His design for the station at Kelvinside set for some years a new fashion in the lay-out of supply stations. In 1910 he severed his connection with the firm of Anderson and Munro and devoted himself entirely to his consulting work. During the war he was attached to the Royal Flying Corps and was officer in charge of the Portsmouth Group for the construction of seaplanes and flying boats. Mr. Munro was the author of numerous technical articles and papers. Being deeply interested in the complete reconciliation of science and theology he published two books "Spiritual Dynamics" and "The Divine Mechanism," both urging the application of a natural basis to religion. He was elected a Member of the Institution in 1890 and was one of the founders of the Glasgow Local Section (now Scottish Centre), the chair of which he occupied in 1905. D. S. M.

ERNEST ROBERTON MYERS received his general education at Mill Hill School, London, and his technical education at Owens College, Manchester, where he specialized in electrical engineering. He served his apprenticeship with the British Electrical and Manufacturing Co., Trafford Park, Manchester, and for a period of five years was constructional engineer in charge of the Manchester and Liverpool districts. During the latter period he was responsible for the carrying out of a number of large installations, including four turbo-alternators, auxiliaries and switchgear, at the Lister-drive power station of the Liverpool Corporation. He also installed motor-generators and switchgear at a number of the Corporation substations. In 1912 he received an appointment with Messrs. Balfour, Beatty and Co., Ltd., as electrical engineer in charge of a number of tramway undertakings controlled by that company. In 1920 he was appointed to the position of overhead lines superintendent of the Liverpool Corporation Tramways, and until the date of his death was responsible for the construction and maintenance of 160 miles of overhead lines. Since the time when he was appointed, many new routes have been opened, and he carried out all the necessary new work in connection with the overhead equipment. He was a man who took very great interest in his work, and his sudden death in June, 1925, was a great loss to the tramways undertaking and to his numerous friends, both in the Corporation and outside. He joined the Institution in 1908 as an Associate Member, and became a Member in 1924. P. P.

FREDERICK ALBERT NIXON died on the 3rd July, 1926, at the age of 60. He received his early education at All Saints' School, Bloxham, and when 17 years of age attended for two years at the City and Guilds of London Technical Institute, afterwards taking a three-year course at University College, London, studying mechanical and electrical engineering. In

1889 he went to the Brush Electrical Engineering Co. as a pupil, passing through the various departments of their works in London and Loughborough, including locomotive, stationary engine, dynamo work, and also spent some time in the drawing office. He was subsequently on the staff of the company, being employed on mains and station work in connection with a contract with the City of London Electric Lighting Co. In 1892 he was appointed third engineer at the Eccleston-place station of the Westminster Electric Supply Corporation, and was promoted subsequently to second engineer. In 1894 he was appointed superintendent of mains and underground work for this company under the direction of Dr. (now Sir) A. B. W. Kennedy, holding that appointment until 1897. In that year he was appointed resident engineer for Messrs. Kincaid Waller and Manville, in connection with the South London Electric Supply Corporation undertaking, becoming in 1899 chief engineer to that company. Later, as assistant to Messrs. Kennedy and Jenkin, he acted as resident engineer on the construction and equipment of the Greenhill electricity station at Oldham and was subsequently resident engineer for the Handsworth Urban District Council's electricity supply. In 1905 he was appointed chief engineer for this local authority's supply undertaking. In 1911 he received an appointment as engineer attached to the London staff of the Victoria Falls and Transvaal Power Co., Ltd., and when this company established an engineering department in London he organized the staff and was made head of the department, subsequently being appointed chief London engineer. During his 15 years' service with this company, Mr. Nixon was engaged upon important extensions to the Brakpan, Simmerpan and Rosherville stations. These extensions involved the installation of two 11 000 kW turbo-generators, three 12 500 kW turbo-generators, and three 7 135 kW turbo-compressors which, together with the boilers and auxiliaries, represented in the aggregate an additional 108 000 h.p. of plant. During 1922 the company, on the recommendation of its engineers in South Africa, decided to build a power station at Witbank, and in 1923 the work in connection with this station, which it had been arranged should be the property of the Electricity Supply Commission of South Africa, was started. The Witbank station consists of three turbo-generators, each of 20 000 kW capacity, with the necessary boilers, switchgear, transformers, pumping and other plant. Mr. Nixon, as chief London engineer, was in charge of the engineering work carried out by the company in London which, subject to the approval of Messrs. Merz and McLellan, the consulting engineers to the Electricity Supply Commission, comprised the negotiation, preparation and completion of contracts, designs, plans and specifications in connection with the establishment of the generating station and transmission lines, all the contracts for the plant being placed in the United Kingdom. The first section of the station went into commission on the 14th May, just about two months prior to his death. During the war he acted as manager and engineer to one of the Government explosive factories. He joined the Institution in 1889 as an Associate and was elected a Member in 1912. He was also a Member of the Institution of Civil Engineers.

SAITARO OI, a member of the second class of the Imperial Japanese Order of the Sacred Treasure, died on the 31st December, 1924, at Tokio, after a short illness. He was born in November, 1857, at Yamada, Miye Province, Japan, and graduated in May, 1882, after taking the electrical engineering course in the Imperial Japanese College of Engineering. He then obtained an appointment as an engineer in the Imperial Japanese Telegraph and Telephone Department, and later became head of the Department, a position which he held until his retirement in 1913. He joined the Institution as a Foreign Member in 1885 and was elected a Member in 1911. He was also a member of the Japanese Institution of Electrical Engineering and served for two years (1917–19) as president. I. N.

MARTIN FENN ROBERTS, who died suddenly on the 22nd February, 1926, was born at Lichfield in 1853. After studying at King's College, London, he entered the Engineering Department of the Post Office in 1871—the year following the transfer of the telegraphs to the State. In 1880 he was appointed Superintendent of Factories, and in 1898 an assistant engineer-in-chief. He retired from the Service in 1908 and subsequently, until his death, his extraordinary vitality and marked ability found outlet in the practice of a consulting engineer and as a director of Messrs. Henley's Telegraph Works, Co., Ltd. Throughout his career he was in close touch with all aspects of the design and manufacture of the wide range of materials in use in the Post Office and he aimed at, and spared no effort to secure, a standard of reliability and finish which was of the greatest possible value in establishing an efficient service of telegraph and telephone communications. He was quick to see the weak point of any design or scheme, but in his case the critical and the constructive faculties were equally well developed, and it was seldom that he was unable to contribute towards the solution of the many problems which presented themselves. From 1898 onwards Mr. Roberts, in association with Mr. (afterwards Sir John) Gavey, was responsible for the whole of the engineering work involved in the establishment of the Post Office London telephone system. The decision to provide the main channels of communication by means of underground plant produced many problems of a novel character, and to the solution of these Mr. Roberts contributed not only his sound engineering knowledge but also a degree of foresight which evoked the admiration of all who took part in that pioneer work—the foundation on which the present telephone system in London is based. Apart from his contribution to the purely telegraphic and telephonic side of Post Office engineering work, Mr. Roberts was for many years largely responsible for the considerable amount of mechanical and heavier electrical engineering work involved in the equipment of the Post Office factories and the provision of electric light, lifts, and heating and ventilating services in Post Office buildings generally, and it was from this standpoint that, in 1904 and, therefore, in the early days of three-phase transmission, he was deputed, together with the writer, to visit and report upon three-phase installations in Italy and Switzerland: this step was taken as a result of the decision to erect

the Post Office generating station at Blackfriars. In spite of his many professional interests, Mr. Roberts was by no means an engineer only: he was a lover of art and good literature—in particular of the poems of Keats and Shelley—and was himself a writer of more than average ability. Outdoors he was a keen yachtsman until in later years golf claimed his allegiance. During the war of 1914–18 he gave his services on the engineering side of the Ministry of Munitions. He joined the Institution as an Associate in 1874, and was elected a Member in 1887. He served on the Council in 1884-5.

J. M. G. T.

Captain MATTHEW HENRY PHINEAS RIALL SANKEY, C.B., C.B.E., R.E., son of the late General W. Sankey, C.B., was born at Menagh (Co. Tipperary) on the 9th November, 1853. He was educated at Morges and Schaffhausen, Switzerland; the Royal Military Academy, Woolwich, and the School of Military Engineering, Chatham. He received his commission in the Royal Engineers in 1873 and served in England, in Gibraltar, and, later, as Instructor in Fortification at the Royal Military College at Kingston, Canada. In 1882 he was appointed to the Ordnance Survey at Southampton in charge of the Trigonometrical Division, Electrotyping Department and Workshops, where he introduced the use of dynamos in the copperplate process of map printing. He described this process in a paper which he read before the Institution on "Electrolytic Deposition of Copper," and for which he was awarded the Fahie Premium. Another paper of his, entitled "A Problem relating to the Economical Deposition of Copper," gained the Paris Premium. In 1889 Captain Sankey retired from the Service and became a director of Messrs. Willans and Robinson, Ltd., continuing on the Board until 1904, when he took up consulting work. In 1909 he joined the boards of Marconi's Wireless Telegraph Co., Ltd., and the Marconi International Marine Communication Co., Ltd., of which companies he remained a director until the time of his death. A number of valuable books and technical papers are due to Captain Sankey. Among these are "The Energy Chart and its Practical Application to Reciprocating Engines"; Part IV Rimmington's "Building Construction" (published anonymously); translation from the German of Professor Ritter's "Bridges and Roofs"; the editing of the posthumous works of the late P. W. Willans on "Steam Engine Trials"; a paper on "The Thermal Efficiency of Steam Engines" for the Institution of Civil Engineers; a paper on "Governing of Steam Engines" for the Institution of Mechanical Engineers; and a series of papers on "Heavy Oil Engines" in the Howard Lectures for the Royal Society of Arts. In addition to the I.E.E. awards referred to above, Captain Sankey received the Telford Medal and Premium and the George Stephenson Medal of the Institution of Civil Engineers, and the Willans Premium of the Institution of Mechanical Engineers. He was a Past-President of the Institution of Mechanical Engineers and a Member of the Council of the Institution of Civil Engineers. He was also a Member of the Governing Board of the National Physical Laboratory, and of the Wireless Telegraphy and Gaseous Explosives Committees of the British Association. During the war he was Hon. Engineering Adviser to the Director of Fortifications and Works, and a member of the Hon. Valuation Committee, as well as of other war committees. Captain Sankey will be much missed by a large circle of personal and professional friends to whom he was known as an indefatigable worker with a great variety of technical interests on which he was actively engaged up to the date of his death, which occured suddenly at his home in Ealing on the 3rd October, 1925. He was elected an Associate of the Institution in 1885, and became a Member in 1886. In 1901 he served on the Committee of the Birmingham Local Section (now South Midland Centre).

A. G.

JOHANNES SCHUIL was educated in Holland and came to England during the latter part of the nineteenth century, and was for some time in the employ of the A.E.G. He later became the electrical engineer to the industrial establishments of the Salvation Army. In 1902 he joined the firm of A. Reyrolle and Co., Ltd., which had just recently been transferred from London to Hebburn-on-Tyne, in which place the remainder of his work was carried out. During the 19 years he was engaged by Messrs. Reyrolle he was responsible for the experimental and testing departments, and in addition was largely responsible for the design and development of several lines of the firm's manufactures, including a complete range of d.c. motor starters of the faceplate and drum types. The drum-type starter which he designed included an ingenious arrangement of interlocked double-pole automatic circuit breaker, as well as the well-known graphite resistance with current-growing characteristic. Other products which he developed while with the Reyrolle Co. were a line of tubular ventilated fuses, and flame-proof enclosures for fuses and motor starters. In 1921 he started business in Hebburn under the style of Schuil and Cullinan (which was subsequently altered to the J. Schuil Engineering Co.), manufacturing d.c. motor starters and other small parts. Towards the end of his business career he was engaged on the production of a form of oil-immersed metal-clad switchgear and high-voltage transformer for pressure-testing. He was elected a Member of the Institution in 1922, and was a regular attender at the meetings of the North-Eastern Centre, where he will be much missed by the members.

R. P.

GEORGE STEVENSON died on the 7th March, 1926, in the course of a journey to the Riviera where he was proceeding for the purpose of recuperating after a comparatively slight illness. His health had not been particularly good for a year or more, but his death at the early age of 49 was entirely unexpected. He commenced his engineering career as a student at the Royal Technical College, Glasgow, and his early practical training was obtained in the service of the London and Glasgow Engineering and Shipbuilding Co., and later with Messrs. Mavor and Coulson, also of Glasgow. In 1904 he became chief electrical engineer to the Carron Co., and, after a period of two years with that company,

joined the British Thomson-Houston Co., Ltd., as a sales engineer in their office at Glasgow. Remaining in that position until 1915 he became a very well-known figure in the electrical life of the great industrial district which surrounds Glasgow. He then was transferred to the Rugby works of the British Thomson-Houston Co., spending four years in the contract and export departments, and then, until June 1922, became an assistant to the commercial director of the same company in London. Finally, he joined the Chloride Electrical Storage Co., of Clifton Junction, as assistant sales manager, and remained with them in that position until the time of his death. Although the greater part of Mr. Stevenson's life was spent on the commercial side of engineering and electrical work, he was none the less a man of great technical ability. As a Member of the Institution he served on the Committee of the Scottish Centre and contributed technical papers at various times. He was also an Associate Member of the Institution of Civil Engineers. Throughout the whole of his business career he threw himself whole-heartedly into the service of the particular organization which employed him, and the fact that he never in any way spared himself probably led, in no small measure, to his early death. His passion for efficiency in others as well as in himself, made him a rigid upholder of discipline and gave him a seriousness of aspect in business affairs which belied his real kindly personality. To those who knew him best, he was a staunch friend and a charming companion, utterly unselfish and always concerned for the happiness and comfort of those around him. He became an Associate of the Institution in 1902, an Associate Member in 1904 and a Member in 1913. E. A. G.

BENTARA TAMAKI, a member of the fourth class of the Imperial Japanese Order of the Sacred Treasure, died on the 31st December, 1923, at Tokio after a long illness. He was born in November, 1859, at Kyoto, and graduated in May, 1883, after taking the electrical engineering course of the Imperial Japanese College of Engineering. On leaving the College he was appointed an engineer of the Imperial Japanese Telegraph and Telephone Department and subsequently served in the Testing Department. In 1890 he resigned his position to become an engineer of the Tokio Electric Light Co., but in 1895 again became a Government official as an engineer of the Imperial Japanese Communication Department. In December 1908 he was appointed head of the electrical department of the Imperial Japanese Railways, retiring in 1915. He was elected a Foreign Member of the Institution in 1888 and a Member in 1911. I. N.

LEONARD GEORGE TATE, general secretary of the Electrical Contractors' Association (Incorporated) and director of the National Electrical Contractors' Trading Association, Ltd., died on the 24th January, 1926, in his sixty-first year. His early training was with Pilsen Joel and the General Electric Engineering Co., which he joined in 1883. Here he came under the late Mr. Margary and Mr. Charles Robertson, of lamp fame. One year later Mr. Tate accepted the management of the lamp department of the Schuylar Electric Co. of Hartford, Conn., U.S.A., and remained in America for five years. In 1899 he was employed by the Brush Electrical Engineering Co., Ltd., under Mr. Dawbarn; and in 1892 joined Mr. Leslie Fuller in founding the business of Fuller and Tate, at 20 Bucklersbury, E.C., and it was this business which Mr. Tate carried on alone as Leonard G. Tate and Co., prior to associating himself wholly and whole-heartedly with the Electrical Contractors' Association. It may be said in all simplicity and sincerity that he devoted his life to the welfare of the British electrical installation trade. In all E.C.A. affairs he was an unfailing guide, philosopher and friend. As a man, he was upright, frank and true, and was loved and respected by all. He joined the old National Electrical Contractors' Association in 1902 and was soon afterwards elected to the "Managing Committee." In this capacity he assisted in the incorporation of the E.C.A. and in the formation of its present constitution. In 1905 he accepted the position of hon. secretary to the Incorporated Association, and in this capacity he continued to act until 1918, when he severed his connection with the firm of Leonard G. Tate and Co. and became the whole-time general secretary of the E.C.A. Allied Associations. On the occasion of the E.C.A. Annual General Meeting held in June, 1925, the Allied Associations presented Mr. Tate with a silver salver and cheque "as a token of esteem and mark of appreciation for the valuable services rendered by him during the past 21 years." He joined the Institution as an Associate Member in 1902, and became a Member in 1924. R. W. K.

JAMES HAY THOW died in his fifty-ninth year on the 22nd April, 1926, after a short illness. He entered the Post Office Engineering Department as a telegraphist at Glasgow in October, 1884, and was transferred in March, 1892, to the engineering branch, in which department he passed through the grades of junior clerk, second-class clerk, and first-class clerk prior to 1897 when he became a second-class engineer. In 1902 he came to London as a first-class engineer in the (then) South Metropolitan District, and took charge of the Ealing Exchange area when the Ealing Exchange was opened in 1904. After some years in charge of the Western Exchange Section he was engaged for a short time in the Technical Section of the Superintending Engineer's Office, and was then transferred to the Central Telegraph Office Section. In this Section he took a very active interest in the Dudley pneumatic tube (continuous suction, low vacuum) system, and made many attempts to solve some of the difficulties inherent in the street tube system in London, but his experiments came to a close on his promotion to Assistant Superintending Engineer in the South Midland District, with headquarters at Reading. During the war, he took special charge of the installation and maintenance of works in connection with air defence in the South Midland District, with headquarters at Reading. After the war extensive underground works, including the South Midland District portion of the London–Bristol, London–Southampton, and a number of the London toll cables,

were mainly under his control. In 1922 he was transferred to the London Engineering District where he dealt more particularly with telegraph matters, buildings, and the technical training of the minor staff. His interests and hobbies were many. At Ealing he was well known in local circles and for many years was a member of the choir of the Parish Church. On his return to London from Reading he lived at Tulse Hill and became a member of the church choir there. In all, his services as a chorister extended to 50 years. Mr. Thow was a very capable amateur mechanic and was skilled in the use of tools. He was also expert in cabinet making and wood working, and his work would be creditable to a professional craftsman. He possessed an exceptionally bright and cheerful personality, and was popular with all grades of the staff. He was a devoted husband and father, and those who knew him intimately mourn the loss of a sincere friend. An indication of the love and respect of those with whom he came in contact is contained in the fact that upwards of 200 letters of condolence were received by his family. He was elected a Member of the Institution in 1922.

R. A. W.

ALEXANDER WYLLIE died on the 5th June, 1925, at the age of 55. He was born in Adelaide, South Australia, and came to England to receive his technical education. His first appointment was as borough electrical engineer of Walsall, and in 1907 he resigned that position to go to Auckland, New Zealand, as the city electrical engineer. The first section of the plant was installed in 1908, and when further additions were planned in 1920 Mr. Wyllie re-visited this country, where he purchased most of the necessary machinery. In 1922, when the control of the city electric supply was vested in the newly-constituted Auckland Power Board, he was appointed general manager. He was elected a Member of the Institution in 1905.
